painful dressing changes and potential tissue fluid loss. The general principle of these synthetic products is to provide sterile coverage of superficial partial-thickness burn wounds to allow rapid spontaneous re-epithelialization of the involved areas. Biobrane is a bilaminate thin membrane composed of thin semipermeable silicone bonded to a layer of nylon fabric mesh that is coated with a monomolecular layer of type I collagen of porcine origin. This dressing provides a hydrophilic coating for fibrin ingrowth that promotes wound adherence. Its porosity allows for drainage of exudates while remaining permeable to topical antibiotics, and it simultaneously acts as a barrier to the ingress of bacteria and evaporation to prevent dessication.[39] It is supplied in simple sheets or preshaped gloves (Fig. 26-6). After it is placed onto clean fresh superficial second-degree burn wounds using Steri-strips and bandages, the Biobrane dressing dries up and becomes well adhered to burn wounds within 24 to 48 hours. Once adherent, the covered areas are kept open to air and examined closely for the first few days to detect any signs and symptoms of infection. As the epithelialization occurs beneath the Biobrane sheet, it is easily peeled off the wound. When serous fluid accumulates beneath the Biobrane, a sterile needle aspiration can preserve its use. However, once foul-smelling exudate is detected, it should be removed and topical antimicrobial dressings applied. When used as directed, Biobrane has been found to reduce pain levels, fluid loss, healing time, instances of hypothermia, and hospital stay when compared with traditional dressings.[39,40]

Alternatively, Opsite or Tegaderm (3M Pharmaceuticals, St. Paul, Minn.) can also be used to cover superficial partial-thickness burns. Commonly used as postoperative dressings, it is easy to apply and provides an impervious barrier to the environment. It is also relatively inexpensive, and its transparent nature allows for easier monitoring of burn wounds. Despite lacking any special biologic factors (i.e., collagen, growth factors) to enhance wound healing, it promotes spontaneous re-epithelialization process. Biobrane and Opsite are preferred to topical antimicrobial dressings when dealing with small superficial second-degree burn wounds, especially in the outpatient settings to alleviate pain associated with dressing changes. TransCyte (Advanced BioHealing, Westport, Conn.), composed of human fibroblasts that are then cultured on the nylon mesh of Biobrane, is also an alternative option.

**FIGURE 26-6** Biobrane glove for superficial second-degree burn. Biobrane is an ideal synthetic wound coverage for superficial second-degree burns, promoting rapid re-epithelialization without painful dressing changes.

Synthetic and biologic dressings are also available to provide coverage for full-thickness burn wounds. Integra (Integra LifeSciences, Plainsboro, NJ) consists of an inner layer made of a porous matrix of bovine collagen and the glycosaminoglycan chrondroitin-6-sulfate, which facilitates fibrovascular growth. The outer layer is composed of polysiloxane polymer with vapor transmission characteristics similar to normal epithelium. In the treatment of full-thickness burn wounds, Integra serves as a matrix for the infiltration of fibroblasts, macrophages, lymphocytes, and capillaries derived from the wound bed, and it promotes rapid neodermis formation. After the collagen matrix engrafts into the wound in approximately 2 weeks, the outer silicone layer is replaced with epidermal autografts. Epidermal donor sites heal rapidly without significant morbidity.

Although synthetic dermal substitutes have a tremendous potential for minimizing scar contractures with improvement in cosmetic and functional outcome, they are also susceptible to wound infection and must be monitored carefully. The use of Integra for children with large TBSA burns was evaluated for short- and long-term follow-up.[41] Burned children treated with Integra demonstrated significantly decreased resting energy expenditure as well as increased bone mineral content and density, along with improved scarring at 24 months after burn injury, thus validating the use of this dermal substitute in the management of pediatric burned patients.[41] Moreover, some advocate that Integra can be successfully used in extensive postburn scar revisions in younger patients.[42] Recently, the use of Integra with negative-pressure therapy and a vacuum-assisted closure system has been shown to shorten the time between the application of Integra and skin grafting by fixing the dermal substitute to the wound bed and promoting neovascularization.[43] In addition, this method simplifies wound care, evacuates fluid, and provides a sterile covering.

Biologic dressings, such as xenografts from swine and allografts from cadaver donors, can also be used to cover full-thickness burn wounds as a temporary dressing. Alloderm (LifeCell, Branchburg, NJ) is a dermal substitute procured from decellularized cadaveric dermis. This synthetic dermal substitute also has a potential for minimizing scar contractures, particularly at joints, and improving cosmesis and functional outcomes. Particularly useful when dealing with large TBSA burns, biologic dressings can provide the immunologic and barrier functions of normal skin. The areas of xenograft and allograft are eventually rejected by the immune system and sloughed off, leaving healthy recipient beds for subsequent autografts. Although extremely rare, the transmission of viral diseases from the allograft is of potential concern.

Finally, human amnion has been used as a dressing for burns, because it not particularly antigenic. It contains substantial amounts of many growth factors that stimulate epithelial proliferation, but it also minimizes evaporative fluid losses and reduces bacterial counts in the burn wound.[44] Several preservation methods are currently described, including cryopreservation, glycerol preservation, lyophilization, and $\gamma$-irradiation. Its use has been limited to dressing partial-thickness burns in specialized areas such as the face. One study compared the use of amnion and traditional topical treatment in pediatric patients with facial burns. Although patients in the amnion group had significantly fewer dressing changes, the overall time to healing, length of stay, and hypertrophic scarring were not different between the two treatment groups. Importantly, the use of amnion was not associated with an increased

risk of infection, which suggested that it is a safe alternative dressing for superficial partial-thickness burns.[45]

## EXCISION AND GRAFTING

Early excision with skin grafting has been shown to decrease operative blood loss, length of hospital stay and ultimately improve overall survival of burn patients.[46,47] Similar to earlier clinical reports in patients, two separate murine studies found that early excision of full-thickness burns can reduce proinflammatory cytokines, such as IL-6 and tumor necrosis factor-α (TNF-α), in rats with 30% TBSA burn injuries, allowing for abrogation of the systemic inflammatory response.[48,49] Adequate surgical debridement does rely on experience and judgment to determine which tissues are devitalized and should be excised as opposed to those that are still viable. Moreover, aggressive debridement can result in poor functional and cosmetic results, whereas inadequate debridement will often result in infection and poor healing. One group has recommended intraoperative staining of the burn wound with methylene blue to demarcate normal epithelium from granulation tissue and eschar, which can aid in excision. There were no reports of adverse reactions, alterations in skin graft take, or wound healing problems with topical application of methylene blue, though no objective measures of these findings were provided.[50]

Excision and grafting may be staged, with the goal of removing all eschar as early as possible, to not only blunt the inflammatory cascade but also to prevent wound colonization. However, since burn depth from scald burns is more difficult to assess, a more conservative approach is taken with delayed excision. Typically, tangential excision of the full-thickness burn wound is performed 1 to 3 days after burn injury, when relative hemodynamic stability has been achieved. The eschar is sequentially shaved off using a powered dermatome (Zimmer) and/or knife blades (Watson, Weck) until a viable tissue plane is achieved, which is usually characterized by punctate bleeding (Fig. 26-7). Particularly in burns greater than 30% TBSA, early excision of the eschar (usually < 24 hours after burns) generally decreases operative blood loss resulting from vasoconstrictive substances, such as thromboxane and catecholamines, in the burn wounds. Once the burn wounds become hyperemic 48 hours after burns, bleeding at the time of excision of the eschar can be excessive. Tourniquet and subcutaneous injections of an epinephrine-containing solution can lessen the blood loss, but these techniques can potentially hinder the surgeon's ability to differentiate viable from nonviable tissues. Topical hemostatic agents, such as thrombin, can also be used, but they are expensive and not very effective in preventing excessive bleeding from open wounds. In patients with deep full-thickness burns, electrocautery is useful to rapidly excise eschar with minimal blood loss. The use of Versajet hydrosurgery (Smith & Nephew), which utilizes a high-powered stream of sterile saline for tissue excision, is becoming increasingly popular. Because it is capable of small-scale incremental debridement, the Versajet preserves more dermis than traditional tangential excision techniques and allows for more precise contouring. It has been shown to reduce bleeding and healing times, with improved adherence of biologic dressings.[51] It has the advantage of dermal preservation, which is necessary to minimize hypertrophic scarring and contracture formation, and a significant reduction in bleeding associated with traditional excision. It has been suggested that large TBSA pediatric burn patients receiving blood products have increased morbidity because of being immunocompromised and succumbing to subsequent infections.[52] Thus limiting blood loss and transfusions are critical.

FIGURE 26-7 Tangential excision of eschar. Eschar is excised to the depth of viable, bleeding tissue plane. (With permission from Herndon DN [ed]: Total Burn Care, ed 2. Philadelphia, WB Saunders, 2002, plate 2.)

Ideally, the excised burn wound is covered with autograft from donor sites, such as the upper leg, back, or abdomen. For burns less than 20% to 30% TBSA, debrided wounds can be covered at one operation with split-thickness autografts if the wound bed is amenable. It is preferable to use sheets of autografts for better long-term aesthetic outcome, but narrowly meshed autografts (1:1 or 2:1) have the advantage of allowing better drainage of fluid at the grafted sites. However, this also means that they require larger donor areas than more widely meshed grafts. With massive burns, the closure of burn wounds is achieved by a combination of widely meshed autografts (4:1 to 6:1) with an allograft (2:1) overlay (Fig. 26-8). Alternatively, it may be necessary to use only temporary biologic dressings, cadaveric allograft, or a dermal replacement until autologous donor sites are available. Once split-thickness autografts are harvested, the donor sites are dressed with a petroleum-based gauze, such as Xeroform or Scarlet-red (Covidien, Mansfield, Mass.). OpSite can be used to cover donor sites. Repeat grafting is required for large burns, with sequential harvesting of split-thickness autograft from limited

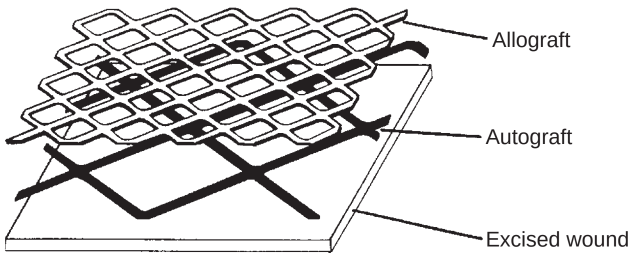

FIGURE 26-8 Schematic diagram of wound covering with 4:1 meshed autograft with 2:1 meshed allograft overlay. (With permission from Eichelberger MR [ed]: Pediatric Trauma: Prevention, Acute Care, Rehabilitation, St Louis, Mosby, 1993, p 581.)

donor sites, until the entire burn wound is covered. As meshed autografts heal, the allografts slough. However, the formation of significant scar remains the major disadvantage of this technique. Therefore the use of widely meshed graft is avoided on the face and hands. Full-thickness grafts that include both dermal and epidermal components provide the best outcome for wound coverage, with less contractures and better pigment match. However, its use is generally limited to small areas because of the lack of abundant full-thickness donor skin.

The limitation of donor sites in patients with burns over massive areas is partially addressed with the use of recombinant human growth hormone (rHGH). Administration of rHGH has resulted in accelerated donor-site healing, allowing more frequent donor-site harvest in a given period of time.[53] The use of rHGH decreased donor-site healing time by an average of 2 days, which ultimately shortened the overall length of hospitalization from 0.8 to 0.54 days per percentage of TBSA burned.[53] These effects from rHGH are thought to result from stimulation of insulin-like growth factor (IGF)-1 release and induction of IGF-1 receptors in the burn wound.[54] Given alone, insulin has been shown to decrease donor-site wound protein synthesis, accelerating healing time from 6.5 to 4.7 days.[55] The decrease in donor-site healing by 1 day between each harvest can significantly impact overall length of hospital stay in patients with massive burns who require multiple grafting procedures. The administration of rHGH in burned children was associated with a 23% reduction in total cost of hospital care for a typical 80% TBSA burn.[53]

The use of cultured keratinocytes from the patient's own skin has continued to generate considerable interest as a potential solution for massively burned patients with limited donor sites. Cultured epithelial autografts (CEA) can theoretically be used to provide complete coverage, but it is wrought with problems in its practical application. Although cultured keratinocytes grow slowly, they are particularly fragile and very susceptible to shear trauma. In noncritically ill patients who are otherwise not sedated, strict bedrest may be necessary to prevent loss of the graft, which consequently delays mobilization and rehabilitation. Thus the successful take rate of CEAs is only 50% to 70%. In one burn center's experience, they recommended CEA in the following subpopulation: large full-thickness burns (>50% TBSA), moderate burns (30% to 50% TBSA) with limited donor-site availability, and burns in which the donor site presents a significant functional or cosmetic issue. They also noted an estimated graft take rate of 72.7% at discharge, but that children had a higher contracture rate than their adult counterparts (90% vs. 57%).[56] It has been reported that there is a significantly longer hospitalization with these grafts in patients with burns of more than 80% TBSA. However, this technology continues to hold promise in treating massive burns.

## Hypermetabolic Response

Burn patients demonstrate dramatic increases in metabolic rate. The hypermetabolic response, which is generally greater with increasing burn size, reaches a plateau at 40% in a TBSA burn.[57] The hypermetabolic response to burn injury is characterized by catabolic metabolism, hyperdynamic circulation, insulin resistance, delayed wound healing, and increased risk of infection.[58] These physiologic changes of increased energy expenditure, oxygen consumption, proteolysis, lipolysis, and nitrogen losses are induced by up-regulation of catabolic agents, such as cortisol, catecholamine, and glucagons, which act synergistically to increase the production of glucose, a principal fuel during acute inflammation. Cortisol stimulates gluconeogenesis, proteolysis, and sensitizes adipocytes to lipolytic hormones. Catecholamines stimulate the rate of glucose production through hepatic gluconeogenesis and glycogenolysis, as well as promoting lipolysis and peripheral insulin resistance. Thus serum insulin levels are elevated, but the cells themselves become insulin resistant.[59] The increase in glucagon, which is stimulated by catecholamines, further promotes gluconeogenesis. Recent trials have demonstrated that intensive insulin therapy aimed at maintaining a daily average glucose of 140 mg/dL improves postburn outcomes.[60,61] Patients with intensive insulin treatment have demonstrated improved immune function and decreased sepsis, along with an attenuation of the inflammatory and acute phase response. As such, tight glucose control is thought to be critical in improving the overall recovery of burn patients.

Significant protein catabolism occurs in severe burns. Cortisol is catabolic and is partially responsible for the loss of tissue protein and negative nitrogen balance. In addition, burn injury is associated with decreased levels of anabolic hormones, such as growth hormone and IGF-1, which contribute significantly to net protein loss. The synthesis of protein (essential for the production of collagen for wound healing) and antibodies and leukocytes participating in the immune response, requires a net positive nitrogen balance. Excess catecholamines in postburn patients also contribute to persistent tachycardia and lipolysis. The consequences of these physiologic insults are cardiac failure and fatty infiltration of the liver. The use of a beta blocker, propranolol, has been shown to lower resting heart rate and left ventricular work and decrease peripheral lipolysis without adversely affecting cardiac output or the ability to respond to cold stress.[62,63] Propranolol also increases lean body mass and decreases skeletal muscle wasting. Herndon and colleagues[57] demonstrated that beta blockade using propranolol during hospitalization attenuated hypermetabolic response and reversed muscle-protein catabolism in burned children. Propranolol was given at a standard starting dose (1.98 mg/kg/day) and then titrated to achieve a decrease in the heart rate of approximately 20% from a baseline values. At 2 weeks of treatment, resting energy expenditure and oxygen consumption had increased in the control group. In contrast, patients in the propranolol group had significant decreases in these variables. Concurrent with the decline in energy expenditure, beta blockade also improved the kinetics of skeletal-muscle protein. The muscle protein net balance improved by 82% compared with pretreatment baseline values, whereas it decreased only by 27% in untreated controls.[57] Furthermore, the administration of propranolol to burned children receiving simultaneous human growth hormone has salutary cardiovascular effects, a decrease in the recent release of free fatty acids from adipose tissue, and an increase in efficiency of the liver's handling of secreted free fatty acids and very-low-density lipoproteins. Administration of propranolol has been shown to decrease peripheral lipolysis and fat deposition in the liver of burn patients.[57] A recent report also suggested that administration of propranolol (4 mg/kg/q24h) markedly decreases the amount of insulin necessary to decrease elevated glucose level postburn.[64] The mechanism

by which propranolol exerts its effects is still unknown, but it appears to be secondary to increased protein synthesis despite persistent protein breakdown.

Growth hormone and IGF-1 levels are shown to decrease after burn injury. Pharmacologic agents have been used to attenuate catabolism and to stimulate growth despite a burn injury.[65] Growth hormone, insulin, IGF-1/IGF-binding protein-3, testosterone, and oxandrolone improve nitrogen balance and promote wound healing.[66–68] Exogenous administration of rHGH, which increases protein synthesis, has been shown to improve nitrogen balance, preserve lean muscle mass, and increase the rate of wound healing.[69] The anabolic action of growth hormone appears to be mediated by an increase in protein synthesis, whereas IGF-1 decreases protein degradation. Growth hormone also enhances wound healing by stimulating hepatic and local production of IGF-1 to increase circulating and wound-site levels.[70] Plasma growth hormone levels, which are decreased following severe burns, can be restored by administration of rHGH (0.2 mg/kg/day) in massively burned children to accelerate skin graft donor-site wound healing and shorten hospital stay by more than 25%.[71] rHGH in severely burned children has shown to be safe and efficacious. In one randomized prospective trial in pediatric burn patients, rHGH administration led to elevations in serum growth hormone, IGF-I, and IGFBP-3, whereas the percent body fat content significantly decreased when compared with the control group. Long-term administration of 0.1 and 0.2 mg/kg/day rHGH also significantly improved scarring at 12 months postburn.[72] However, it has previously been shown that rHGH is associated with hyperglycemia, along with increased free fatty acids and triglycerides, which limits its clinical applicability. A prospective randomized control trial showed efficacy in rHGH and propranolol treatment in attenuating hypermetabolism and inflammation in severely burned children.[73] In this study, patients receiving rHGH (0.2 mg/kg/day) and propranolol (to decrease heart rate by 15%) for more than 15 days demonstrated significantly decreased percent predicted resting energy expenditure, C-reactive protein, cortisone, aspartate aminotransferase, alanine aminotransferase, free fatty acid, IL-6, IL-8, and macrophage inflammatory protein-1 when compared with controls. Other markers, such as serum IGF-1, IGF-binding protein-3, growth hormone, prealbumin, and IL-7 increased in rHGH/propranolol-treated burned patients.[73] These findings further validate the beneficial role of combination treatment with rHGH and a beta blocker in pediatric burn patients.

In severely burned patients, muscle anabolism can result from administration of submaximum dosages of insulin by stimulating muscle protein synthesis. Insulin administration has also been demonstrated to improve skin graft donor-site healing and wound matrix formation.[74] Testosterone production is greatly decreased after severe burn injury, which may last for months in postpubertal males. Increased protein synthesis with testosterone administration is accompanied by a more efficient use of intracellular amino acids derived from protein breakdown and an increase in inward transport of amino acids. An increase in net protein synthesis is attainable in adults with large burns by restoring testosterone concentrations to the physiologic range.[66] An analog of testosterone with less androgenic effect, oxandrolone (Upsher-Smith Laboratories, Minneapolis, Minn.), has been used in acute and rehabilitating adult burn patients, with promising results regarding weight gained. Oxandrolone, an oral synthetic derivative of testosterone with a lower androgenic/anabolic ratio, has been safely used to improve lean body mass and weight gain in severely burned adults and children. A large prospective double-blind randomized study involving 235 severely burned children (TBSA > 40%) showed that oxandrolone treatment significantly increased lean body mass along with serum total protein, prealbumin levels, and mean muscle strength. Interestingly, the oxandrolone-treated group also had a shorter hospital stay.[75] Similar results were reported in adult burn patient population.[76]

## Nutrition

The metabolic rate of patients with burns increases from 1.5 times the normal rate in a patient with 25% TBSA burns to 2 times the normal rate in 40% TBSA burns.[77] Children are particularly vulnerable for protein-calorie malnutrition because of their proportionally lower body fat and smaller muscle mass, in addition to increased metabolic demands. This malnutrition is associated with dysfunction of various organ systems, including the immune system, and delayed wound healing. To ensure that patients remain caught up nutritionally, enteral feeding should be initiated early after a burn injury, especially since early enteral feedings have been shown to decrease the level of catabolic hormones, improve nitrogen balance, maintain gut mucosal integrity, and decrease the incidence of sepsis and overall hospitalization. Feeding tubes are generally placed under fluoroscopy immediately after the initial evaluation of burns, and enteral nutrition is started within hours after burns. Early enteral feedings have been shown to decrease the level of catabolic hormones, improve nitrogen balance, maintain gut mucosal integrity, and decrease overall hospital stay.[78] Although hyperalimentation can deliver sufficient calories, its use in burn patients has been associated with deleterious effects on immune function, small bowel mucosal atrophy with increased incidence of bacterial translocation, and decrease in survival.[79] Enteral nutrition through a feeding tube placed into the stomach or duodenum is always preferred to parental nutrition, and is associated with decreased metabolic rate and decreased sepsis in burn patients.

Several formulas are used to calculate caloric requirement in burn patients. Both Curreri (25 kcal/kg plus 40 kcal/% TBSA burned) and modified Harris-Benedict (calculated or measured resting metabolic rate times injury factor) formulas use the principle of providing maintenance caloric needs plus the additional caloric needs related to the burn size. Similar to fluid resuscitation guidelines, a caloric requirement guideline based on total and burned BSA is more appropriate for pediatric burn patients (Table 26-7).[80] The exact nutrient requirements of burn patients are not clear, but it is generally

**TABLE 26-7**
**Caloric Requirements for Burned Children (Shriners Hospital for Children-Galveston)**

| *Age Group* | *Daily Caloric Requirements* |
|---|---|
| Infant and toddler | 2100 kcal/m$^2$ total + 1000 kcal/m$^2$ burn |
| Child | 1800 kcal/m$^2$ total + 1300 kcal/m$^2$ burn |
| Adolescent | 1500 kcal/m$^2$ total + 1500 kcal/m$^2$ burn |

accepted that maintenance of energy requirement and replacement of protein losses are vital. The recommended enteral tube feedings should have 20% to 40% of the calories as protein, 10% to 20% as fat, and 40% to 70% as carbohydrates. Milk is one of the least expensive and best tolerated forms of nutrition, but, to avoid dilutional hyponatremia, sodium supplementation may be needed when milk is used in large quantity. There are also numerous commercially available enteral formulas, such as Vivonex (Nestlé-Nutrition, Vevey, Switzerland) or Pediasure (Abbott Laboratories, Abbott Park, Ill.). One study compared outcomes with the use of Vivonex and milk in 944 pediatric burn patients and found that patients receiving Vivonex had shorter stays in the intensive care unit, a lower incidence of sepsis, and lived significantly longer until death than those receiving milk. Although there was no difference in mortality between the two groups, autopsies demonstrated decreased hepatic steatosis.[81] One report evaluated the efficacy of an anti-inflammatory, pulmonary enteral formula in the treatment of pediatric burn patients with respiratory failure.[82] Based on evidence that the inclusion of dietary lipids (e.g., omega-3 fatty acid, eicosapentaenoic acid) is known to modulate the inflammatory response, and the addition of antioxidants may improve cardiopulmonary function and respiratory gas exchange, this study evaluated the role of a specialized pulmonary enteral formula (SPEF) containing anti-inflammatory and antioxidant-enhanced components in pediatric burn patients. The use of SPEF was shown to be safe in pediatric patients and resulted in an improvement in oxygenation and pulmonary compliance in burned patients with acute respiratory distress syndrome.[82]

# Pharmacotherapy

## ANALGESIA

Burn wound treatment and rehabilitation therapy produce pain for patients of all age groups. Infants and children do not express their pain in the same way that adults do and may display pain through behaviors of fear, anxiety, agitation, tantrums, depression, and withdrawals. In older children, allowing the child to participate in providing wound care can help the child to have some control and alleviate fear and pain. Various combinations of analgesics with anxiolytic medications are used effectively during procedures and wound dressing changes (Table 26-8). A successful pain management regimen for burned children requires understanding by the entire burn team on how the pain is associated with burn depth and the phase of wound healing. Pain management protocols should be tailored to control background pain as well as that incurred with procedures, such as dressing changes, vascular access placement, and physical therapy. Physical therapy rehabilitation, which is vital to optimize good functional outcome, can more effectively be used if there is appropriate pain control. However, caution must be exercised to prevent any potential injury because of overmedication. Scheduled administration of acetaminophen can often address background pain, and it is not uncommon for dose escalation to occur as patients experience tolerance to a particular pain regimen. Morphine sulfate or fentanyl is frequently used to manage postoperative pain. The use of ketamine (0.5 to 2.0 mg/kg IV) is quite effective and ideal for short procedures, such as dressing changes and vascular access placements. For burned children requiring deeper sedation and analgesia, a combination of propofol and ketamine has also been shown to be effective. Advanced pain management protocols can be administered safely by those experienced with the use of conscious sedation. Physical therapy, which is vital to optimize good functional outcome, can more effectively be used if there is appropriate pain control. However, caution must be exercised to prevent any potential injury because of overmedication. In children as young as 5 years of age, a patient-controlled analgesia may be used to provide steady-state background infusion of narcotic with additional bolus regimen.[83] Burn injuries are traumatic for the burned child as well as for the family. Burn care professionals must do everything possible to make the experience as tolerable as possible in assisting burn patients to a successful recovery.

**TABLE 26-8**
**Pharmacotherapy Agents**

| *Agent* | *Dosages* | *Indications* |
|---|---|---|
| Morphine Sulfate | 0.05-0.1 mg/kg IV or 0.3 mg/kg PO | Acute pain; procedures and dressing changes |
| Demerol | 1-2 mg/kg PO or IV | Acute pain; procedures and dressing changes |
| Ketamine | 1-2 mg/kg IV or 5-7 mg/kg IM | Surgery; procedures and dressing changes |
| Diazepam | 1-2 mg PO or IV | Preoperative; anxiety |
| Chloral hydrate | 250-500 mg PO | Preoperative; insomnia |
| Midazolam | 0.25-0.5 mg/kg PO or IV | Anxiety; used in combination with narcotics |
| Lorazepam | 0.03 mg/kg PO or IV | Background anxiety |

As mentioned earlier, the physiologic changes that occur with a burn injury alter metabolism and pharmacodynamics of many medications, including narcotics. In one study, 20 adult patients with a mean burn size of 49% TBSA were compared with a control group after receiving 200 μg of fentanyl. Plasma concentrations were sampled at various times after administration, and it was noted that the burn patients had lower fentanyl concentrations at all time points, with no difference in clearance. This is likely related to the increased volumes of distribution in burn patients, which further suggests that the volume of distribution needs to be carefully considered when administering narcotics and titrating to clinical effect.[84]

## SEDATIVES AND ANXIOLYTICS

Ketamine is a commonly used procedural sedative/anesthetic in burn patients. Derived from phencyclidine, it is characterized by dissociative anesthesia and has excellent analgesic properties. Given at a dose of 1 to 2 mg/kg IV or 5 to 7mg/kg IM, an effect is achieved rapidly with a relatively short duration of action. In addition, ketamine is also frequently used as an anesthetic agent for operative procedures without compromising airway reflexes. The use of ketamine is contraindicated in patients with increased intracranial pressure. Benzodiazepines are commonly used to control burn-related anxiety as well as to enhance the effects of narcotics for pain control. Lorazepam (Ativan) at a dosage of 0.03 mg/kg PO or IV, is an effective anxiolytic agent. It is also useful as a hypnotic agent to improve patient restfulness in the acute care setting. Diazepam (Valium) has a longer duration of action than

lorazepam and therefore is useful in more chronic settings. Diazepam also improves muscle relaxation, which can be beneficial to facilitate rehabilitative therapy. Midazolam (Versed) has a rapid onset of action, with peak plasma levels achieved within 30 minutes and a half-life of 2 to 5 hours. It is commonly used to achieve a desired level of sedation for procedures and dressing changes. Because of the anterograde amnesia property, it is used commonly as a premedication agent on operative days.

Dexmedetomidine (DEX) is another adjunct being used in the pediatric population for pain and sedation management. It is a selective $\alpha_2$-adrenergic agonist that can provide sedation, anxiolysis, and analgesia with less respiratory depression than other sedatives. In one retrospective review of 65 ventilated pediatric burn patients, DEX was continuously infused after loading, and patients were noted to be "adequately sedated," which was in contrast to their sedation failure with opioids and benzodiazepines alone. The patients were successfully extubated while on the DEX infusion, and no patient showed evidence of DEX-induced respiratory depression.[85] In another study, intranasal DEX or oral midazolam was administered to 100 pediatric burn patients preoperatively. Ninety-four percent of the patients who received DEX were appropriately sedated as opposed to 82% in the midazolam group. There were no significant differences in narcotic requirements during the operation, nor increased adverse effects in patients receiving DEX.[86] Thus DEX may prove to be a safe alternative to benzodiazepines in burn patients.

### INTRAVENOUS ANTIBIOTICS

The use of perioperative IV antibiotics has significantly contributed to an overall improvement in the survival of major burn patients during the past 2 decades. Bacteria colonized in the burn eschar can potentially shed systemically at the time of eschar excision and contribute to sepsis. Perioperatively, IV antibiotics against *Streptococcus*, *S. aureus*, and *Pseudomonas* are generally administered until quantitative cultures of the excised eschar are finalized. The antibiotic regimen can then be guided by culture results and used under the appropriate clinical conditions. In acute burns, gram-positive cocci are generally the predominate organism involved, but colonization with gram-negative bacteria, and even fungi, are frequently encountered in chronic burn wounds and therefore must be covered with appropriate IV antibiotics during excision and grafting. In addition to burn wound sepsis, graft loss may be attributed to the presence of an infected wound at the time of skin grafting or colonization of the grafted bed shortly after surgery. The most common organisms responsible for graft loss are beta-hemolytic streptococci (*S. pyogenes, S. agalactiae, or S. viridans*). They are generally sensitive to third-generation cephalosporin and fluoroquinolones. The emergence of multiresistant bacteria, such as methicillin-resistant *S. aureus*, has become a serious problem for burn centers. Hence, IV antibiotics should be used with diligence, limiting their use for perioperative coverage and treatment of identified sources of infection.

One consideration that should be taken into account is the tissue penetration of IV antibiotics in burned tissue. One study compared the distribution of cephalothin in burned and nonburned tissue, and cephalothin levels were found to be elevated with decreased clearance in both tissues when compared with controls. It was postulated that this resulted from altered blood flow in injured tissue, an increase in capillary leakage, or leakage of albumin-bound cephalothin into the interstitium.[87] This finding suggests that antibiotic pharmacodynamics may need to be re-interpreted in burned patients.

## Nonthermal Injuries

### CHEMICAL BURNS

Children accidentally come in contact with various household cleaning products. Treatment of chemical burns involves immediate removal of the causative agent and lavage with copious amount of water, with caution for potential hypothermia. Fluid resuscitation is started, and care should be taken to ensure that the effluent does not contact uninjured areas. Decontamination is not performed in a tub, but rather, the wounds are irrigated toward a drain as in a shower. After completion of copious irrigation, wounds should be covered with a topical antimicrobial dressing and appropriate surgical plans made. The rapid recognition of the offending chemical agent is crucial to the proper management. When in doubt, a local poison control center should be contacted for identification of chemical composition of the product involved. The common offending chemical agents can be classified as alkali or acid. Alkali, such as lime, potassium hydroxide, sodium hydroxide, and bleach, are among the most common agents involved in chemical injury.[88] Mechanisms of alkali-induced burns are saponification of fat resulting in increased cell damage from heat, extraction of intracellular water, and formation of alkaline proteinates with hydroxyl ions. These ions induce further chemical reaction into the deeper tissues. Attempts to neutralize alkali are not recommended, because the chemical reaction can generate more heat and add to injury. Acid burns are not as common. Acids induce protein breakdown by hydrolysis, resulting in formation of eschar, and therefore do not penetrate as deeply as the alkaline burns. Formic acid injuries are rare but can result in multiple systemic organ failures, such as metabolic acidosis, renal failure, intravascular hemolysis, and acute respiratory distress syndrome. Hydrofluoric acid burns are managed differently from those of other acid burns in general.[89] After copious local irrigation with water, fluoride ion must be neutralized with topical application of 2.5% calcium gluconate gel. If not appropriately treated, free fluoride ion causes liquefaction necrosis of the affected soft tissues, including bones. Because of potential hypocalcemia, patients should be closely monitored for prolonged QT intervals.

### ELECTRICAL BURNS

Three to five percent of all admitted burn patients are injured from electrical contact. Fortunately, electrical burns are rare in children. Electrical burns are categorized into high- and low-voltage injuries. High-voltage injuries are characterized by varying degree of local burns, with destruction of deep tissues.[90] The electrical current enters a part of the body and travels through tissues with lowest resistance, such as nerves, blood vessels, and muscles. Heat generated as electrical current passes through deep tissues with relatively high resistance, such as bone, and damages adjacent tissues that may not be readily visible. Skin is mostly spared because of its high resistance to electrical current. Primary and secondary surveys, including electrocardiography, should be completed. If the initial electrocardiogram is normal, no further monitoring

is necessary; however, any abnormal findings require continued monitoring for 48 hours and appropriate treatment of dysrhythmias when detected. The key to management of electrical burns lies in the early detection and proper treatment of injuries to deep structures. Edema formation and subsequent vascular compromise is common to extremities. Fasciotomies are frequently necessary to avoid potential limb loss. Intra-abdominal complications can arise from bowel perforation. If myoglobinuria is present, vigorous hydration with administration of sodium bicarbonate, to alkalinize the urine and mannitol to achieve diuresis and as a free radical scavenger, is indicated. Repeated wound exploration and debridement of affected areas are required before ultimate wound closure, because there is a component of delayed cell death and thrombosis. The mechanism of electrical burn injury is to overwhelm the cellular systems that operate at millivolt/milliamp levels, so that cells that survive the initial injury may slowly die during a week's time as ion gradients deteriorate while thrombosis of the microvasculature proceeds. Electrical injuries may also have a thermal, nonconductive component as clothes burn or the electricity flashes. This is treated as if it were a conventional thermal burn. Low-voltage injury is similar to thermal injury, without transmission of electrical current to deep tissues, and usually only requires local wound care.

## Outpatient Therapy

The majority of pediatric burns are minor, often resulting from scald less than 10% TBSA or isolated small areas of thermal injuries from contact with hot objects. Such injuries are usually limited to partial thickness of the skin and can be treated on an outpatient basis. After an initial assessment, the burn wound is gently washed with water and a mild bland soap with appropriate pain control. Blisters can be left intact when they are small and not likely to spontaneously rupture, especially when present on the palm of hand. Blisters can provide a natural barrier against the environment and are beneficial in avoiding daily dressing changes. Spontaneous resorption of the fluid occurs in approximately 1 week, concomitant with the re-epithelialization process. Larger areas of blisters should be debrided and topical antimicrobial dressings applied. Silvadene is most commonly used because of its broad-spectrum antimicrobial property as well as its soothing effect on superficial second-degree burns. However, because silver sulfadiazine can impede epithelialization, its use should be discontinued when healing partial-thickness wounds are devoid of necrotic tissue and evidence of re-epithelialization is noted. Alternatively, antimicrobial dressings with triple antibiotic ointment (neomycin, bacitracin, and polymyxin B sulfate) and Polysporin, which do not have any negative effects on epithelialization, are commonly used. For small superficial partial-thickness burns, nonmedical white petrolatum-impregnated fine mesh, porous mesh gauze (Adaptic; Johnson & Johnson, New Brunswick, NJ), or fine mesh absorbent gauze impregnated with 3% bismuth tribromophenate in a nonmedicinal petrolatum blend (Xeroform, Covidien) are usually sufficient without the need for topical antimicrobials.

Superficial burns to the face can be treated with application of triple antibiotic ointment alone, without any dressings. The frequency of dressing change varies from twice daily to once a week, depending on the size, depth of burns, and drainage. Those who advocate twice daily dressing changes base their care on the use of topical antimicrobials whose half-life is about 8 to 12 hours. Others who use petrolatum-based or bismuth-impregnated gauze recommend less frequent, once every 3- to 5-day dressing changes. The use of synthetic wound dressings (e.g., Biobrane) is also ideal for treatment of superficial partial-thickness burns as an outpatient.[91] When applied appropriately to fresh, partial-thickness wounds, Biobrane adheres to the wound rapidly and is very effective in promoting re-epithelialization in 1 to 2 weeks (see Fig. 26-6). Although daily dressing changes are eliminated, Biobrane-covered wounds should still be monitored closely for signs of infection.

## Rehabilitation

Rehabilitation therapy is a vital part of burn care. During the acute phase of burn care, splints are used to prevent joint deformities and contractures. By using thermoplastic materials, which are amenable to heat manipulation, splints are fitted individually to each patient. Application of splints at all times, except during an exercise period, can potentially prevent severe contractures that occur in large-burn patients. Patients are mobilized out of bed immediately after the graft takes, and aggressive physical therapy is implemented. After the acute phase, hypertrophic scar formation is of major concern. The burn depth, patient's age, and genetic factors all play an important role in hypertrophic scar formation. In general, deep second-degree burn wounds, requiring 3 weeks or more to heal, will produce hypertrophic scarring. Children are more prone to hypertrophic scar formation than adults, probably because of the high rate of cell mitosis associated with growth. Continuously applied pressure 24 hours a day is the most effective method to minimize the hypertrophic scar formation. Pressure garments should be worn until scars mature, but they may be associated with skin breakdown and patient discomfort. Silicone gel is a commonly used treatment modality, even though its mechanism of action is poorly understood. Silicone treatment is reported to soften, increase elasticity, and improve the appearance of hypertrophic scars, but conflicting results remain in the literature that may be attributed to patient compliance.[92] Nonetheless, scar maturation usually occurs 6 to 18 months after injury. In younger patients, scars mature at a much slower rate. In addition to splints and pressure garments, physical therapy is a crucial component of rehabilitation therapy. Families should be thoroughly instructed on a program of active and passive range-of-motion exercises and muscle strengthening. It is not uncommon for patients to require inpatient or outpatient rehabilitation to return them to a functional quality of life. Burned survivors and families need rehabilitation therapy for extended periods of time both on a physical and psychological level. All must deal with feelings ranging from guilt to post-traumatic stress. A program such as *summer camp for children with burn injuries* has played an important role during the chronic phase of rehabilitation by helping children to improve self-esteem and to promote coping, social skills.[93]

# CHAPTER 27

# Child Abuse and Birth Injuries

Dennis W. Vane

## Child Abuse

Child abuse encompasses physical abuse, sexual abuse, emotional abuse, and neglect. This maltreatment of children has become a significant focus of attention in our society. The media routinely publish accounts of the alleged traumatic and sometimes fatal abuse of children among all socioeconomic classes and levels of celebrity. The myth that child abuse and other violence in the home occur only among the poor and the uneducated has been debunked. Child abuse is a worldwide problem that affects all levels of society. Prevention and effective treatment depend on the timely detection of epidemiologic situations that lend themselves to the maltreatment of children.

Unfortunately, the "minor" status of children leads to the justifiable issue of the relative rights of parents and guardians. In most societies, it is an accepted premise that parents have the authority and responsibility to provide for their children. This is based on the assumption that parents have the best interests of their children in mind when making these decisions. Unfortunately, not all parents are willing or capable of basing their care decisions on their children's best interests; rather, they make these decisions in a more self-centered manner. As a result, these children may become victims of abuse and neglect through actions or the lack of actions by these parents.

Religious and societal "norms" have created barriers to the identification of child abuse victims in many nations. Around the globe, relatively few nations have addressed this problem at all.[1] In the United States and Canada, legislation aimed at identifying child abuse and neglect was enacted beginning in the 1960s.[2] Since that time, the reporting of child abuse to civil authorities has been mandated for almost all professionals dealing with children. The legislation protects the reporting individual from liability (usually by using the phrase "suspicion of" or "injuries consistent with"), supersedes all professional–client privilege, and sometimes even imposes penalties for failure to report abuse.[3]

### EPIDEMIOLOGY

In 2007 in the United States, Children's Protective Services investigated 3.5 million reports of child abuse. Of these investigations, 794,000 children were found to be victims of abuse. Thirty percent of all the children were less than the age of 4 years, 20% were between the ages of 4 and 7 years, and 20% were between 8 and 11 years.[4] In about 160,000 children, this maltreatment is considered physically serious or life threatening. Between 1,000 and 2,000 deaths are attributed to child abuse each year in the United States, and 80% of those children are younger than 5 years. Forty percent of the deaths occur in the first year of life and occur in an equal sex distribution.[5] Although deaths occur predominantly in the younger age groups, maltreatment of children is felt to increase with age. In teenagers, the incidence of abuse is thought to be twice that in preschool children; however, that statistic includes sexual abuse.[6] Intentional physical injury is most common in children less than 2 years of age, because they are essentially defenseless victims.[4] Patterns of child abuse occur with differing frequencies over the social strata. Sexual and emotional abuse have no socioeconomic associations, whereas physical abuse and neglect are more frequently associated with poverty.[6] Often, several types of abuse are perpetrated on the same child or within the same family. Additionally, abuse commonly occurs in families with other forms of intrafamilial violence, such as spousal abuse and violence among siblings.[7]

There is no single cause for abuse. However, multiple factors have been described that place a child at high risk to be abused. Commonly, more than one risk factor is present in a family at one time. It is important to remember, however, that the presence of risk factors in a child's environment does not necessarily indicate that abuse has or will occur. It is important to identify those situations where risk factors for child abuse exist. Local family services can often provide assistance to high-risk homes to aid families that may be in crisis. These early interventions potentially reduce or eliminate the risk of abuse.[4]

Risk factors for abuse are generally classified into four broad categories. First, there are the character and personality traits of the caregiver or parent; second, the individual characteristics of the child; third, the family dynamics; and finally, the environment in which the family is living.

#### Caregiver or Parent

Approximately 80% of all abusers are the parents.[4] Often, the abuser is described as having poor impulse control, antisocial behavior, and low self-esteem. Commonly, they were victims of abuse or witnessed domestic violence in the home themselves. Often, the abuser will have substance abuse problems. In many cases the parent's or caregiver's perception of the child is

negative and associated with unrealistic expectations of the child's abilities. The age of the parent is another risk factor—the younger the parent or caregiver, the greater the risk of abuse.

### The Child

The profile of the victim related to abuse rates has been studied in great depth.[4] The age of the child clearly impacts the risk, with children less than 3 years of age having the highest rates of abuse. These children require constant care and attention. They are small in stature compared with the adult and clearly are unable to adequately defend themselves. The child may be in a learning phase, such as toilet training, and may not be responding as the caregiver expects. Subsequently, children with cognitive, physical, or emotional disabilities are at significantly greater risk to suffer abuse. This higher risk holds true for premature and low-birth-weight infants as well. Some authors suggest that these factors interfere with appropriate parental bonding early in the child's life.

### Family Dynamics

The existing family structure clearly impacts the risk for abuse.[4] A single-parent household significantly increases the risk for abuse, particularly when the father is absent. Households where there are large numbers of individuals living together, including family and nonfamily members, compounds the potential risk for abuse as well. In families where domestic violence has been documented, reports indicate that children suffer a 30% to 60% risk of abuse.

Finally, environmental factors, such as poverty, unemployment, lack of education, and living in high-crime areas, have all been identified as predisposing to potential child abuse. These factors are often coupled with a scarcity of social services to aid these families in these areas, thus adding stress to the dynamics fostering the environment for abuse.[4]

Child abuse is a self-perpetuating social and economic problem. Problems with substance abuse and depression are reportedly 2 to 3 times more likely in abused children than in the general population, and abused children are likely to be far more physically aggressive with their peers.[8,9] It is estimated that approximately 30% of abuse victims eventually abuse their own children.[10] Some authors have suggested that this perpetual cycle of abuse is attributable, in part, to changes in the neuroendocrine system, influencing arousal, learning, growth, and the individual's pain threshold.[10]

What is clear is that the incidence of child abuse is significantly underreported, because professional contact or recognition is often required to identify abuse in the first place. Physicians must recognize not only abuse that has already occurred but also the factors indicating a high potential for abuse, if this dramatic worldwide problem is to be prevented.

## Presentation

Physicians must be aware that abused children are often withdrawn and avoid eye contact with their interviewers. Interviewers must be cognizant of the fact that children often respond with answers that they think will please the interviewer; so, care must be taken not to influence the child's responses. Young children are prone to associative fabrication, which may influence or even alter reality. The clinical history in suspected child abuse cases should include a detailed history of the family situation, unrelated caregivers, substance abuse in the household, and any history of past abuse. Even with these indicators, child abuse is extremely hard to accurately diagnose.

Given the wide spectrum of abuse, presenting symptoms vary accordingly. In the youngest victims, the diagnosis often depends on physical signs, such as bruising, patterned burn injuries, retinal hemorrhages, and long-bone fractures. Among all children, presentations that should raise a high level of suspicion in the clinician include multiple injuries in different stages of healing; injuries not consistent with the history provided by the caregiver; a history that changes when retold, particularly when the incident was "unwitnessed"; and injuries to the perineum. Wisslow[2] provided an excellent summary of the presenting physical injuries in cases of child abuse and neglect (Table 27-1). In children,

**TABLE 27-1**
**Signs and Symptoms Suggesting Child Abuse or Neglect**

| |
|---|
| Subnormal growth |
| Weight, height, or both less than 5th percentile for age |
| Weight less than 5th percentile for height |
| Decreased velocity of growth |
| Head injuries |
| Torn frenulum of upper or lower lip |
| Unexplained dental injury |
| Bilateral black eyes with history of single blow or fall |
| Traumatic hair loss |
| Retinal hemorrhage |
| Diffuse or severe central nervous system injury with history of minor to moderate fall (< 3 m) |
| Skin injuries |
| Bruise or burn shaped like an object |
| Bite marks |
| Burn resembling a glove or stocking, or with some other distribution, suggests an immersion injury |
| Bruises of various colors (in different stages of healing) |
| Injury to soft tissue areas that are normally protected (thighs, stomach, upper arms) |
| Gastrointestinal or genitourinary injuries |
| Bilious vomiting |
| Recurrent vomiting or diarrhea witnessed only by parent |
| Chronic abdominal or perineal pain with no identifiable cause |
| History of genital or rectal pain |
| Injury to genitals or rectum |
| Sexually transmitted disease |
| Bone injuries |
| Rib fracture in the absence of major trauma, such as a motor vehicle accident |
| Complex skull fracture after a short fall (< 1.2 m) |
| Metaphyseal long-bone fracture in an infant |
| Femur fracture (any configuration) in a child younger than 1 year |
| Multiple fractures in various stages of healing |
| Laboratory studies |
| Implausible or physiologically inconsistent laboratory results (polymicrobial contamination of body fluids, sepsis with unusual organisms, electrolyte disturbances inconsistent with the child's clinical state or underlying illness, wide and erratic variations in test results) |
| Positive toxicologic tests in the absence of a known ingestion or medication |
| Bloody cerebrospinal fluid (with xanthochromic supernatant) in an infant with altered mental status and no history of trauma |

From Wissow LS: Child abuse and neglect. N Engl J Med 1995;332:1425-1431.

essentially any injury can be the result of abuse; however, particular injuries and injury patterns have a high degree of association with abuse.

### Traumatic Brain Injury

Head injury is the most common injury associated with child abuse, and is responsible for the majority of deaths.[11–16] Penetrating head injury is rare in abuse victims, and most head injuries occur in younger children.[14] Blunt head injury most commonly manifests as "shaken baby syndrome" or, more accurately, "shaken impact syndrome," in which the insult is caused by an acceleration and deceleration of the brain within the cranial compartment resulting from violent shaking (Fig. 27-1). Recent studies indicate that some sort of contact with an object is necessary for the classical brain injury to occur, but that object may be relatively soft and produce no external indication of trauma (Fig. 27-2).[17] Angular forces created during shaking and eventual percussion against an object result in rotation of the brain within the skull. This causes diffuse axonal injury and tearing of the subdural bridging veins, often resulting in subdural hematoma. Spontaneous subdural hematoma or its occurrence from unintentional trauma is uncommon in children; so, its presence should raise the suspicion of child abuse (Fig. 27-3). Acute contact with stationary objects results in the characteristic multiple skull fractures associated with repetitive injury. Secondary brain injury is also frequently associated with abuse, resulting in intracranial hemorrhage, anoxia secondary to apnea, hypoperfusion, cardiac arrest, and potentially, herniation of the brainstem.[18] Brain injury secondary to abuse carries a reported mortality rate of 15% to 38%, which is significantly higher than that of similar injuries caused by unintentional trauma.[17] Nonfatal outcomes in abused children with traumatic brain injuries are also significantly worse than in those whose injuries were sustained unintentionally.[19] Nonenhanced computed tomography is considered the most appropriate diagnostic tool for the identification of intentional head injury. Intracranial lesions are easily identified, as are the often associated skull fractures.[20]

Although most commonly seen in younger children, head injury associated with child abuse occurs in older children as well. Whereas external signs of trauma are infrequent in

FIGURE 27-1 **A** and **B,** Shaken baby syndrome is often recognizable by external bruising about the chest, shoulders, and neck caused by the fingers and hands. (Used with permission of the American Academy of Pediatrics: Visual Diagnosis of Child Abuse CD-ROM, ed. 3, American Academy of Pediatrics, 2008.)

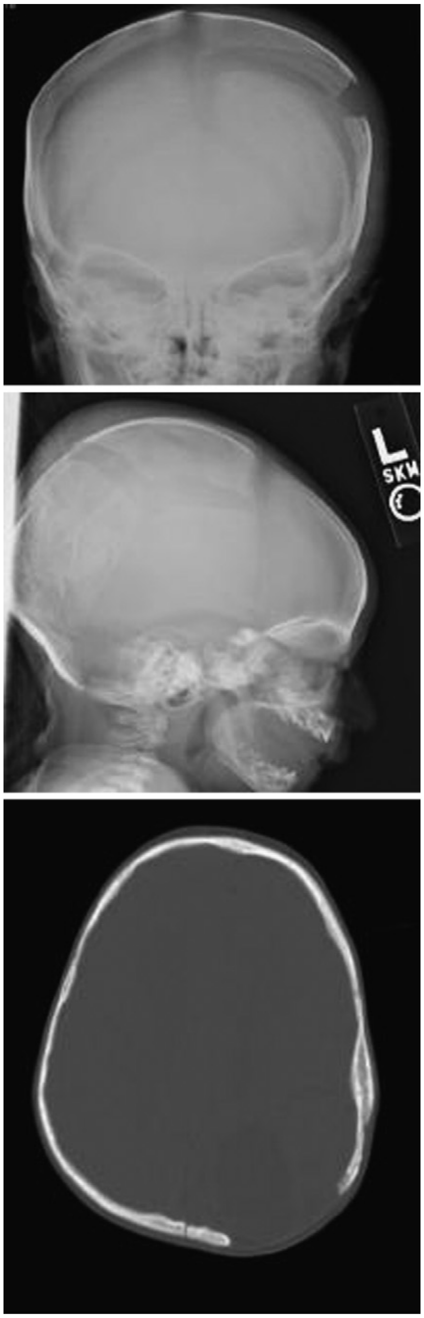

**FIGURE 27-2** The radiographs demonstrate a diastatic skull fracture secondary to forcibly striking the child's head against a hard object. These fractures are often associated with later complications from healing and development of leptomeningeal cysts. (Used with permission of the American Academy of Pediatrics: Visual Diagnosis of Child Abuse CD-ROM, ed. 3, American Academy of Pediatrics, 2008.)

younger children, older children usually present with visible injuries secondary to violent external trauma. These injuries are often severe, with poor outcomes.[21]

The identification of retinal hemorrhage has been deemed almost pathognomonic of child abuse[22]; however, recent studies indicate that retinal hemorrhage occurs in cases of nonintentional injury as well, including normal vaginal delivery, which can cause compression of the baby's soft skull.[23,24] The presence of retinal hemorrhage from nonintentional injury is so rare, however, that it should stimulate a high

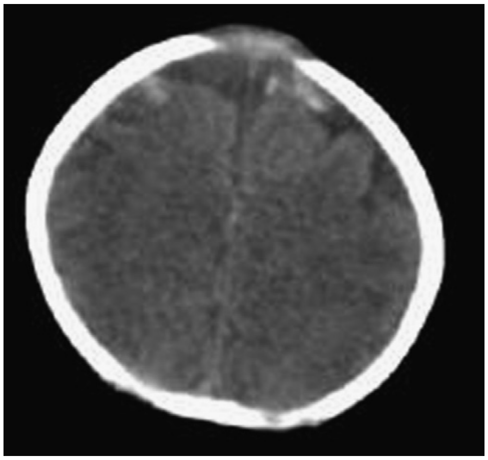

**FIGURE 27-3** The computed tomography (CT) scan demonstrates a subdural hematoma in a 6-week-old infant. Subdural hematomas may not present as space-occupying lesions but may cause significant morbidity when evacuated because of significant brain swelling. (Used with permission of the American Academy of Pediatrics: Visual Diagnosis of Child Abuse CD-ROM, ed. 3, American Academy of Pediatrics, 2008.)

level of suspicion for child abuse. When it is identified, the physician should begin an appropriate workup to investigate that possibility.

## Fractures

It is postulated that approximately 80% of child abuse cases in the United States are identified radiographically.[25] Fractures secondary to child abuse can be found in any age group, although fractures in older children are more commonly from high-impact unintentional injury.[26] This is the reverse of what is found in younger children where 55% to 70% of fractures associated with abuse occur in children less than 1 year of age; yet, only 2% of unintentional fractures occur in this age group.[12,14,27] The presence of a long-bone fracture in any child younger than 2 years of age has a high association with intentional injury.[28,29] Investigators have historically associated several fracture types with abuse, but it is probably more accurate to state that all fracture types can be associated with multiple causes. Spiral fractures, once reported as the most common type of fracture in abuse victims, have been replaced in more recent studies with single transverse fractures.[30] Spiral fractures are the result of torsional force applied to the extremity secondary to rotation of some sort. Transverse fractures are the result of a direct injury to the bone. This information should be used by the evaluating physician in conjunction with the history of injury to determine whether the history coincides with the presenting injury.

Diaphyseal fractures of the long bones are the most common fractures associated with child abuse, particularly those of the tibia, femur, and humerus. If the child is not ambulatory, the association between these fractures and abuse is extremely high.[30] Epiphyseal-metaphyseal fractures, although much less common than diaphyseal injuries, are reportedly far more specific for intentional injury.[31] The forces required to sustain these injuries greatly exceed the forces normally associated with falls and other minor trauma. Epiphyseal-metaphyseal fractures are also commonly known as corner fractures or bucket-handle fractures.

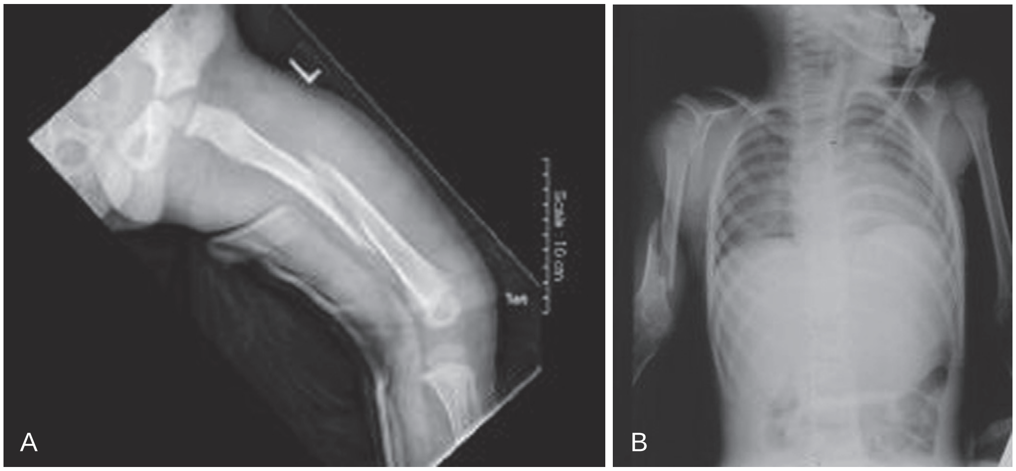

**FIGURE 27-4** **A,** The radiograph demonstrates a fracture of the femur in a 2-year-old child. Femur fractures are highly suspicious in this age group. The parents brought the child in, because it would not bear weight on its leg. **B,** The right humerus fracture in this child was accompanied by significant pulmonary contusions. The history of falling on the arm is inconsistent with this level of injury. (Used with permission of the American Academy of Pediatrics: Visual Diagnosis of Child Abuse CD-ROM, ed. 3, American Academy of Pediatrics, 2008.)

Type 1 fractures of the femur and humerus have a high association with abuse when encountered outside of the neonatal period.[32] This is particularly true if the history of injury does not contain significant high-force violent trauma. These injuries require considerable force to occur and, when nonintentional, are commonly associated with significant soft tissue damage and other injuries. Other types of Salter-Harris injuries do not appear to have a strong association with intentional abuse (Fig. 27-4).

Clavicular fractures can also be associated with abuse, but there is a low specificity. Clavicular fractures of either end, rather than the midshaft, are usually the result of significant traction or the trauma of shaking.[15] Rib fractures, in contrast, have an extremely high association with abuse. It is postulated that the relatively elastic rib cage in children prevents most fractures secondary to accidental trauma. When fractures of the ribs do occur, the association with abuse is high—up to 82%.[33] In general these fractures occur at the posterior segment of the rib near the costovertebral junction (Fig. 27-5).

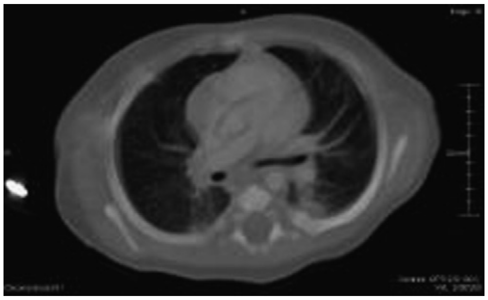

**FIGURE 27-5** Posterior rib fractures in children are rare results of accidental injury. Their presence most commonly indicates intentional injury. (Used with permission of the American Academy of Pediatrics: Visual Diagnosis of Child Abuse CD-ROM, ed. 3, American Academy of Pediatrics, 2008.)

Spinal fractures are rare in children, as is cord injury. The difficulty in diagnosing vertebral body injuries and the relatively protected spine make any association with abuse difficult to determine. Suffice it to say that any injury of the spine or spinal cord requires an extremely violent force, and the cause must be carefully investigated.

It is critical for any physician treating children to investigate all fractures, particularly in the younger age groups. Minimal trauma does not commonly cause fractures, except when associated with other pathology. Getting an accurate history is critical. The presence of multiple fractures associated with a history of minimal trauma always requires an investigation for potential child abuse. The identification of multiple fractures, particularly when the age of the fractures is different, is almost pathognomonic of abuse. When abuse is suspected, skeletal surveys are indicated. The American College of Radiology has published standards for these surveys.[34]

## Burns

Burns are a fairly common indication of child abuse, representing approximately 20% of pediatric burn injuries. Most commonly, the victims are less than 2 years of age.[35] Abuse victims often have characteristic patterns of burn infliction of which physicians should be aware.[36] Common patterns include circumferential burns, particularly when the burns are on more than one extremity; "pattern" burns or branding; burns to the buttocks, genitalia, or perineum; and punctate or cigarette burns (Figs. 27-6 and 27-7). Burn victims who are abused are usually younger than unintentional burn victims and have a history of being burned in the bathroom.[37] The demographics of intentionally burned children are striking. These children are often being raised by single mothers or are in foster care, they are in homes where other children have previously been removed because of abuse, and there is an almost 40% chance that past abuse has already been investigated.[37]

With burns, the history of injury is critical and is often inconsistent with the burn pattern. The burn itself often exhibits uncharacteristic features, such as lack of splash marks from falling liquids, consistent depth throughout the burn rather than the normal "feathering" of depth, and larger surface areas than expected based on the history. These burns, which are often the result of immersion, present with clear lines of demarcation, indicating that the child was unable to move during the incident and was probably restrained. Inflicted burns to the buttocks and perineum often occur in children being toilet trained when a caregiver becomes frustrated about an

**FIGURE 27-6** Pattern burns are almost pathognomonic of intentional injury. In this case, the silverware found in the home directly matches the injury seen here. (Used with permission of the American Academy of Pediatrics: Visual Diagnosis of Child Abuse CD-ROM, ed. 3, American Academy of Pediatrics, 2008.)

**FIGURE 27-7** Bilateral foot and ankle burns accompanied by burns to the perineum indicate abuse. These burns are commonly seen in children being toilet trained, who are in the care of a nonbiologic parent. (Used with permission of the American Academy of Pediatrics: Visual Diagnosis of Child Abuse CD-ROM, ed. 3, American Academy of Pediatrics, 2008.)

"accident." Burns on the dorsum of the hand are suggestive of abuse, whereas burns to the palm are more likely unintentional. Children, similar to adults, explore with the palmar surface, not the back of the hand. The depth of burn is also important. It takes approximately 1.5 seconds to cause a second-degree burn in adult skin immersed in water at

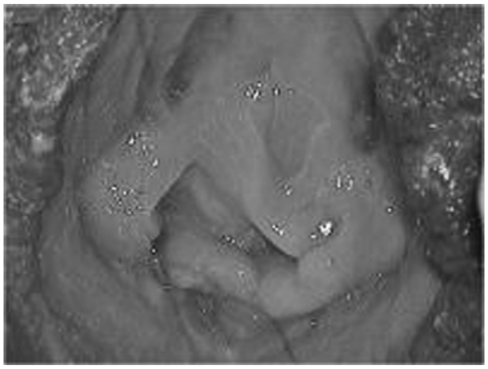

**FIGURE 27-8** Total lateral disruption of the hymen pictured here indicates forceful penetration. (Used with permission of the American Academy of Pediatrics: Visual Diagnosis of Child Abuse CD-ROM, ed. 3, American Academy of Pediatrics, 2008.)

150° F. That is certainly more time than anyone would keep his or her hands immersed volitionally.

Flame burns, while not usually the result of a direct intentional infliction, often do represent potential abuse by neglect or an unsafe habitation. These types of injuries require a high degree of suspicion and may warrant reporting.

A complete history and physical examination are necessary in any child seen for burns or the suspicion of abuse. Other signs of abuse are often discernible, such as healed or healing fractures or, possibly, perineal injuries. Additionally, recent data indicate that some burn injuries mimic chronic skin conditions.[38] Thus a high level of suspicion must be maintained when clinicians see lesions that do not present in characteristic locations or do not respond to normal therapy. Given the high incidence of recurrence in burn injury, physicians must ensure that the child is discharged to a safe environment.[39]

## Thoracoabdominal Injury

Fortunately, significant thoracoabdominal injury secondary to child abuse is uncommon, estimated to occur in about 5% of abused children.[40] Unfortunately, thoracoabdominal injury is the second leading cause of death in these children, following head injury, and has a significantly higher associated mortality than similar unintentional injury.[25,40] Any type of blunt or penetrating abdominal injury can be caused intentionally.[6,34,41–43] Injuries commonly result from severe blows to the abdomen or chest cavity, and as previously stated, rib fractures in children should raise the suspicion of abuse.[33] Most important, the clinician must ascertain the history of injury to determine whether the injury is consistent with the mechanism described. For example, recent reports indicate that a simple fall down a flight of stairs does not generate the force or dynamics necessary for a hollow viscus perforation.[44] Similarly, significant head injury requires a mechanism generating more force than simply rolling out of bed. Studies indicate that a child must fall at least 3 feet onto a hard surface to sustain a skull fracture. This includes wood floors, tile, or cement. Falls on to carpets and mattresses provide adequate cushioning to make a fracture unlikely from this height.[45–47]

Treatment of intentionally inflicted intra-abdominal injuries follows the algorithms of unintentional injuries. Mortality from these intentional injuries exceeds those found with unintentional injuries, mainly because of delay in presentation. Specific organ injuries, such as to the pancreas, carry with

FIGURE 27-9 Lacerations of the anal area, often first noted as blood in the underwear, indicate penetration. (Used with permission of the American Academy of Pediatrics: Visual Diagnosis of Child Abuse CD-ROM, ed. 3, American Academy of Pediatrics, 2008.)

FIGURE 27-10 Bruising in the perineum, scrotum, and penis secondary to intentional injury. (Used with permission of the American Academy of Pediatrics: Visual Diagnosis of Child Abuse CD-ROM, ed. 3, American Academy of Pediatrics, 2008.)

them an increased association of hollow viscus injury versus those of unintentional injury patterns. These associations should prompt a high degree of suspicion for abuse.[49,50]

Injuries to the perineum should always lead to a consideration of child abuse. Aside from burns to the perineum, discussed previously, injuries in this area resulting from abuse tend to be penetrating. Rectal or vaginal trauma resulting in laceration should routinely be investigated, as should lacerations in the penile and scrotal region (Figs. 27-8 to 27-10). Abuse may involve retained foreign bodies as well. The physician should always investigate anal and vaginal orifices that appear to be dilated, particularly those that may result in incontinence. Signs of abuse to the perineum are often chronic, and areas of scar and old lacerations should be noted.

The radiographic and diagnostic workup for children suffering thoracoabdominal abuse is identical to that for unintentional injury. Recommendations for appropriate scans and diagnostics have been updated by the American Academy of Pediatrics.[51] Management of these injuries is also the same as for unintentional thoracoabdominal injuries.[42,52]

# Birth Injuries

Birth injury is estimated to occur in 6 to 8 of every 1000 live births in the United States, but it is responsible for about 2% of the perinatal mortality.[53] Injury most commonly occurs in babies with macrosomia but can also be associated with fetal organomegaly, mass lesions, prematurity, protracted labor, precipitous delivery, breech presentation, and cephalopelvic dissociation. The development and widespread use of prenatal ultrasonography, along with other advances in perinatal care, have allowed the early identification of many of these factors, together with recommendations for the delivery of such high-risk infants.[54]

## SOFT TISSUE INJURY

The most common birth injury encountered is injury to the soft tissue. This can present as a hematoma (often cephalohematoma), simple cutaneous bruising, or fat necrosis manifesting as subcutaneous masses. These lesions resolve spontaneously within months and require no treatment other than reassurance of the parents. Less commonly, lacerations secondary to instrumentation may occur. These lacerations can usually be closed with adhesive strips or cutaneous glue rather than sutures. Suturing may be necessary, however, when adhesive closure cannot achieve the appropriate cosmetic result. Fine material should always be used, and healing is usually excellent. Lacerations are rarely deep, but if they are, standard precautions for wound exploration should be followed.

Torticollis has been ascribed to birth trauma or intrauterine malpositioning.[55] The cause is debatable, because torticollis has been found in infants who were delivered by cesarean section, as well as in those delivered vaginally. The classical presentation is a small, firm mass in the body of the sternocleidomastoid muscle. The head is tilted toward the mass, with the face classically turned to the contralateral side. Physical therapy performed by the parents is successful in the vast majority of cases, and surgical intervention is rarely indicated. Facial asymmetry may result in untreated lesions. Torticollis has been misdiagnosed as a malignancy in the neck. Careful examination and taking a complete history can often prevent this error.[56]

## FRACTURES

The most common fracture associated with birth trauma is clavicular, occurring in about 2.7 of every 1000 births.[57] The fracture is noticed when the infant does not move the arm or swelling occurs over the clavicle. The fracture is commonly in the midshaft and generally requires no treatment, although some authors recommend figure-of-eight splints or pinning the baby's shirtsleeve to the chest on the affected side.[58] Occasionally, because of shoulder dystocia, the clavicle may be intentionally fractured.[59]

Fractures of the humerus usually occur in either the shaft or the proximal epiphysis. Epiphyseal fractures are difficult to diagnose because of a lack of ossification points in the neonatal epiphysis. Associated neurologic findings may be noted with fractures of the humerus, including Erb palsy and radial nerve palsy.[59,60] Shoulder dislocation is most likely not related

to birth trauma but rather to intrauterine causes or therapy for Erb palsy.[61] Distal fractures and dislocations of the radial head may also occur and are often associated with breech delivery.[62,63] Proximal fractures of the humerus can be successfully treated by bandaging the arm to the chest in a neutral position for epiphyseal injuries and by strapping the arm to the chest with an abduction device or possibly a posterior splint for shaft fractures.[64]

Birth trauma can cause fractures of the femur at almost any location. Breech delivery and high birth weight are predisposing factors.[65] Presentation consists of abnormal rotation of the lower extremity, pain, or swelling. Treatment involves application of a traction device, spica cast, or both.[66] Reduction should be close to anatomic, because overgrowth and remodeling of the femur are not usually dramatic.[67]

## NEUROLOGIC INJURY

Brachial plexus injury is the most common neurologic birth injury.[68] Approximately 21% of these injuries are associated with a shoulder dystocia at birth. Erb palsy (C3 to C5) is the most common of the brachial plexus injuries and usually resolves spontaneously, with little residual effect. Presentation involves a lack of motion of the affected shoulder, with the limb adducted and internally rotated to the prone position. Distal sensation and hand function are usually normal. Even after aggressive physical therapy, about 2% of cases are permanent.[69] Lower injuries of the C6 to T1 cervical roots (Klumpke palsy) present with a lack of hand and wrist function. These lesions may be accompanied by Horner syndrome, with the associated physical findings. Microsurgical repair has been described for recalcitrant brachial plexus injuries, with relatively good success, but this should be reserved only for infants failing aggressive physical therapy.[70] Phrenic nerve paralysis is a commonly associated finding and should be investigated whenever brachial plexus injury is identified. Isolated brachial plexus injury can cause significant shoulder abnormalities, and therapy should not be delayed.[71]

Phrenic nerve injury can also occur in isolation.[53] Treatment of phrenic nerve injury depends on the severity of the respiratory embarrassment experienced by the child. Asymptomatic injuries should not be treated; injuries resulting in respiratory impairment should be treated with diaphragmatic plication or other procedures designed to reduce the paradoxical movement of the diaphragm with respiration.[21]

Certainly the most devastating neurologic birth injuries involve the central nervous system. Lesions of the cervical spine are rare but are devastating when they occur. The cause of injury is usually a vaginal delivery with a breech or transverse lie.[72] As with all cervical spine injuries, high lesions require mechanical ventilation, and lower lesions have devastating physical sequelae. Survival is poor in neonates with complete transection. Partial injury may mimic cerebral palsy.[73]

Subdural, subarachnoid, intraventricular, and intraparenchymal bleeds have also been associated with birth trauma. Outcome is dependent on the extent of the lesion and the presentation. Usually these lesions are secondary to vacuum extraction,[74,75] which is also implicated as the cause of subgaleal cephalohematoma. Although most hematomas resolve without incident or sequelae, approximately 25% have been reported to cause death in affected neonates.[76] Traction injury to the internal carotid artery has also been reported in difficult births. Outcome from these injuries is varied and depends on the extent of vascular damage and collateral perfusion.[77] Similarly, direct injury to the optic nerve has been described.[78]

The most common central nervous system injury during childbirth is anoxic brain damage, and the resultant "cerebral palsy." The cause is controversial, but difficult delivery is a common association.

Treatment of neurologic birth trauma is usually expectant, with aggressive physical therapy. Recalcitrant peripheral injuries have responded to surgical repair.

## THORACOABDOMINAL INJURY

Injuries to the chest are believed to be the result of pressure on the thoracic cavity. Pneumothorax, pneumomediastinum, and chylothorax have been described.[53,79] Perforation of the esophagus or cricopharyngeus can also occur. In most cases of birth trauma to the chest, expectant observation is indicated. The clinical course dictates the need for operative intervention. High perforations of the esophagus and cricopharyngeus can usually be treated by observation or occasionally drainage.[53] Lower lesions require drainage or operative repair. With early identification, results are excellent. Perforation of the esophagus can also result from placement of a gastric tube in the neonatal period. The management of these lesions remains controversial and varies from immediate intervention to expectant observation, based on the child's clinical situation.

Liver hematoma is the most common intra-abdominal injury secondary to birth trauma (Fig. 27-11). The usual presentation is anemia, but it can also be shock.[80] Diagnosis is usually made by ultrasonography, but a thorough investigation may be necessary to rule out other hepatic masses in a newborn. Treatment is usually expectant and includes volume resuscitation and correction of any hypothermia or coagulopathy. Occasionally, operative intervention is necessary when the baby is unstable or continued hemorrhage occurs. Hemostatic agents appear to be more helpful than attempts at suture repair in stopping hepatic bleeding in newborns.[81] In any case, control of hepatic hemorrhage is very difficult in this age group.

Splenic injury is rare and presents much like hepatic injury. Intra-abdominal blood may be the only presenting sign, and,

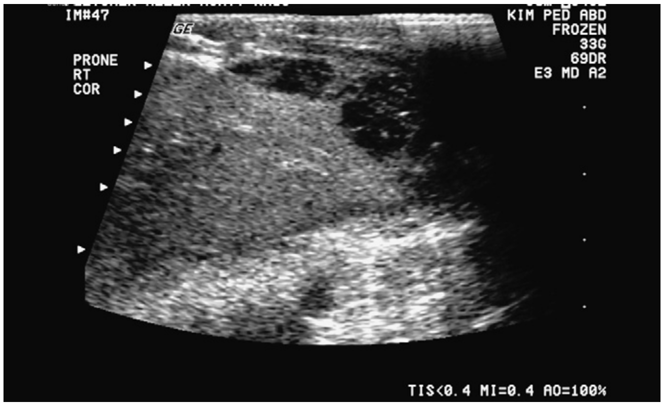

**FIGURE 27-11** Ultrasonography of the abdomen clearly demonstrates this hepatic hematoma caused by birth trauma, which resolved spontaneously. Lesions such as this can be followed by ultrasonography; if they persist, other causes, such as neoplasm, must be investigated.

as in hepatic injury, other pathology must be ruled out.[82] Treatment includes expectant observation and correction of coagulopathy or hypothermia. Operative intervention is difficult and usually results in splenectomy. Hemostatic agents may also be useful.

As with splenic injury, injury to the adrenal glands is uncommon because of the relative protection provided by the thoracic ribs. The presentation may be hemorrhage or adrenal insufficiency in severe cases. Injury can also be identified from calcifications found on a radiograph taken later in life. As with all intra-abdominal solid organs, investigation of hematomas requires a workup to rule out other pathology, such as underlying tumor.

CHAPTER 28

# Principles of Pediatric Oncology, Genetics of Cancer, and Radiation Therapy

Matthew J. Krasin and Andrew M. Davidoff

A number of milestones in the evolution of cancer therapy have come from the field of pediatric oncology. The first clear evidence that chemotherapy could provide effective treatment for childhood malignancy occurred in 1950 when Farber reported temporary cancer remission in children with acute lymphoblastic leukemia (ALL) treated with the folic acid antagonist aminopterin.[1] The first successful use of a multidisciplinary approach to cancer treatment occurred in the 1960s and 1970s through the collaborative efforts of pediatric surgeons, radiation therapists, and pediatric oncologists aiming to improve the treatment of Wilms' tumor in children.[2] Such a multidisciplinary approach is now used throughout the field of oncology. The successful use of a combination of chemotherapeutic agents to cure Hodgkin disease and ALL during the 1960s led to the widespread use of combination chemotherapy to treat virtually all types of cancers. Since the late 1980s, neuroblastoma has been the paradigm for the use of therapies of variable intensity, depending on risk stratification determined by clinical and biological variables, including molecular markers. Other advances in pediatric oncology have included the development of interdisciplinary, national cooperative clinical research groups to critically evaluate new therapies, the efficacy of dose-intensive chemotherapy programs in improving the outcome of advanced-stage solid tumors, and the supportive care necessary to make the latter approach possible. The development and application of these principles and advances have led to substantially increased survival rates for children with cancer and profound improvements in their quality of life.

Additionally, advances in molecular genetic research in the past 3 decades have led to an increased understanding of the genetic events in the pathogenesis and progression of human malignancies, including those of childhood. A number of pediatric malignancies have served as models for molecular genetic research. Chromosomal structural changes, activating or inactivating mutations of relevant genes or their regulatory elements, gene amplification, and gene imprinting may each play a role in different tumor types. In some instances, these genetic events occur early in tumorigenesis and are specific for a particular tumor type, such as the chromosomal translocation t(11;22)(q24;q12) in Ewing sarcoma; other aberrations occur in a variety of different tumor types and are almost always associated with additional genetic changes, such as chromosome 1p deletion in neuroblastoma and Wilms' tumor. Some alterations involve oncogenes—genes that, when activated, lead directly to cancer—whereas others involve tumor suppressor genes, whose inactivation allows tumor progression. The result of alterations in these genetic elements, regardless of the mechanism, is disruption of the normal balance between proliferation and death of individual cells. These discoveries have highlighted the utility of molecular analysis for a variety of purposes, including diagnosis, risk stratification, and treatment planning; the understanding of syndromes associated with cancer; genetic screening and genetic counseling; and prophylactic treatment, including surgical intervention. Soon, treatment regimens are likely to be individualized on the basis of the molecular biological profile of a patient's tumor. In addition, molecular profiling will lead to the development of new drugs designed to induce differentiation of tumor cells, block dysregulated growth pathways, or reactivate silenced apoptotic pathways.

## Epidemiology and Survival Statistics

Cancer in children is uncommon; it represents only about 2% of all cancer cases. Nevertheless, after trauma, it is the second most common cause of death in children older than 1 year. Each year, approximately 130 new cases of cancer are identified per million children younger than 15 years (or about 1 in 7000). This means that in the United States, about 9,000 children younger than 15 years are diagnosed with cancer each year, in addition to 4,000 patients aged 15 to 19 years.[3] Leukemia is the most common form of cancer

**TABLE 28-1**
**Frequency of Cancer Diagnoses in Childhood**

| *Type of Cancer* | *Percentage of Total* |
|---|---|
| Leukemia | 30 |
| Brain tumors | 25 |
| Lymphoma | 15 |
| Neuroblastoma | 8 |
| Sarcoma | 7 |
| Wilms' tumor | 6 |
| Osteosarcoma | 5 |
| Retinoblastoma | 3 |
| Liver tumors | 1 |

in children, and brain tumors are the most common solid tumor of childhood (Table 28-1). Lymphomas are the next most common malignancy in children, followed by neuroblastoma, soft tissue sarcomas, Wilms' tumor, germ cell tumors, osteosarcoma, and retinoblastoma. A slightly different distribution is seen among 15- to 19-year-olds, in whom Hodgkin disease and germ cell tumors are the most frequently diagnosed malignancies; non-Hodgkin lymphoma, nonrhabdomyosarcoma soft tissue sarcoma, osteosarcoma, Ewing sarcoma, thyroid cancer, and melanoma also occur with an increased incidence.

In general, the incidence of childhood cancer is greatest during the first year of life, peaks again in children aged 2 to 3 years, and then slowly declines until age 9. The incidence then steadily increases again through adolescence. Each tumor type shows a different age distribution pattern, however. Variations by gender are also seen. For example, Hodgkin disease, ALL, brain tumors, neuroblastoma, hepatoblastoma, Ewing sarcoma, and rhabdomyosarcoma are more common in boys than in girls younger than 15 years, whereas only osteosarcoma and Ewing sarcoma are more common in boys than in girls older than 15 years. However, girls in the older age group have Hodgkin disease and thyroid cancer more frequently than boys do. Distribution also varies by race: White children generally have a 30% greater incidence of cancer than do black children. This difference is particularly notable for ALL, Ewing sarcoma, and testicular germ cell tumors. The probability of surviving childhood cancer has improved greatly since Farber induced the first remissions in patients with ALL. In the early 1960s, approximately 30% of children with cancer survived their disease. By the mid-1980s, about 65% of children with cancer were cured, and by the mid-1990s, the cure rate had increased to nearly 75%.[4] Currently, greater than 80% are cured. These great strides have resulted from three important factors: (1) the sensitivity of childhood cancer, at least initially, to available chemotherapeutic agents; (2) the treatment of childhood cancer in a multidisciplinary fashion; and (3) the treatment of most children in major pediatric treatment centers in the context of a clinical research protocol using the most current and promising therapy. Although progress in the treatment of some tumor types, such as ALL and Wilms' tumor, has been outstanding, progress in the treatment of others, such as metastatic neuroblastoma and rhabdomyosarcoma, has been modest. Therefore there is still a need for significant improvement in the treatment of childhood cancer.

# Molecular Biology of Cancer

During normal cellular development and renewal, cells evolve to perform highly specialized functions to meet the physiologic needs of the organism. Development and renewal involve tightly regulated processes that include continued cell proliferation, differentiation to specialized cell types, and programmed cell death (apoptosis). An intricate system of checks and balances ensures proper control over these physiologic processes. The genetic composition (genotype) of a cell determines which pathway(s) will be followed in exerting that control. In addition, the environment plays a crucial role in influencing cell fate: Cells use complex signal transduction pathways to sense and respond to neighboring cells and their extracellular milieu.

Cancer is a genetic disease whose progression is driven by a series of accumulating genetic and epigenetic changes influenced by hereditary factors and the somatic environment. These changes result in individual cells acquiring a phenotype that provides them with a survival advantage compared with surrounding normal cells. Our understanding of the processes that occur in malignant cell transformation is increasing; many discoveries in cancer cell biology have been made by using childhood tumors as models. This greater understanding of the molecular biology of cancer has also contributed significantly to our understanding of normal cell physiology.

## NORMAL CELL PHYSIOLOGY

### Cell Cycle

Genetic information is stored in cells and transmitted to subsequent generations of cells through nucleic acids organized as genes on chromosomes. A gene is a functional unit of heredity that exists on a specific site or locus on a chromosome, is capable of reproducing itself exactly at each cell division, and is capable of directing the synthesis of an enzyme or other protein. The genetic material is maintained as DNA formed into a double helix of complementary strands. The cell must ensure that replicated DNA is accurately copied with each cell division or cycle. DNA replication errors that go uncorrected potentially alter the function of normal cell regulatory proteins. The molecular machinery used to control the cell cycle is highly organized and tightly regulated.[5] Signals that stimulate or inhibit cellular growth converge on a set of evolutionarily conserved enzymes that drive cell-cycle progression. Various "checkpoints" exist to halt progression through the cell cycle during certain environmental situations or times of genetic error resulting from inaccurate synthesis or damage. Two of the most well-studied participants in the cell-cycle checkpoint system are TP53 and retinoblastoma (RB) proteins.[6] In normal circumstances, cells divide and terminally differentiate, thereby leaving the cell cycle, or they enter a resting state. Inactivation of the effectors of cell-cycle regulation or the bypassing of cell-cycle checkpoints can result in dysregulation of the cell cycle, a hallmark of malignancy.

### Signal Transduction

Signal transduction pathways regulate all aspects of cell function, including metabolism, cell division, death, differentiation, and movement. Multiple extracellular and intracellular

signals for proliferation or quiescence must be integrated by the cell, and it is this integration of signals from multiple pathways that determines the response of a cell to competing and complementary signals. Extracellular signals include growth factors, cytokines, and hormones; the presence or absence of adequate nutrients and oxygen; and contact with other cells or an extracellular matrix. Signaling mediators often bind to membrane-bound receptors on the outside of the cell, but they may also diffuse into the cell and bind receptors in the cytoplasm or on the nuclear membrane. Binding of a ligand to a receptor stimulates the activities of small-molecule second messengers—proteins necessary to continue the transmission of the signal. Signaling pathways ultimately effect the activation of nuclear transcription factors that are responsible for the expression or silencing of genes encoding proteins involved in all aspects of cellular physiology.

Receptors with tyrosine kinase activity are among the most important transmembrane receptors. Several important transmembrane receptors with protein kinase activity have been identified and grouped in families on the basis of structural similarities.[7] These families include the epidermal growth factor receptors (EGFRs), fibroblast growth factor receptors, insulin-like growth factor receptors (IGFRs), platelet-derived growth factor receptors (PDGFRs), transforming growth factor receptors, and neurotrophin receptors (TRKs). Abnormalities of members of each of these families are often found in pediatric malignancies and therefore are thought to play a role in their pathogenesis. Characteristic abnormalities of these receptors often form the basis of both diagnostic identification of certain tumor types and, more recently, targeted therapy for tumors with these specific abnormalities.

### Programmed Cell Death

Multicellular organisms have developed a highly organized and carefully regulated mechanism of cell suicide to maintain cellular homeostasis. Normal development and morphogenesis are often associated with the production of excess cells, which are removed by the genetically programmed process of cell death called apoptosis. Apoptosis limits cellular expansion and counters cell proliferation. Apoptosis is initiated by the interaction of "death ligands," such as tumor necrosis factor-$\alpha$ (TNF-$\alpha$), FAS, and TNF-related apoptosis-inducing ligand (TRAIL), with their respective receptors. This interaction is followed by aggregation of the receptors and recruitment of adapter proteins to the plasma membrane, which activate caspases.[8] Thus the fate of a cell is determined by the balance between death signals and survival signals.[9]

An alternative to cell death mediated by receptor–ligand binding is cellular senescence, which is initiated when chromosomes reach a critical length. Eukaryotic chromosomes have DNA strands of unequal length, and their ends, called telomeres, are characterized by species-specific nucleotide repeat sequences. Telomeres stabilize the ends of chromosomes, which are otherwise sites of significant instability.[10] With time and with each successive cycle of replication, chromosomes are shortened by failure to complete replication of their telomeres. Thus telomere shortening acts as a biological clock, limiting the life span of a cell. Germ cells, however, avoid telomere shortening by using telomerase, an enzyme capable of adding telomeric sequences to the ends of chromosomes. This enzyme is normally inactivated early in the growth and development of an organism. Persistent activation or the reactivation of telomerase in somatic cells appears to contribute to the immortality of transformed cells.

### Malignant Transformation

Alteration or inactivation of any of the components of normal cell regulatory pathways may lead to the dysregulated growth that characterizes neoplastic cells. Malignant transformation may be characterized by cellular de-differentiation or failure to differentiate, cellular invasiveness and metastatic capacity, or decreased drug sensitivity. Tumorigenesis reflects the accumulation of excess cells that results from increased cell proliferation and decreased apoptosis or senescence. Cancer cells do not replicate more rapidly than normal cells, but they show diminished responsiveness to regulatory signals. Positive growth signals are generated by proto-oncogenes, so named because their dysregulated expression or activity can promote malignant transformation. These proto-oncogenes may encode growth factors or their receptors, intracellular signaling molecules, and nuclear transcription factors (Table 28-2). Conversely, tumor suppressor genes, as their name implies, control or restrict cell growth and proliferation. Their inactivation, through various mechanisms, permits the dysregulated growth of cancer cells. Also important are the genes that regulate cell death. Their inactivation leads to resistance to apoptosis and allows the accumulation of additional genetic aberrations.

Cancer cells carry DNA that has point mutations, viral insertions, or chromosomal or gene amplifications, deletions, or rearrangements. Each of these aberrations can alter the context and process of normal cellular growth and differentiation. Although genomic instability is an inherent property of the evolutionary process and normal development, it is through genomic instability that the malignant transformation of a cell may arise. This inherent instability may be altered by inheritance or exposure to destabilizing factors in the environment. Point mutations may terminate protein translation, alter protein function, or change the regulatory target sequences that control gene expression. Chromosomal alterations create new genetic contexts within the genome and lead to the formation of novel proteins or to the dysregulation of genes displaced by aberrant events.

Genetic abnormalities associated with cancer may be detected in every cell in the body or only in the tumor cells. Constitutional or germline abnormalities either are inherited or occur de novo in the germ cells (sperm or oocyte). Interestingly, despite the presence of a genetic abnormality that might affect growth regulatory pathways in all cells, people are generally predisposed to the development of only certain tumor types. This selectivity highlights the observation that gene function contributes to growth or development only within a particular milieu or physiologic context. Specific tumors occur earlier and are more often bilateral when they result from germline mutations than when they result from sporadic or somatic alterations. Such is often the case in two pediatric malignancies, Wilms' tumor and retinoblastoma. These observations led Knudson[11] to propose a "two-hit" mechanism of carcinogenesis in which the first genetic defect, already present in the germline, must be complemented by an additional spontaneous mutation before a tumor can arise. In sporadic cancer, cellular transformation occurs only when two (or more) spontaneous mutations take place in the same cell.

Much more common, however, are somatically acquired chromosomal aberrations, which are confined to the malignant cells.

**TABLE 28-2**

**Proto-oncogenes and Tumor Suppressor Genes in Pediatric Malignancies**

| *Oncogene Family* | *Proto-oncogene* | *Chromosome Location* | *Tumors* |
|---|---|---|---|
| Growth factors and receptors | *ERBB2* | 17q21 | Glioblastoma |
| | *TRK* | 9q22 | Neuroblastoma |
| Protein kinase | *SRC* | 7p11 | Rhabdomyosarcoma, Osteosarcoma, Ewing sarcoma |
| Signal transducers | *H-RAS* | 11p15.1 | Neuroblastoma |
| Transcription factors | c-*MYC* | 18q24 | Burkitt lymphoma |
| | *MYCN* | 2p24 | Neuroblastoma |
| ***Syndrome*** | ***Tumor Suppressor Gene*** | ***Chromosome Location*** | ***Tumors*** |
| Familial polyposis coli | *APC* | 5q21 | Intestinal polyposis, colorectal cancer |
| Familial retinoblastoma | *RB* | 13q24 | Retinoblastoma, osteosarcoma |
| WAGR* | *WT1* | 11p13 | Wilms' tumor |
| Denys-Drash† | *WT1* | 11p13 | Wilms' tumor |
| Beckwith-Weidemann‡ | *WT2* (?) | 11p15 | Wilms' tumor, hepatoblastoma, adrenal |
| Li-Fraumeni | *TP53* | 17q13 | Multiple (see text) |
| Neurofibromatosis type 1 | *NF1* | 17q11.2 | Sarcomas, breast cancer |
| Neurofibromatosis type 2 | *NF2* | 22q12 | Neurofibroma, neurofibrosarcoma, brain tumor |
| von Hippel-Lindau | *VHL* | 3p25-26 | Renal cell cancer, pheochromocytoma, retinal angioma, hemangioblastoma |

*WAGR: Wilms' tumor, aniridia, genitourinary abnormalities, and mental retardation.
†Denys-Drash: Wilms' tumor, pseudohermaphroditism, mesangial sclerosis, renal failure.
‡Beckwith-Weidemann: multiple tumors, hemihypertrophy, macroglossia, hyperinsulinism.

These aberrations affect growth factors and their receptors, signal transducers, and transcription factors. The general types of chromosomal alterations associated with malignant transformation are shown in Figure 28-1. Although a low level of chromosomal instability exists in a normal population of cells, neoplastic transformation occurs only if these alterations affect a growth-regulating pathway and confer a growth advantage.

## Abnormal DNA Content

Normal human cells contain two copies of each of 23 chromosomes; a normal diploid cell therefore has 46 chromosomes. Although cellular DNA content, or ploidy, is accurately determined by karyotypic analysis, it can be estimated by the much simpler method of flow cytometric analysis. Diploid cells have a DNA index of 1.0, whereas near-triploid (also termed *hyperdiploid*) cells have a DNA index ranging from 1.26 to 1.76. The majority (55%) of primary neuroblastoma cells are triploid or near triploid (e.g., having between 58 and 80 chromosomes), whereas the remainder are near diploid (35 to 57 chromosomes) or near tetraploid (81 to 103 chromosomes).[12] Neuroblastomas consisting of near-diploid or near-tetraploid cells usually have structural genetic abnormalities (e.g., chromosome 1p deletion and amplification of the *MYCN* oncogene), whereas those consisting of near-triploid cells are characterized by three almost complete haploid sets of chromosomes with few structural abnormalities.[13] Of importance, patients with near-triploid tumors typically have favorable clinical and biological prognostic factors and excellent survival rates compared with those who have near-diploid or near-tetraploid tumors.[14]

## Chromosomal Translocations

Many pediatric cancers, specifically hematologic malignancies and soft tissue neoplasms, have recurrent, nonrandom abnormalities in chromosomal structure, typically chromosomal translocations (Table 28-3). The most common result of a nonrandom translocation is the fusion of two distinct genes from different chromosomes. The genes are typically fused within the reading frame and express a functional, chimeric protein product that has transcription factor or protein kinase activity. These fusion proteins contribute to tumorigenesis by activating genes or proteins involved in cell proliferation. For example, in Ewing sarcoma the consequence of the t(11;22)(q24;q12) translocation is a fusion of *EWS*, a transcription factor gene on chromosome 22, and *FLI-1*, a gene encoding a member of the ETS family of transcription factors on chromosome 11.[15] The resultant chimeric protein, which contains the DNA binding region of *FLI-1* and the transcription activation region of *EWS*, has greater transcriptional activity than does *EWS* alone.[16] The EWS–FLI-1 fusion transcript is detectable in approximately 90% of Ewing sarcomas. At least four other *EWS* fusions have been identified in Ewing sarcoma; fusion of *EWS* with *ERG* (another ETS family member) accounts for an additional 5% of cases.[17] Alveolar rhabdomyosarcomas have characteristic translocations between the long arm of chromosome 2 (75% of cases) or the short arm of chromosome 1 (10% of cases) and the long arm of chromosome 13. These translocations result in the fusion of *PAX3*

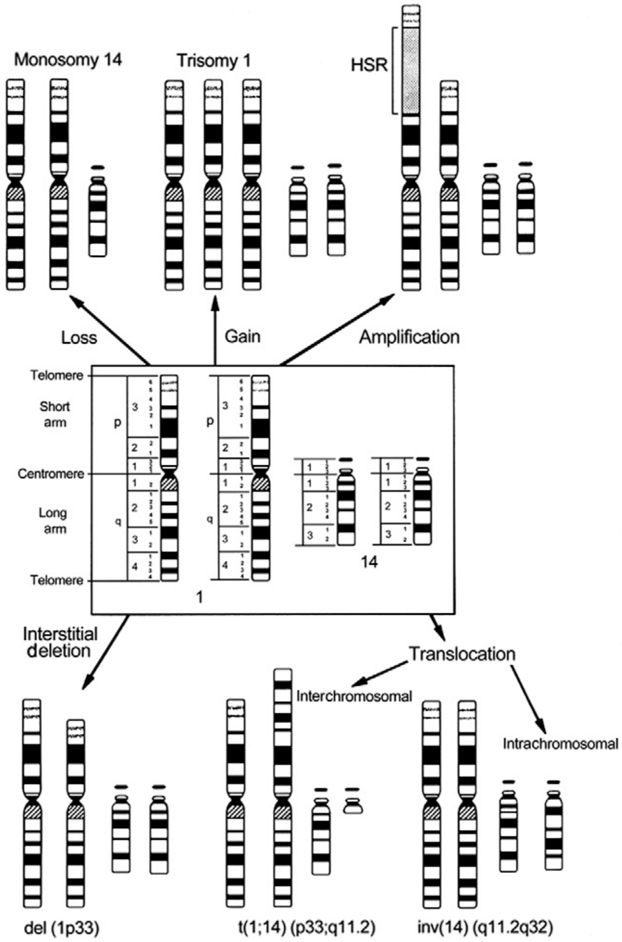

**FIGURE 28-1** Spectrum of gross chromosomal aberrations using chromosomes 1 and 14 as examples. HSR, homogeneously staining regions. (From Look AT, Kirsch IR: Molecular basis of childhood cancer. In Pizzo PA, Poplack DG [eds]: Principles and Practices of Pediatric Oncology. Philadelphia, Lippincott-Raven, 1997, p 38.)

(at 2q35) or *PAX7* (at 1p36) with *FKHR*, a gene encoding a member of the forkhead family of transcription factors.[18] The *EWS-FLI-1* and *PAX7-FKHR* fusions appear to confer a better prognosis for patients with Ewing sarcoma and alveolar rhabdomyosarcoma, respectively.[19,20] Translocations that generate chimeric proteins with increased transcriptional activity also characterize desmoplastic small round cell tumor,[21] myxoid liposarcoma,[22] extraskeletal myxoid chrondrosarcoma,[23] malignant melanoma of soft parts,[24] synovial sarcoma,[25] congenital fibrosarcoma,[26] cellular mesoblastic nephroma,[27] and dermatofibrosarcoma protuberans.[28]

### Proto-oncogene Activation

Proto-oncogenes are commonly activated in transformed cells by point mutations or gene amplification. The classical example of proto-oncogene activation by a point mutation involves the cellular proto-oncogene *RAS*. RAS-family proteins are associated with the inner, cytoplasmic surface of the plasma membrane and function as intermediates in signal transduction pathways that regulate cell proliferation. Point mutations in *RAS* result in constitutive activation of the RAS protein and therefore the continuous activation of the RAS signal transduction pathway. Activation of RAS appears to be involved in the pathogenesis of a small percentage of pediatric malignancies, including leukemia and a variety of solid tumors.

**TABLE 28-3**

From Davidoff AM, Hill DA: Molecular genetic aspects of solid tumors in childhood. Semin Pediatr Surg 2001;10:106-118.

Gene amplification (i.e., selective replication of DNA sequences) enables a tumor cell to increase the expression of crucial genes whose products are ordinarily tightly controlled. The amplified DNA sequences, or amplicons, may be maintained episomally (i.e., extrachromosomally) as double minutes-paired chromatin bodies lacking a centromere or as intrachromosomal, homogeneously staining regions. In about one third of neuroblastomas, for example, the transcription factor and proto-oncogene *MYCN* is amplified. The *MYCN* copy number in neuroblastoma cells can be amplified 5-fold to 500-fold and is usually consistent among primary and metastatic sites and at different times during tumor evolution and treatment.[29] This consistency suggests that *MYCN* amplification is an early event in the pathogenesis of neuroblastoma. Because gene amplification is usually associated with advanced stages of disease, rapid tumor progression, and poor outcome, it is a powerful prognostic indicator.[30,31] The cell surface receptor gene *ERBB2* is another proto-oncogene that is commonly overexpressed because of gene amplification, an event that occurs in breast cancer, osteosarcoma, and Wilms' tumor.[32]

### Inactivation of Tumor Suppressor Genes

Tumor suppressor genes, or antioncogenes, provide negative control of cell proliferation. Loss of function of the proteins encoded by these genes, through deletion or mutational inactivation of the gene, liberates the cell from growth constraints

and contributes to malignant transformation. The cumulative effect of genetic lesions that activate proto-oncogenes or inactivate tumor suppressor genes is a breakdown in the balance between cell proliferation and cell loss because of differentiation or apoptosis. Such imbalance results in clonal overgrowth of a specific cell lineage. The first tumor suppressor gene to be recognized was the retinoblastoma susceptibility gene *RB*. This gene encodes a nuclear phosphoprotein that acts as a "gatekeeper" of the cell cycle. *RB* normally permits cell-cycle-progression through the $G_1$ phase when it is phosphorylated, but it prevents cell division when it is unphosphorylated. Inactivating deletions or point mutations of *RB* cause the protein to lose its regulatory capacity. The nuclear phosphoprotein gene *TP53* has also been recognized as an important tumor suppressor gene, perhaps the most commonly altered gene in all human cancers. Inactivating mutations of the *TP53* gene also cause the TP53 protein to lose its ability to regulate the cell cycle. The *TP53* gene is frequently inactivated in solid tumors of childhood, including osteosarcoma, rhabdomyosarcoma, brain tumors, anaplastic Wilms' tumor, and a subset of chemotherapy-resistant neuroblastoma.[33–35] In addition, heritable cancer-associated changes in the *TP53* tumor suppressor gene occur in families with Li-Fraumeni syndrome, an autosomal dominant predisposition for rhabdomyosarcoma, other soft tissue and bone sarcomas, premenopausal breast cancer, brain tumors, and adrenocortical carcinomas.[36] Other tumor suppressor genes include Wilms' tumor 1 *(WT1)*, neurofibromatosis 1 *(NF1)*, and von Hippel-Lindau *(VHL)*. Additional tumor suppressor genes are presumed to exist but have not been definitively identified.

### Epigenetic Alterations

As stated previously, the hallmark of cancer is dysregulated gene expression. However, not only do genetic factors influence gene expression but epigenetic factors do as well, with these factors being at least as important as genetic changes in their contribution to the pathogenesis of cancer. Epigenetic alterations are defined as those heritable changes in gene expression that do not result from direct changes in DNA sequence. Mechanisms of epigenetic regulation most commonly include DNA methylation and modification of histones, although the contribution of microRNAs (miRNA), a class of noncoding RNAs, is becoming increasingly recognized.

***DNA Methylation*** DNA methylation is a reversible process that involves methylation of the fifth position of cytosine within CpG dinucleotides present in DNA. These dinucleotides are usually in the promoter regions of genes; methylation of these sites typically causes gene silencing, thereby preventing expression of the encoded proteins. This process is part of the normal mechanism for imprinting, X-chromosome inactivation, and generally keeping large areas of genomic DNA silent, but it may also contribute to the pathogenesis of cancer by silencing tumor suppressor genes. However, both abnormal hypomethylation and hypermethylation states exist in human tumors, resulting in both dysregulated expression and silencing, respectively, of affected genes. These modifications of the nucleotide backbone of human DNA are becoming increasingly recognized in human cancer, both for their frequency and importance. For example, promoter methylation resulting in silencing of caspase 8, a protein involved in apoptosis, likely contributes to the pathogenesis of *MYCN*-amplified neuroblastoma[37] as well as Ewing sarcoma.[23]

***Histone Modification*** Histones are the proteins that give structure to DNA and, together with the DNA, form the major components of chromatin. The functions of histones are to package DNA into a smaller volume to fit in the cell, to strengthen the DNA to allow replication, and to serve as a mechanism to control gene expression. Alterations in histones can mediate changes in chromatin structure. The compacted form of DNA, termed heterochromatin, is largely inaccessible to transcription factors and therefore genes in the affected regions are silent. Other modifications of histones can cause DNA to take a more open or extended configuration (euchromatin), allowing for gene transcription. The N-terminal tails of histones can be modified by a number of different processes including methylation and acetylation, mediated by histone acetyl transferases (HAT) and deacetylases (HDAC), and histone methyltransferases (HMT). Each of these processes alters histone function, which, in turn, alters the structure of chromatin and therefore the accessibility of DNA to transcription factors. Methylation of the DNA itself can also effect changes in chromatin structure.

***MicroRNA*** As stated above, miRNAs are a group of small, regulatory noncoding RNAs that appear to function in gene regulation. These miRNAs are single-stranded RNA fragments of 21 to 23 nucleotides that are complementary to encoding mRNAs.[25] Their function is to down-regulate expression of target mRNAs; it is estimated that miRNAs regulate the expression of about 30% of all human genes.[38] These miRNAs regulate gene expression primarily by incorporating into silencing machinery called RNA-induced silencing complexes (RISC). MiRNAs are involved in a number of fundamental biological processes, including development, differentiation, cell-cycle regulation, and senescence. However, broad analyses of miRNA expression levels have demonstrated that many miRNAs are dysregulated in a variety of different cancer types, including neuroblastoma and other pediatric tumors,[39] frequently losing their function as gene silencers/tumor suppressors. The activity of miRNAs, like gene expression, is also under epigenetic regulation.

## METASTASIS

Metastasis is the spread of cancer cells from a primary tumor to distant sites and is the hallmark of malignancy. The development of tumor metastases is the main cause of treatment failure and a significant contributing factor to morbidity and mortality resulting from cancer. Although the dissemination of tumor cells through the circulation is probably a frequent occurrence, the establishment of metastatic disease is a very inefficient process. It requires several events, including the entry of the neoplastic cells into the blood or lymphatic system, the survival of those cells in the circulation, their avoidance of immune surveillance, their invasion of foreign (heterotopic) tissues, and the establishment of a blood supply to permit expansion of the tumor at the distant site. Simple, dysregulated cell growth is not sufficient for tumor invasion and metastasis. Many tumors progress through distinct stages

that can be identified by histopathologic examination, including hyperplasia, dysplasia, carcinoma in situ, invasive cancer, and disseminated cancer. Genetic analysis of these different stages of tumor progression suggests that uncontrolled growth results from progressive alteration in cellular oncogenes and inactivation of tumor suppressor genes, but these genetic changes driving tumorigenicity are clearly distinct from those that determine the metastatic phenotype.

Histologically, invasive carcinoma is characterized by a lack of basement membrane around an expanding mass of tumor cells. Matrix proteolysis appears to be a key part of the mechanism of invasion by tumor cells, which must be able to move through connective tissue barriers, such as the basement membrane, to spread from their site of origin. The proteases involved in this process include the matrix metalloproteinases and their tissue inhibitors. The local environment of the target organ may profoundly influence the growth potential of extravasated tumor cells.[40] The various cell surface receptors that mediate interactions between tumor cells and between tumor cells and the extracellular matrix include cadherins, integrins (transmembrane proteins formed by the noncovalent association of alpha and beta subunits), and CD44, a transmembrane glycoprotein involved in cell adhesion to hyaluronan.[41] Tumor cells must decrease their adhesiveness to escape from the primary tumor, but at later stages of metastasis, the same tumor cells need to increase their adhesiveness during arrest and intravasation to distant sites.

### ANGIOGENESIS

Angiogenesis is the biological process of new blood vessel formation. This complex, invasive process involves multiple steps, including proteolytic degradation of the extracellular matrix surrounding existing blood vessels, chemotactic migration and proliferation of endothelial cells, the organization of these endothelial cells into tubules, the establishment of a lumen that serves as a conduit between the circulation and an expanding mass of tumor cells, and functional maturation of the newly formed blood vessel.[42,43] Angiogenesis involves the coordinated activity of a wide variety of molecules, including growth factors, extracellular matrix proteins, adhesion receptors, and proteolytic enzymes. Under physiologic conditions, the vascular endothelium is quiescent and has a very low rate of cell division, such that only 0.01% of endothelial cells are dividing.[42–44] However, in response to hormonal cues or hypoxic or ischemic conditions, the endothelial cells can be activated to migrate, proliferate rapidly, and create tubules with lumens.

Angiogenesis occurs as part of such normal physiologic activities as wound healing, inflammation, the female reproductive cycle, and embryonic development. In these processes, angiogenesis is tightly and predictably regulated. However, angiogenesis can also be involved in the progression of several pathologic processes in which there is a loss of regulatory control, resulting in persistent growth of new blood vessels. Such unabated neovascularization occurs in rheumatoid arthritis, inflammatory bowel disease, hemangiomas of childhood, ocular neovascularization, and the growth and spread of tumors.[45]

Compelling data indicate that tumor-associated neovascularization is required for tumor growth, invasion, and metastasis.[46–49] A tumor in the prevascular phase (i.e., before new blood vessels have developed) can grow to only a limited size, approximately 2 to 3 $mm^3$. At this point, rapid cell proliferation is balanced by equally rapid cell death by apoptosis, and a nonexpanding tumor mass results. The switch to an angiogenic phenotype with tumor neovascularization results in a decrease in the rate of apoptosis, thereby shifting the balance to cell proliferation and tumor growth.[50,51] This decrease in apoptosis occurs, in part, because the increased perfusion resulting from neovascularization permits improved nutrient and metabolite exchange. In addition, the proliferating endothelium may supply, in a paracrine manner, a variety of factors that promote tumor growth, such as IGF-I and IGF-II.[52]

In experimental models, increased tumor vascularization correlates with increased tumor growth, whereas restriction of neovascularization limits tumor growth. Clinically, the onset of neovascularization in many human tumors is temporally associated with increased tumor growth,[53] and high levels of angiogenic factors are commonly detected in blood and urine from patients with advanced malignancies.[107] In addition, the number and density of new microvessels within primary tumors have been shown to correlate with the likelihood of metastasis, as well as the overall prognosis for patients with a wide variety of neoplasms, including pediatric tumors such as neuroblastoma and Wilms' tumor.[54,55]

## Molecular Diagnostics

The explosion of information about the human genome has led not only to an improved understanding of the molecular genetic basis of tumorigenesis but also to the development of a new discipline: the translation of these molecular events into diagnostic assays. The field of molecular diagnostics has developed from the need to identify abnormalities of gene or chromosome structure in patient tissues and as a means of supporting standard histopathologic and immunohistochemical diagnostic methods. In most instances, the result of genetic testing confirms light microscopic- and immunohistochemistry-based diagnosis. In some instances, however (e.g., primitive, malignant, small round cell tumor; poorly differentiated synovial sarcoma; lipoblastic tumor), molecular analysis is required to make a definitive diagnosis.

The molecular genetic methods most commonly used to analyze patient tumor material include direct metaphase cytogenetics or karyotyping, fluorescence in situ hybridization (FISH), and reverse transcriptase polymerase chain reaction (RT-PCR). Additional methods, such as comparative genomic hybridization, loss of heterozygosity analysis, and complementary DNA (cDNA) microarray analysis, may eventually become part of the routine diagnostic repertoire but are currently used as research tools at referral centers and academic institutions. Each standard method is summarized in Table 28-4. As with any method, molecular genetic assays have advantages and disadvantages, and it is important to understand and recognize their limitations.

The value of molecular genetic analysis of patient tissue is not limited to aiding histopathologic diagnosis. Many of the most important markers provide prognostic information as well. *MYCN* amplification in neuroblastomas,[13] for example, is strongly associated with biologically aggressive behavior. Amplification of this gene can be detected by routine

**TABLE 28-4**

**Comparison of the Cytogenetic and Molecular Methods Routinely Used as Aids in Pathologic Diagnosis of Soft Tissue Tumors**

| *Method* | *Purpose* | *Advantages* | *Disadvantages* |
|---|---|---|---|
| Cytogenetics | Low resolution analysis of metaphase chromosomes of cells grown in culture | Does not require a priori knowledge of genetic abnormalities<br>Available in most diagnostic centers | Requires fresh, sterile tumor tissue for growth in culture<br>Low sensitivity; will only detect large structural abnormalities<br>No histologic correlation<br>Slow and technically demanding (takes up to several weeks to perform) |
| In situ hybridization | Detection of translocations, amplifications, and gene deletions by hybridization of nucleic acid probes to specific DNA or mRNA sequences | Can be applied to chromosomal preparations as well as cytologic specimens, touch preparations, and paraffin sections<br>Morphologic correlation is possible<br>Multiple probes can be assayed at the same time<br>Rapid (usually only requires 2 days) | Cannot detect small deletions or point mutations<br>Interpretation can be difficult, especially with formalin-fixed, paraffin-embedded material<br>Only a limited number of specific nucleic acid probes are available commercially |
| PCR and RT-PCR | Extremely sensitive detection of DNA sequences and mRNA transcripts for the demonstration of fusion genes, point mutations, and polymorphisms | Highest sensitivity and specificity of all the molecular diagnostic techniques<br>DNA sequencing of PCR products can confirm result and provide additional information<br>Requires minimal tissue<br>Versatile; can be applied to fresh tissue as well as formalin-fixed, paraffin-embedded tissue<br>Morphologic correlation is possible<br>The presence of normal tissue will usually not affect test results<br>Rapid (usually requires 3-5 days) | Formalin-fixation diminishes sensitivity<br>Combinatorial variability within fusion gene partners requires appropriate redundant primer design to avoid false-negative test results<br>Extreme sensitivity requires exacting laboratory technique to avoid false-positive test results |

PCR, polymerase chain reaction; RT-PCR, reverse transcriptase polymerase chain reaction.

metaphase cytogenetics or by FISH, and current neuroblastoma protocols include the presence or absence of *MYCN* amplification in their stratification schema. Some fusion gene variants are also thought to influence prognosis. In initial studies, two examples noted to confer relatively favorable prognoses are the type 1 variant fusion of *EWS-FLI1* in Ewing sarcoma or primitive neuroectodermal tumor[20] and the *PAX7-FKHR* fusion in alveolar rhabdomyosarcoma.[19]

New technologies are emerging that permit accurate, high-throughput analysis or profiling of tumor tissue: Gene expression can be analyzed by using RNA microarrays, and proteins by using proteomics. These approaches identify a unique fingerprint of a given tumor that can provide diagnostic or prognostic information. Proteomic analysis can also identify unique proteins in patients' serum or urine; such a profile can be used for early tumor detection, to distinguish risk categories, and to monitor for recurrence. Additional types of "omics" that are currently being used to evaluate tumor or patient specimens include transcriptomics (RNA and gene expression), metabolomics (metabolites and metabolic networks), and pharmacogenomics (how genetics affects host drug responses). Information from each of these areas of investigation provides an increasingly precise and unique perspective on the biology, clinical behavior, and responsiveness to specific therapeutic interventions of individual patient tumors. It is through these analyses that personalized therapy is likely to be realized. In addition, it is anticipated that with the identification of new, critical components of oncogenesis and tumor progression will come new "druggable" targets for cancer therapy. Drugs that act on these targets will not only be effective anticancer agents but, because of their specificity, will also have a broader therapeutic window, thereby improving safety and minimizing toxicity.

## Childhood Cancer and Heredity

Advances in molecular genetic techniques have also improved our understanding of cancer predisposition syndromes. Constitutional gene mutations that are hereditary (i.e., passed from parent to child) or nonhereditary (i.e., de novo mutations in the sperm or oocyte before fertilization) contribute to an estimated 10% to 15% of pediatric cancers.[56] Constitutional chromosomal abnormalities are the result of an abnormal number or structural rearrangement of the normal 46 chromosomes and may be associated with a predisposition to cancer. Examples are the predisposition to leukemia seen with trisomy 21 (Down syndrome) and to germ cell tumors with Klinefelter syndrome (47XXY). Structural chromosomal abnormalities include interstitial deletions resulting in the constitutional loss of one or more genes.

Wilms' tumors may be sporadic, familial, or associated with specific genetic disorders or recognizable syndromes. A better understanding of the molecular basis of Wilms' tumor has been achieved largely through the study of the latter two types of tumors. The WAGR syndrome (Wilms' tumor, aniridia, genitourinary abnormalities, and mental retardation) provides an easily recognizable phenotype for grouping children likely to have a common genetic abnormality. Constitutional deletions from chromosome 11p13 are consistent in children with

WAGR syndrome[57] and also occur in approximately 35% of those with sporadic Wilms' tumor.[58] A study of a large series of patients identified the gene deleted from chromosome 11p13 as *WT1*.[59] This gene encodes a nuclear transcription factor that is essential for normal kidney and gonadal development[60] and appears to act as a tumor suppressor, but its precise role is unclear at this time. Aniridia in patients with WAGR syndrome is thought to occur after the loss of one copy of the *PAX6* gene located close to *WT1* on chromosome 11.[61] Denys-Drash syndrome, which is characterized by a very high risk of Wilms' tumor, pseudohermaphroditism, and mesangial sclerosis leading to early renal failure, is associated with germline mutations in the DNA binding domain of *WT1*.[62] The mutated WT1 protein appears to function by a dominant negative effect. Only 6% to 18% of sporadic Wilms' tumors have *WT1* mutations.[62,63]

In another subset of patients with Wilms' tumor, there is loss of genetic material in a region distal to the *WT1* locus toward the telomeric end of chromosome 11 (11p15).[39] It has therefore been suggested that there is a second Wilms' tumor susceptibility gene, tentatively named *WT2,* in 11p15. Loss of heterozygosity at this locus has also been described in patients with Beckwith-Wiedemann syndrome, a congenital overgrowth syndrome characterized by numerous growth abnormalities as well as a predisposition to a variety of malignancies, including Wilms' tumor.[64]

Neurofibromatosis type 1 (NF1) is one of the most common genetic disorders. The NF1 protein normally inhibits the proto-oncogene *RAS,* but in patients with NF1, mutation of one copy of the gene combined with deletion of the other permits uncontrolled RAS pathway activation. These patients are then susceptible to myelogenous disorders, benign tumors, gliomas, and malignant peripheral nerve sheath tumors. An inherited predisposition to pediatric cancers is also associated with Li-Fraumeni syndrome (which results from mutations which inactivate the *TP53* gene and put patients at risk for osteosarcoma, rhabdomyosarcoma, adrenocortical carcinoma, and brain tumors, among other tumors), familial retinoblastoma (which results from mutations that inactivate the *RB* gene and put patients at risk for osteosarcoma as well as retinoblastoma), familial adenomatous polyposis, and multiple endocrine neoplasia syndromes. Another set of inherited risk factors is represented by mutations of DNA repair genes (so-called caretaker genes), as seen in xeroderma pigmentosa and ataxia-telangiectasia.[65] Understanding these complex syndromes and their pathogenesis is important in efforts to screen for early detection and, possibly, for prophylactic therapy.

Recently, the germline mutation associated with hereditary neuroblastoma has been identified as activating mutations in the tyrosine kinase domain of the anaplastic lymphoma kinase (*ALK*) oncogene on the long arm of chromosome 2 (2p23).[66] Further molecular studies have revealed that common genetic variation at chromosome bands 6p22[1] and 2q35[67] are associated with susceptibility to, and likely contribute to the etiology of, high-risk neuroblastoma, providing the first evidence that childhood cancers also arise because of complex interactions of polymorphic variants. Finally, the same group has also shown that inherited copy number variation at chromosome 1q21.1 is associated with neuroblastoma, implicating a neuroblastoma breakpoint family gene in early neuroblastoma genesis.[68]

## Genetic Screening

Along with an increased understanding of the molecular basis of hereditary childhood cancer has come the opportunity to identify children who are at high risk of malignancy and, in some cases, to intervene before the cancer develops or when it is still curable. Two examples include familial adenomatous polyposis and familial thyroid cancer.

Familial adenomatous polyposis is an autosomal dominant inherited disease in which hundreds to thousands of adenomatous intestinal polyps develop during the second and third decades of life. Mutations of the adenomatous polyposis coli *(APC)* gene on chromosome 5q21 occur in approximately 80% of kindreds of persons who have the disease.[69,70] These mutations initiate the adenomatous process by allowing clonal expansion of individual cells that, over time, acquire additional genetic abnormalities that lead to the development of invasive colorectal carcinoma.[71] Prophylactic colectomy is recommended for patients with this germline mutation, although the most appropriate timing for this intervention in children with familial adenomatous polyposis is controversial. These patients are also at increased risk of hepatoblastoma.[72]

Medullary thyroid carcinoma (MTC) is a rare malignancy that may occur sporadically or as part of two syndromes: multiple endocrine neoplasia (type 2A or 2B) syndrome or familial MTC syndrome. In children, MTC is much more likely to occur in association with a familial syndrome. An apparently 100% association between germline *RET* mutations[73] and MTC guides the recommendation for prophylactic thyroidectomy in affected patients. There is no effective adjuvant treatment other than surgery for MTC, highlighting the need for early intervention. Patients with germline *RET* mutations should also be screened for pheochromocytoma, which occurs in 50% of patients with multiple endocrine neoplasia type 2A, and hyperparathyroidism, which occurs in 35% of such patients, although these entities generally arise in older patients beyond the pediatric age range.[74] In addition, patients who are at risk for MTC or have newly diagnosed MTC, as well as their relatives, should be screened for the germline *RET* mutation so that appropriate surgical and genetic counseling can be given.

## General Principles of Chemotherapy

Cytotoxic agents were first noted to be effective in the treatment of cancer in the 1960s, after alkylating agents, such as nitrogen mustard gas, used during World War II, were observed to cause bone marrow hypoplasia. Chemotherapy is now an integral part of nearly all cancer treatment regimens. The overriding goal of cancer chemotherapy is to maximize the tumoricidal effect (efficacy) while minimizing adverse side effects (toxicity). This goal can be difficult to achieve, however, because the dose at which tumor cells are affected is often similar to the dose that affects normal proliferating cells, such as those in the bone marrow and gastrointestinal tract. Despite the early promise of chemotherapy and the observation that most tumor types are initially sensitive to chemotherapy, often

exquisitely so, the successful use of chemotherapy is often thwarted by two factors: the development of resistance to the agent and the agent's toxicity to normal tissues. Nevertheless, chemotherapy remains an integral part of therapy when used as an adjunct to treat localized disease or as the main component to treat disseminated or advanced disease.

A number of principles and terms are essential to the understanding of chemotherapy as a therapeutic anticancer modality. Adjuvant chemotherapy refers to the use of chemotherapy for systemic treatment following local control generally by surgical resection or radiation therapy of a clinically localized primary tumor. The goal in this setting is to eliminate disease that is not detectable by standard investigative means at or beyond the primary tumor's site. Neoadjuvant chemotherapy refers to chemotherapy delivered before local therapeutic modalities, generally in an effort to improve their efficacy; to treat micrometastatic disease as early as possible, when distant tumors are smallest; or to achieve both of these aims. Induction chemotherapy refers to the use of chemotherapeutic agents as the primary treatment for advanced disease. In general, chemotherapy given to children with solid tumors and metastatic disease at the time of first examination has a less than 40% chance of effecting long-term, disease-free survival. Exceptions include Wilms' tumor with favorable histologic features, germ cell tumors, and paratesticular rhabdomyosarcoma, but most children with metastatic disease are at high risk of disease recurrence or progression. Combination chemotherapy refers to the use of multiple agents, which generally have different mechanisms of action and nonoverlapping toxicities, that provide effective, synergistic antitumor activity and minimal side effects.

The mechanisms of action and side effects of commonly used agents are listed in Table 28-5. Alkylating agents interfere with cell growth by covalently cross-linking DNA and are not cell-cycle specific. Antitumor antibiotics intercalate into the double helix of DNA and break the DNA strands. Antimetabolites are truly cell-cycle specific, because they interfere with the use of normal substrates for DNA and RNA synthesis, such as purines and thymidine. The plant alkaloids can inhibit microtubule function (vinca alkaloids, taxanes) or DNA topoisomerases (camptothecins inhibit topoisomerase I; epipodophyllotoxins inhibit topoisomerase II), and these actions also lead to breaks in DNA strands. Topoisomerases are a class of enzymes that alter the supercoiling of double-stranded DNA. They act by transiently cutting one (topoisomerase I) or both (topoisomerase II) strands of the DNA to relax the DNA coil and extend the molecule. The regulation of DNA supercoiling is essential to DNA transcription and replication, when the DNA helix must unwind to permit the proper function of the enzymatic machinery involved in these processes. Thus topoisomerases maintain the transcription and replication of DNA.

The common toxic effects of these agents are also listed in Table 28-5. Most toxicity associated with chemotherapy is reversible and resolves with cessation of treatment. However, some chemotherapeutic agents may have lifelong effects. Of particular concern is that certain drugs can lead to a second malignancy. Most notable is the development of leukemia after the administration of the epipodophyllotoxins and cyclophosphamide.[75]

Finally, understanding the metabolism of chemotherapeutic agents is important. Certain agents require metabolism at a specific site or organ for their activation or are eliminated from the body by a specific organ (see Table 28-5). The processes of activation and elimination require normal organ function (e.g., the liver for cyclophosphamide); therefore children with liver or kidney failure may not be able to receive certain agents.

## RISK STRATIFICATION

Major advances in the variety of chemotherapeutic agents and dosing strategies used to treat pediatric cancers in the past 30 years are reflected in improved patient survival rates. Regimen toxicity (including late effects, which are particularly important in the pediatric population) and therapeutic resistance are the two main hurdles preventing further advancement. As more information about diagnostically and prognostically useful genetic markers becomes available, therapeutic strategies will change accordingly. With molecular profiling, patients can be categorized to receive a particular treatment on the basis of not only the tumor's histopathologic and staging characteristics but also its genetic composition. Some patients whose tumors show a more aggressive biological profile may require dose intensification to increase their chances of survival. Patients whose tumors do not have an aggressive biological profile may benefit from the lower toxicity of less intensive therapy. Such an approach may allow the maintenance of high survival rates while minimizing long-term complications of therapy in these patient populations.

The paradigm for the use of different therapeutic intensities on the basis of risk stratification drives the management of pediatric neuroblastoma. There is increasing evidence that the molecular features of neuroblastoma are highly predictive of its clinical behavior. Most current studies of the treatment of neuroblastoma are based on risk groups that take into account both clinical and biological variables. The most important clinical variables appear to be age and stage at diagnosis, and the most powerful biological factors appear to be *MYCN* status, ploidy (for patients younger than 1 year), and histopathologic classification. These variables currently define the Children's Oncology Group risk strata and therapeutic approach, which are further refined by determining whether there is 1p/11q LOH. At one extreme, patients with low-risk disease are treated with surgery alone; at the other extreme, patients at high risk for relapse are treated with intensive multimodality therapy that includes multiagent dose-intensive chemotherapy, radiation therapy, and stem cell transplantation. Other factors, such as 17q gain, caspase 8 inactivation, and TRKA/B expression, are currently being evaluated and may help further refine risk assessment in the future. The management of other solid pediatric tumors is also shifting to risk-defined treatment. For example, the current protocol for the management of patients with Wilms' tumor includes risk stratification and therapy adjustment based on molecular analysis of the primary tumor for 16q and 1p deletions.

## TARGETED THERAPY

Another major change in the approach to the treatment of cancer has been the concept of targeted therapy. Until recently, the development of anticancer agents was based on the empirical screening of a large variety of cytotoxic compounds without particular regard to disease specificity or mechanism of action. Now, one of the most exciting prospects for improving the

| Miscellaneous | L-Asparaginase | Erwinia | Elspar | L-Asparagine depletion, inhibits protein synthesis | CNS, H, coagulopathy, pancreatitis, anaphylaxis | | degraded | Limited |
| | Corticosteroids | | | Nuclear receptor–mediated apoptosis | avascular necrosis, hyperglycemia, hypertension, myopathy, pancreatitis, peptic ulcers, psychosis, salt imbalance, weight gain | H | H, R (minor) | BT |

Toxic effects: A, alopecia; CNS, central nervous system toxicity; H, hepatotoxicity; M, myelosuppression; N/V, nausea and vomiting; P, pulmonary toxicity; R, renal toxicity; SIADH, syndrome of inappropriate antidiuretic hormone; XRT, x-ray therapy.
Solid tumors: BMT, conditioning for bone marrow transplantation; BT, brain tumor; EWS, Ewing sarcoma; GCT, germ cell tumors; NBL, neuroblastoma; OS, osteosarcoma; RMS, rhabdomyosarcoma; STS, soft tissue sarcoma; W, Wilms' tumor.

therapeutic index of anticancer agents, as well as overcoming the problem of therapy resistance, involves targeted therapy. As the molecular bases for the phenotypes of specific malignancies are being elucidated, potential new targets for therapy are becoming more clearly defined. The characterization of pathways that define malignant transformation and progression has focused new agent development on key pathways involved in the crucial processes of cell-cycle regulation, receptor signaling, differentiation, apoptosis, invasion, migration, and angiogenesis, which may be perturbed in malignant tissues. Information about the molecular profile of a given tumor type can be assembled from a variety of emerging methods, including immunohistochemistry, FISH, RT-PCR, cDNA microarray analysis, and proteomics. This information can then be used to develop new drugs designed to counter the molecular abnormalities of the neoplastic cells. For example, blocking oncogene function or restoring suppressor gene activity may provide tumor-specific therapy. In addition, molecular profiling may lead to the development of drugs designed to induce differentiation of tumor cells, block dysregulated growth pathways, or reactivate silenced apoptotic pathways.

Some agents target alterations in the regulation of cell proliferation. Trastuzumab (Herceptin) is a monoclonal antibody that binds to the cell surface growth factor receptor ERBB2 with high affinity and acts as an antiproliferative agent when used to treat ERBB2-overexpressing cancer cells.[76] Pediatric high-grade gliomas that overexpress EGFR may be amenable to a similar therapeutic agent, gefitinib (Iressa), a small-molecule inhibitor of EGFR (ERBB1).[77] In addition, small-molecule tyrosine kinase inhibitors, such as imatinib (Gleevec), designed to block aberrantly expressed growth-promoting tyrosine kinases—ABL in chronic myelogenous leukemia[78] and c-KIT in gastrointestinal stromal tumors[79]—are being evaluated in clinical trials. Imatinib may also be useful in treating pediatric tumors in which PDGF signaling plays a role in tumor cell survival and growth. Also of potential therapeutic utility are small-molecule inhibitors that recognize antigenic determinants on unique fusion peptides or one of the fusion peptide partners in tumors that have chromosomal translocations (e.g., sarcomas). Tumors that depend on autocrine pathways for growth (e.g., overproduction of IGF-II in rhabdomyosarcoma or PDGF in dermatofibrosarcoma protuberans) may be sensitive to receptor blocking mediators (e.g., antibodies to the IGF-II or PDGFR).

Other agents target alteration of the cell death and differentiation pathways. Caspase 8 is a cysteine protease that regulates programmed cell death, but in tumors such as neuroblastoma, DNA methylation and gene deletion combine to mediate the complete inactivation of caspase 8, almost always in association with *MYCN* amplification.[80] Caspase 8-deficient tumor cells are resistant to apoptosis mediated by death receptors and doxorubicin; this resistance suggests that caspase 8 may be acting as a tumor suppressor. However, brief exposure of caspase 8–deficient cells to demethylating agents, such as decitabine, or to low levels of interferon gamma can lead to the reexpression of caspase 8 and the resensitization of the cells to chemotherapeutic drug-induced apoptosis. Histone deacetylase also seems to have a role in gene silencing associated with resistance to apoptosis[81]; therefore histone deacetylase inhibitors, such as suberoylanilide hydroxamic acid (SAHA), are also being tested for the treatment of certain pediatric malignancies. Finally, cells with alterations in programmed cell death as a result of the persistence or reactivation of telomerase activity, which somatic cells normally lose after birth, can be targeted by various telomerase inhibitors.

Several methods of targeting tumor cell differentiation are being used for the treatment of neuroblastoma. Treatment with 13-cis-retinoic acid, a vitamin A derivative that signals through receptors that mediate transcription of different sets of genes of cell differentiation, including *HOX* genes, is now standard of care for maintenance therapy in patients with high-risk neuroblastoma.[82,83] Also, different neurotrophin receptor pathways appear to mediate the signal for both cellular differentiation and malignant transformation of sympathetic neuroblasts to neuroblastoma cells. Neurotrophins are expressed in a wide variety of neuronal tissues and other tissues that require innervation. They stimulate the survival, maturation, and differentiation of neurons and exhibit a developmentally regulated pattern of expression.[84,85] Neurotrophins and their TRK tyrosine kinase receptors are particularly important in the development of the sympathetic nervous system and have been implicated in the pathogenesis of neuroblastoma. Three receptor–ligand pairs have been identified: TRKA, TRKB, and TRKC, which are the primary receptors for nerve growth factor, brain-derived neurotrophic factor (BDNF), and neurotrophin 3 (NT-3), respectively.[84] TRKA appears to mediate the differentiation of developing neurons or neuroblastoma in the presence of nerve growth factor ligand and to mediate apoptosis in the absence of nerve growth factor.[85] Conversely, the TRKB-BDNF pathway appears to promote neuroblastoma cell survival through autocrine or paracrine signaling, especially in *MYCN*-amplified tumors.[86] TRKC is expressed in approximately 25% of neuroblastomas and is strongly associated with TRKA expression.[87] Studies are ongoing to test agonists of TRKA in an attempt to induce cellular differentiation. Conversely, blocking the TRKB-BDNF signaling pathway with TRK-specific tyrosine kinase inhibitors such as CEP-751 may induce apoptosis by blocking crucial survival pathways.[66,86] This targeted approach has the attractive potential for increased specificity and lower toxicity than conventional cytotoxic chemotherapy.

## Inhibition of Angiogenesis

Because tumor growth and spread appear to be dependent on angiogenesis, inhibition of angiogenesis is a logical anticancer strategy. This approach is particularly appealing for several reasons. First, despite the extreme molecular and phenotypic heterogeneity of human cancer, it is likely that most, if not all, tumor types, including hematologic malignancies, require neovascularization to achieve their full malignant phenotype. Therefore antiangiogenic therapy may have broad applicability for the treatment of cancer. Second, the endothelial cells in a tumor's new blood vessels, although rapidly proliferating, are inherently normal and mutate slowly. They are therefore unlikely to evolve a phenotype that is insensitive to an angiogenesis inhibitor, unlike the rapidly proliferating tumor cells, which undergo spontaneous mutation at a high rate and can readily generate drug-resistant clones. Finally, because the new blood vessels induced by a tumor are sufficiently distinct from established vessels to permit highly specific targeting,[88,89] angiogenesis inhibitors should have a

high therapeutic index and minimal toxicity. The combination of conventional chemotherapeutic agents with angiogenesis inhibitors appears to be particularly effective.

The first clinical demonstration that an angiogenesis inhibitor could cause regression of a tumor came with the use of interferon alpha in a patient treated for life-threatening pulmonary hemangioma.[90] An increasing number of natural and synthetic inhibitors of angiogenesis, which inhibit different effectors of angiogenesis, have since been identified, and many of these agents have been tested in clinical trials. Examples include drugs that directly inhibit endothelial cells, such as thalidomide and combretastatin; drugs that block activators of angiogenesis, such as bevacizumab (Avastin), a recombinant humanized anti-VEGF antibody, or "VEGF trap"; drugs that inhibit endothelium-specific survival signaling, such as Vitaxin, an anti-integrin antibody; and drugs with nonspecific mechanisms of action, such as celecoxib and interleukin-12 (IL-12).

# Immunotherapy

The immune system has evolved as a powerful means to detect and eliminate molecules or pathogens that are recognized as "foreign." However, because tumors arise from host cells, they are generally relatively weakly immunogenic. In addition, malignant cells have evolved several mechanisms that allow them to elude the immune system. These mechanisms include the ability to down-regulate the cell surface major histocompatibility complex molecules required for activation of many of the immune effector cells, to produce immunosuppressive factors, and to variably express different proteins that might otherwise serve as targets for the immune system in a process known as antigenic drift. Nevertheless, because of the large number of mutations and chromosomal aberrations occurring in cancer cells, which results in the expression of abnormal, new, or otherwise silenced proteins, it is likely that most, if not all, cancers contain unique tumor-associated antigens that can be recognized by the immune system. Examples include the fusion proteins commonly found in pediatric sarcomas and the embryonic neuroectodermal antigens that continue to be produced by neuroblastomas.

Recruiting the immune system to help eradicate tumor cells is an attractive approach for several reasons. First, circulating cells of the immune system have ready access to even occult sites of tumor cells. Second, the immune system has powerful effector cells capable of effectively and efficiently destroying and eradicating targets, including neoplastic cells. Initial efforts to recruit the immune system to recognize and destroy tumor cells by using cytotoxic effector mechanisms that are T-cell dependent or independent focused on recombinant cytokines. Cytokines act by directly stimulating the immune system[66] or by rendering the target tumor cells more immunogenic.

Neuroblastoma has been a popular target for immunotherapy in the pediatric population. Although a particular neuroblastoma antigen has not been defined, murine monoclonal antibodies have been raised against the ganglioside GD2, a predominant antigen on the surface of neuroblastoma cells. These antibodies elicited therapeutic responses,[37,91] but with substantial toxicity, particularly neuropathic pain.[92] Because the induction of antibody-dependent cell-mediated cytotoxicity with anti-GD2 antibodies is enhanced by cytokines, such as granulocyte-macrophage colony-stimulating factor[92] and interleukin-2 (IL-2),[93] current antineuroblastoma antibody trials are evaluating the use of a humanized, chimeric anti-GD2 antibody (ch14.18) with these cytokines and a fusion protein (hu14.18:IL2) that consists of the humanized 14.18 antibody linked genetically to human recombinant IL-2. A recently completed randomized phase III trial using ch14.18 alternating with cycles of granulocyte-macrophage colony-stimulating factor (GM-CSF) or interleukin-2 added to maintenance therapy of cis-retinoic acid demonstrated a significant improvement in 2-year event-free survival for those who received immunotherapy in addition to retinoic acid.[94]

# General Principles of Radiation Therapy

Radiation therapy is one of the three primary modalities used to manage pediatric cancers in the modern era. Radiation therapy is delivered to an estimated 2000 or more children per year for the primary treatment of tumor types as diverse as leukemia, brain tumors, sarcomas, Hodgkin disease, neuroblastoma, and Wilms' tumor.[95] Delivery of radiation therapy in the pediatric setting differs from that in the adult setting because of the balance between curative therapy and an anticipated long life span during which long-term morbidity may result from the therapy.

## CLINICAL CONSIDERATIONS

Radiation therapy for the management of pediatric cancer is most frequently combined with surgery and chemotherapy as part of a multidisciplinary treatment plan. The sensitive nature of pediatric tumors requires the use of a combined therapy approach to maximize tumor control while minimizing the long-term side effects of treatment. Radiation may be delivered preoperatively, postoperatively (relative to a definitive surgical resection), or definitively without surgical management. Systemic therapy may also be integrated into this management approach.

### Definitive Irradiation

Definitive radiation therapy is an alternative local approach to surgical resection of primary solid tumors. It is often the only local therapeutic approach for children and adolescents with leukemia or lymphoma.[96,97] Definitive radiation therapy for rhabdomyosarcoma has been used as an alternative to surgical resection, which has potentially greater morbidity; it has achieved high rates of local tumor control while allowing preservation of function.[38] The Ewing sarcoma family of tumors may also be considered candidates for definitive radiation therapy as an alternative to surgery. With careful patient selection, excellent local tumor control rates can be maintained while reducing or avoiding the morbidity associated with difficult surgical resections.[98,99]

### Preoperative Irradiation

Targeting of a localized tumor is straightforward in the preoperative setting; the tumor has clearly defined margins undisturbed by a surgical procedure. The volume of normal, healthy tissues receiving high doses of radiation may be

reduced, because the areas at risk for disease involvement can be better defined. Preoperative radiation therapy has been used rarely in the management of Wilms' tumor to decrease the chance of tumor rupture[100] and in the management of nonrhabdomyosarcoma soft tissue sarcoma and Ewing sarcoma to facilitate surgical resection.[101,102] One of the limitations may be the slightly higher incidence of postoperative wound complications noted in the sarcoma population.[102]

### Postoperative Irradiation

Postoperative radiation therapy combined with surgical resection is the most common application of adjuvant radiation treatment in the United States. Despite some degree of difficulty in targeting, a postoperative approach allows a review of tumor histology from the complete tumor specimen, including identification of the tumor margins and the response to any previous therapy. Wound healing complications appear to be reduced with this approach, and the radiation dose can be more accurately tailored to the pathologic findings after primary resection.

### Interactions of Chemotherapy and Radiation

Most children's cancers are managed with systemic chemotherapy. In children receiving radiation therapy as well as systemic chemotherapy, issues of enhanced local efficacy and enhanced local or regional toxicity need to be considered. Solid tumors that are frequently treated with combined chemotherapy and radiation therapy include Wilms' tumor, neuroblastoma, and sarcomas. These tumors are subdivided into those in which chemotherapy is given concomitantly with radiation therapy[103,104] and those in which it is given sequentially, before or after radiation therapy.[83,100,105] When delivering radiation therapy concurrently with or temporally close to a course of chemotherapy, several issues must be considered.

### Chemotherapeutic Enhancement of Local Irradiation

Several systemic chemotherapeutic agents used against pediatric tumors may enhance the efficacy of radiation therapy when delivered concomitantly. Cisplatin, 5-fluorouracil, mitomycin C, and gemcitabine, for example, are well-known radiation sensitizers.[106–108] Concomitant delivery of any of these drugs with radiation therapy may require that they be administered at a dose and schedule different from those typically used when the drugs are delivered alone. Despite the potential of increased toxicity, significant improvements in local tumor control have been shown in randomized studies of concomitant drug and radiation therapy.[106,107]

### Irradiation Combined with Agents Having Limited or No Sensitizing Effect

In the management of pediatric malignancies, radiation is often combined with systemic therapy not to increase its local efficacy but to allow continued delivery of systemic therapy to control micrometastatic or metastatic disease. Agents combined with radiation therapy in this setting are common in the management of pediatric sarcomas and include ifosfamide and etoposide, which are delivered concurrently with radiation therapy for Ewing sarcoma, and vincristine and cyclophosphamide, which are delivered concurrently with radiation therapy for rhabdomyosarcoma.[103,104] Although local toxicity may be increased by such an approach, this risk is often outweighed by the benefit of continuously delivered systemic therapy, particularly in tumors associated with a high incidence of micrometastatic disease.

### Agents That Increase Radiation Toxicity

Several agents significantly increase the local toxicity of radiation. For this reason, these agents are not given concomitantly with irradiation and are often withheld for a period after the completion of radiation therapy. The two most notable agents are doxorubicin and actinomycin, both of which can induce significant skin and mucosal toxicity when delivered concurrently with radiation therapy.[38,109] The camptothecins (including irinotecan and topotecan) also potentiate mucosal toxicity when delivered concurrently with radiation therapy.[110,111] Although this increase in toxicity suggests a possible increase in local efficacy, this benefit has not been noted with current treatment approaches and chemotherapeutic dosing guidelines. For this reason, these agents are avoided during the delivery of radiation therapy and are withheld for 2 to 6 weeks after the completion of treatment.

The current era of systemic therapy continues to broaden with the availability of many new agents that target molecular pathways. It is important to consider the possibility of new toxicities when combining novel agents with a known therapy such as radiation.

## FRACTIONATION OF RADIATION THERAPY

Conventional, external beam irradiation is delivered in a fractionated form. Fractionation implies daily doses of radiation delivered 5 days per week and amounting to the prescribed dose for a particular tumor type. Radiation delivered once daily at a fraction size between 1.5 and 2.0 Gy on 5 days per week is considered "conventionally" fractionated. This daily dose is well tolerated by normal tissues adjacent to the tumor and appears to effect local tumor control in many tumor systems. Though adult malignancies may be treated with increased doses per fraction to overcome the radioresistance of many carcinomas (termed hypofractionation), nearly all the literature describing radiation therapy, its efficacy, and its toxicity in children is based on conventional fractionation.

## RADIATION THERAPY TREATMENT TECHNIQUES

### Traditional Radiation Therapy

The planning and delivery of traditional, or conventional, radiation therapy are based on nonvolumetric imaging studies (i.e., conventional radiographs). Patients are positioned in a manner that allows the orientation of radiation beams from the conventional directions: anterior, posterior, and lateral. Limitations of this approach are related to the ability of conventional radiographs to accurately convey the location of tumor-bearing tissue. Although treatment beams are oriented around the tumor, adjacent normal tissues also receive high doses of radiation. Depending on the accuracy of the delineation of adjacent normal tissues on radiographs, the dose to those tissues may not be known. Radiation is delivered by a photon beam generated by a linear accelerator.

### Focal Radiation Therapy

Focal radiation therapy comprises a group of techniques that deliver radiation to a defined volume, usually delineated by computed tomography (CT) or magnetic resonance imaging (MRI). Relatively low doses may be incidentally delivered to surrounding normal tissues. Radiation therapy may be described as image guided when four criteria are met: (1) three-dimensional imaging data (CT or MRI) are acquired with the patient in the treatment position; (2) imaging data are used to delineate and reconstruct the tumor volume and normal tissues in three dimensions; (3) radiation beams can be freely oriented in three dimensions in the planning and delivery processes, and structures traversed by the beam can be visualized with the eye of the beam; and (4) the distribution of doses received by the tumor volume and any normal tissue is computable on a point-by-point basis in three-dimensional space. Several different methods of delivering image-guided photon radiation are currently in use and are discussed here.

### Conformal Radiation Therapy

The delivery of three-dimensional conformal radiation therapy allows specific targeting of tumor volumes on the basis of imaging studies performed with the patient in the treatment position. This method of delivery uses multiple fields or portals, with each beam aperture shaped to the tumor volume, and it is performed daily. Beam modifiers, such as wedges, are used to conform the radiation beam to the tumor and to ensure that the tumor volume receives a homogeneous dose. Conformal radiation therapy has been intensively studied in adults with head and neck cancer, lung cancer, and prostate cancer and has been shown to excel when the target volume is convex and crucial structures do not invaginate the target volume. Available data demonstrate that it has low toxicity despite high doses of radiation to the target volume.[112]

### Intensity-Modulated Radiation Therapy

Intensity-modulated radiation therapy is another method of delivering external beam radiation that requires imaging of the patient in the treatment position and delineation of target volumes and normal tissues. Radiation is delivered to the target as multiple small fields that do not encompass the entire target volume but collectively deliver the prescribed daily dose. Intensity-modulated radiation therapy differs from conformal radiation therapy in that it (1) increases the complexity and time required for the planning and delivery of treatment, (2) increases the amount of quality-assurance work required before treatment is delivered, (3) increases dose heterogeneity within the target volume such that some intralesional areas receive a relatively high dose, and (4) can be used to treat concave targets while sparing crucial structures that invaginate the target volume. The last point holds promise for better protecting normal tissue and reducing late toxic effects. Preliminary data from adult patients given intensity-modulated radiation therapy demonstrate its potential for reducing treatment toxicity when applied to pediatric brain tumors and other adult tumors.[113]

### Proton Beam Radiation Therapy

Proton radiation therapy and other approaches using heavy charged particles have been investigated at a limited number of centers. The primary benefit of therapy with proton or other heavy charged particle beams is the capacity to end the radiation beam at a specific and controllable depth. This may allow the protection of healthy, normal tissues directly adjacent to tumor-bearing tissues.[114] However, the use of proton therapy has been limited because of the expense of constructing a suitable treatment facility. Several new facilities have opened in the United States, and pediatric malignancies are always noted as one of the tumors systems on which the centers will focus their research efforts. With appropriately designed studies and comparisons with current state-of-the-art focal radiation therapy delivered with photon beams, a determination of the potential benefits of this treatment modality may be made.

### Brachytherapy

Brachytherapy is a method of delivering radiation to a tumor or tumor bed by placing radioactive sources within or adjacent to the target volume, usually at the time of surgical resection and under direct vision. Planning of the dose to be delivered to the target volume is accomplished after resection and may use CT or MRI studies; the appropriate strength of the radioactive source is determined prospectively. Sources commonly used in children include iridium 192 and iodine 125. Brachytherapy may consist of either low dose-rate treatments (approximately 40 to 80 cGy per hour) or high dose-rate treatments (approximately 60 to 100 cGy per minute). Low dose-rate treatments are delivered during a period of days, often while the patient remains hospitalized, whereas high dose-rate treatments are divided into fractions and delivered on several days during 1 to 2 weeks. The primary advantage of brachytherapy is that a radiation source can be placed into or adjacent to the tumor, often at the time of resection. Preoperative planning and cooperation between the surgical and radiation oncology teams are necessary to ensure the appropriate and accurate implementation of brachytherapy. Nonrhabdomyosarcoma soft tissue sarcomas and some rhabdomyosarcomas are the pediatric tumors most commonly treated with brachytherapy.[115,116] Most other pediatric solid tumors are not amenable to brachytherapy, however, because of the tumor's behavior (e.g., radioresistance) or its anatomic location (e.g., retroperitoneal).

Intraoperative radiation therapy has been used intermittently after resection in the management of localized tumors.[117] Although of limited availability in the United States, intraoperative radiation therapy has the distinct advantage of allowing the operative tumor bed to be visible in the operating theater while radiation is delivered, thereby enhancing the accuracy of delivery and providing the opportunity to displace or temporarily move mobile crucial structures (e.g., bowel, bladder) from the field of delivery. The primary limitation of intraoperative radiation therapy is that it can deliver only a single fraction of radiation, usually in the 10 to 20 Gy range. Radiation tolerances of normal tissues that cannot be removed from the treatment field must be respected and may limit the ability to deliver an effective treatment dose.

## PALLIATIVE RADIATION THERAPY

Despite substantial success in the management of pediatric cancer, some children experience disease recurrence and ultimately die from their malignancy. Palliative radiation therapy is often a valid intervention for these patients.[118] The ultimate goal of a palliative approach is to maintain quality of life for

patients who will not survive their disease by palliating their symptoms while minimizing the number of disruptive interventions they must undergo. Painful sites of disease, particularly those with bony involvement, and symptoms resulting from compression of vital structures, including spinal cord, peripheral nerves, and respiratory tract are often palliated with radiation. A palliative course of therapy is highly individualized, and its success or failure depends on the histologic diagnosis, previous therapy, duration of symptoms, and symptom(s) being treated.

## ACUTE AND LATE TOXICITIES OF RADIATION THERAPY

The treatment-related effects of radiation therapy, both acute and chronic, are well described for pediatric and adult patients, but unfortunately, their incidence and relation to the dose and volume of treatment are poorly characterized.[119] Historically, treatment-related effects have been classified as acute or late; an arbitrary time point of 90 days after the completion of treatment defines the division between the two classifications. Current guidelines for assessing adverse events related to treatment no longer recognize this arbitrary distinction, but the use of early and late time points is instructive in the discussion of radiation-related effects. Essentially all such effects originate from within the confines of the treatment beams, usually the high-dose regions of treatment. The most common early and late treatment-related effects arising from radiation are listed in Table 28-6. Despite the arbitrary nature of the division into early and late effects, this classification distinguishes effects from which the patient is likely to recover completely from those that are likely to be permanent. Early treatment-related effects, if managed appropriately, will resolve as normal, healthy tissues adjacent to the tumor-bearing tissues, gradually recovering from the effects of radiation. The period of recovery can range from days to months, but the patient is often left with minimal sequelae. Treatment-related effects that are observed later, after the completion of radiation therapy, are more likely to be chronic or permanent. They appear to be related to the normal healing response of healthy irradiated tissue, resulting in the formation of an unwanted effect such as fibrosis. Many late treatment effects can be managed but are not reversible. For children receiving curative therapy, long-term effects are a primary concern and are best managed with a preventive approach. Some of the long-term effects of treatment in children should be ameliorated by limiting the volume of normal tissue irradiated at high doses and by implementing approaches that minimize the radiation dose to adjacent healthy tissues.

**TABLE 28-6**

**Radiation-Related Adverse Events in Children and the Associated Radiation Doses**

| *Organ/Site* | *Acute* | *Chronic* | *Dose Relation* | *Reference* |
|---|---|---|---|---|
| Skin | Erythema<br>Desquamation | Atrophy<br>Hyperpigmentation | Doses more than 40 Gy increase incidence of moist desquamation | 121 |
| Subcutaneous tissue | Edema | Fibrosis | – | |
| Mucosa | Mucositis | Ulceration | – | |
| Central nervous system | Headache<br>Edema | Necrosis<br>Myelitis<br>Decline in cognition | 2.5% incidence of brainstem necrosis with doses of 59.4 Gy<br>Reduction in intelligence quotient with younger age and doses of radiation to the supratentorial brain more than 30 Gy | 122, 123 |
| Eye | Conjunctivitis | Cataract<br>Retinopathy<br>Dry eye | 43% incidence of cataract with doses of total body irradiation of $\geq$ 12 Gy | 124 |
| Thyroid | – | Hypothyroidism | 20% incidence at $\leq$ 21 Gy; 61% incidence when $>$ 21 Gy | 125 |
| Heart | – | Pericarditis<br>Myocarditis<br>Valvular disease | 2.5% incidence of pericarditis at doses of 30 Gy to the heart | 126, 127 |
| Lung | Pneumonitis | Pulmonary fibrosis | Increasing risk of pneumonitis with volume of lung receiving 24 Gy and bleomycin chemotherapy | 128 |
| Bowel | Nausea<br>Diarrhea | Necrosis | – | |
| Kidney | – | Nephritis<br>Renal insufficiency | – | |
| Bladder | Dysuria<br>Urgency<br>Frequency | Hemorrhagic cystitis | – | |
| Muscle | Edema | Fibrosis<br>Hypoplasia | Acute edema in adjacent muscle receiving doses above 40 Gy<br>Volume of jaw muscles $>$ 40 Gy increases chronic fibrosis | 129 |
| Bone | – | Hypoplasia<br>Fracture<br>Premature physis closure | Increasing reduction in growth above 35 Gy, but effects seen even at 23.4 Gy<br>Weight-bearing bones in patient radiated for sarcomas have a 29% incidence of fracture | 130–132 |

## General Principles of Stem Cell Transplantation

Infusion or transplantation of hematopoietic cells capable of reconstituting the hematopoietic system is used in two broad instances. First, hematopoietic stem cell transplantation (HSCT) can be used to replace missing or abnormal components of a defective hematopoietic system. Second, HSCT can be used to reconstitute elements of the hematopoietic system destroyed by intensive chemotherapy or radiation therapy for solid tumors or disorders of the hematopoietic system itself. The transplanted cells can be the patient's own (i.e., autologous), in which case the cells are obtained before the administration of myelosuppressive therapy, or they may come from a donor (i.e., allogeneic) who is generally a histocompatibility leukocyte antigen (HLA)–identical sibling, a mismatched family member, or a partially matched unrelated donor. The latter two circumstances require immunosuppressive and graft engineering strategies to permit successful engraftment and avoid graft-versus-host disease. Hematopoietic progenitor cells are usually obtained from the bone marrow or peripheral blood. They are the crucial component of the transplant, because they are capable of self-renewal and therefore long-term production of cells of the various hematopoietic lineages. Occasionally, when available, banked umbilical cord blood may be used as the source of hematopoietic stem cells (HSCs). In general, although autologous cells are the safest to use for HSCT, they may be contaminated with tumor cells. Graft-versus-host disease, which may occur with allogeneic HSCT, can be life threatening, but a modest graft-versus-host reaction may be beneficial if directed against the host's tumor cells.

Bone marrow is normally harvested from the posterior iliac crest to a total volume of 10 to 20 mL/kg body weight of the recipient. Peripheral blood stem cells are harvested after their mobilization with recombinant granulocyte colony-stimulating factor, given daily for up to a week before harvest. The exact nature of the crucial cellular component responsible for the reconstitution of the hematopoietic system is unknown, but the number of cells having the surface marker CD34 has been shown to be related to the rate of engraftment.[120] Before HSCT, the recipient receives a preparative (or "conditioning") chemotherapeutic regimen. This treatment serves several purposes, including killing residual tumor cells, providing immunosuppression for allogeneic HSCT, and providing "space" in the marrow into which transplanted HSCs can engraft. Before reinfusion, the HSC product may be manipulated ex vivo to enrich it for putative progenitor cells (e.g., $CD34^+$ or $CD133^+$ cells), using positive or negative selection methods to facilitate hematopoietic reconstitution; to remove donor T lymphocytes, thereby decreasing the risk of graft-versus-host disease in allogeneic HSCT; or to purge contaminating tumor cells from the product used in autologous HSCT.

Complications of HSCT can be significant. The most common early complication is infection, which results from the transient but profound immunosuppression of the patient, combined with the breakdown of mucosal barriers. Another common complication is veno-occlusive disease, which is characterized clinically by painful enlargement of the liver, jaundice, and fluid retention. Ultrasound examination shows reversal of flow in the portal vein. Liver biopsy samples show a classic histologic appearance of obliterated hepatic venules and necrosis of centrilobular hepatocytes. There is no specific treatment for this condition; only supportive care can be given, and mild or moderate veno-occlusive disease is self limited. Other acute complications of HSCT include graft-versus-host disease, a process mediated by donor T cells targeting host cells with antigenic disparities, and graft failure. Late complications include chronic graft-versus-host disease, endocrine insufficiency, secondary malignancies, growth failure, and other sequelae related to the use of total-body irradiation as part of some preparatory regimens. Nevertheless, despite the toxicity, HSCT is now an integral part of successful therapy for many high-risk malignancies in children.

## Clinical Trials

As previously stated, the past 40 years have seen a significant increase in overall survival rates for children with cancer. This increase has been achieved through the development of new drugs and treatment approaches, improved supportive care, and better diagnostic modalities to permit earlier cancer detection. The benefits of these advances have been confirmed by carefully designed and analyzed clinical trials. Because childhood cancer is relatively rare, excellent organization and planning of these trials are essential. In the United States and other participating countries, clinical trials are largely conducted by the Children's Oncology Group, with smaller pilot studies being run by large individual institutions or small consortia.

Clinical trials are generally divided into three phases. Phase I studies are designed to evaluate the potential toxicity of a new diagnostic or therapeutic agent. Small numbers of patients are usually required for a phase I study, which typically uses a dose-escalating design in which cohorts of patients are observed for signs of toxicity before they advance to higher doses. The end point of this type of study is generally a determination of the safety of the agent or the maximum tolerated dose (or both). However, the increasing number of biologic reagents being introduced and tested may require a shift to the assessment of the optimal biologic dose. Enrollment in a phase I toxicity study is often restricted to patients whose disease has not responded to conventional, or standard-of-care, therapy. Phase II trials are conducted to determine whether a new agent or treatment approach is sufficiently efficacious to warrant further study. Phase II agents are often given to newly diagnosed patients before they begin or just after they complete standard therapy. The testing of new agents in an "upfront window" (i.e., before standard therapy) has been shown not to have an adverse effect on the efficacy of delayed standard therapy. Finally, phase III studies are designed to compare the efficacy of an experimental therapy with that of standard therapy. They are best done as prospective, randomized trials, but often, because of small patient numbers, a phase III study is done by comparing the efficacy of an experimental therapy with that of standard therapy given to historical control subjects. It is through such systematic assessment of the risks and benefits of new therapies that approaches are rejected or accepted as the new standard of care and the field of pediatric oncology is advanced.

## Conclusion

Advances in molecular genetic research in the past 3 decades have led to an increased understanding of the genetic events in the pathogenesis and progression of human malignancies, including those of childhood. A number of pediatric malignancies serve as models for the molecular genetic approach to cancer. The pediatric experience highlights the utility of molecular analysis for a variety of purposes. Demonstration of tumor-specific translocations by cytogenetics, FISH, and RT-PCR confirms histopathologic diagnoses. Detection of chromosomal abnormalities, gene overexpression, and gene amplification is used in risk stratification and treatment planning. Elucidation of pathways involving tumor suppressor genes has increased our understanding of syndromes associated with cancer and has led the way for genetic screening and counseling and prophylactic surgical intervention. And in the near future, translation of the molecular profile of a given tumor will form the basis of a new therapeutic approach. Treatment will be tailored such that patients with biologically high-risk tumors receive intensified regimens to achieve a cure, whereas patients with biologically low-risk tumors may experience a cure and benefit from the lower toxicity of nonintensive therapy. Elucidation of the complex molecular pathways involved in tumorigenesis will also encourage the production of targeted anticancer agents with high specificity, efficacy, and therapeutic index.

CHAPTER 29

# Biopsy Techniques for Children with Cancer

James D. Geiger and Douglas C. Barnhart

The importance of biopsy techniques in the management of children with cancer has increased as the use of preoperative chemotherapy has become commonplace for many childhood cancers. Historically, definitive diagnosis was made at the time of surgical resection of the primary tumor. Currently, many children will undergo percutaneous, minimal access surgical, or open incisional biopsy rather than initial resection. Moreover, with increasing understanding of the molecular changes associated with these malignancies, definitive diagnosis can be accomplished with smaller specimens. This should allow a decrease in the morbidity associated with establishing the diagnosis of solid malignancies in children.

Ironically, this progression to less invasive biopsy has complicated rather than simplified the selection of technique in individual cases, as multiple factors must be considered. Percutaneous needle biopsy,[1,2] minimal access surgical biopsy,[3] and open biopsy have all been demonstrated to be effective in safely establishing initial diagnosis as well as verification of recurrent or metastatic disease. However, the success of these techniques is obviously dependent upon local institutional experience, which must be considered in the selection. In addition, it is critical to realize that many of the advances in risk stratification and improved therapy of pediatric malignancies has been facilitated by the development of large accessible tumor banks and the associated biology studies. Without large biopsy specimens, these tumor banks and the development of research cell lines would not have been possible. For a number of tumors, including neuroblastoma and Wilms' tumor, collection of such specimens remains important to further our understanding of the disease.

Biopsies may be required in a variety of settings including primary diagnosis, determination of metastatic disease, and assessment for viable tumor in residual masses after therapy. Therefore a biopsy must be considered as a component of the overall plan of care and not simply as a surgical procedure. It is, therefore, essential that the surgeon have a thorough understanding of the therapeutic plan prior to performing a biopsy. This is well-illustrated in the current management of a child with a Wilms' tumor and a solitary pulmonary nodule. Standard therapy for a pulmonary metastasis is lung irradiation. It could, therefore, be important to histologically confirm this metastasis by excisional biopsy prior to proceeding. This approach is complicated, however, by a current Children's Oncology Group research question of whether children in whom the pulmonary lesions respond completely after 6 weeks of chemotherapy can be spared lung irradiation and more intensive chemotherapy. In this research protocol setting, resection of this solitary lesion would be contraindicated, because it would commit the child to lung irradiation and more intensive medical treatment.

Current pediatric oncology protocols use risk-stratified treatment regimens.[4] Information needed from biopsy specimens is disease specific. The surgeon must be knowledgeable about the stratification schema that will be used for multimodality therapy to select the biopsy method that will be least morbid and yet yield all essential information. This concept is demonstrated by considering two patients with abdominal masses suggestive of neuroblastoma with apparent bone marrow involvement as they would be treated under the current Children's Oncology Group schema. The first patient is less than 1 year of age. This patient's treatment group could be low, intermediate, or high risk. Risk group assignment will require MYC-N amplification status, Shimada histology status, and DNA ploidy to determine stratification. This will require sampling of the primary lesion with an adequate sample of the tumor to allow Shimada staging. In contrast, an older child with similar presentation would be classified as high risk, regardless of any of the previous factors. Therefore one could confirm the diagnosis and assign a risk group with bone marrow biopsy alone.[5] Clearly, knowledge of the multimodality therapy decision making is essential in selection of biopsy technique.

## Handling of Specimens

Historically most diagnoses were made based on hematoxylin and eosin histology performed on permanent sections. This was supplemented by immunohistochemistry, which could similarly be performed on formalin fixed specimens. There has been extensive progress made in the molecular diagnosis of childhood malignancies, including recognition of genetic

aberrations, which has both diagnostic and prognostic significance.[6–9] Techniques used to detect these changes include reverse transcriptase–polymerase chain reaction (rt-PCR),[10] fluorescence in situ hybridization (FISH), microarray analysis, and flow cytometry. Inappropriate specimen handling can preclude these analyses. For example, phenotypic classification of lymphoma cannot be performed using flow cytometry on formalin-fixed lymph nodes. Given the rapidly evolving field of molecular diagnosis, it is essential that the surgeon consult with the pathologist regarding specimen handling prior to performing the biopsy. Additionally, if the patient is eligible for a research protocol, care must be taken to assure the specimen is handled in accordance with the protocol requirements. This requires a coordinated effort by the surgeon, medical oncologist, and pathologist.

## Percutaneous Needle Biopsy

Fine-needle aspiration was first introduced as a technique to obtain specimens for cytopathology by Grieg and Gray in 1904. Jereb and colleagues reported success with the use of needle biopsy for the diagnosis of pediatric solid tumors in 1978.[11] Subsequently, extensive experience from multiple institutions has confirmed the accuracy and safety of both needle aspiration and core needle biopsy techniques. The appeal of these techniques is that they both may provide diagnosis without requiring a significant delay in therapy and can be performed as outpatient procedures. Needle biopsies are often performed under either general anesthesia or sedation. In selected older children, some sites may be biopsied under local anesthesia alone.[12]

Percutaneous needle biopsies may be performed by palpation in the extremities and other superficial locations such as lymph nodes. However, deeper biopsies require guidance with either ultrasonography or CT scan. Ultrasonography that can be supplemented with Doppler mode allows clear identification of large vessels and other structures and provides real-time visualization as the needle is advanced.[13] Some core needle devices also deposit a small air bubble that allows verification of the site that was biopsied. CT scan, on the other hand, allows clear visualization of aerated lung and is not obscured by bowel gas.[14] It also allows measurement and planning of depth of biopsy.[1] Decision making regarding image guidance is made in conjunction with the radiologist, and ideally, biopsies should be performed with both modalities available if required.

## Fine-Needle Aspiration Biopsy

Fine-needle aspiration biopsy (FNAB) holds the obvious appeal of being the least invasive of all biopsy techniques. It is typically performed using a 22- to 25-gauge needle with multiple passes into the lesion if necessary. Successful diagnosis using FNAB requires coordination with an experienced cytopathologist. To improve the diagnostic yield, the specimens should be examined immediately by the cytopathologist. Additional aspirations may be taken if initial samples are inadequate.[15] Large series with fine-needle aspirates in both children and adults have confirmed the safety of the technique.[16,17]

Historically, diagnosis using fine-needle aspiration was based primary on cytologic appearance with conventional stains and light microscopy. Successful diagnosis using FNAB is dependent upon the availability of an experienced cytopathologist. In adult patients with the higher prevalence of carcinomas, FNA is a popular method for confirming the presence of malignancy in suspicious lesions. Often, in these adult cases, a diagnosis of carcinoma and primary site are sufficient to make initial treatment decisions. However, given the fact that multimodality therapy is histiotype-specific in pediatric patients, FNAB has been used less frequently in children. Recent application of molecular techniques and electron microscopy to supplement light microscopy has increased the histiotype specificity of FNAB and may lead to increased application in pediatric solid malignancies.[18,19] FNAB has been used in several pediatric settings with sufficient data reported for consideration.

The use of FNAB in the evaluation of thyroid nodules in adults is well-established. Although thyroid nodules are less common in children, the techniques and interpretation of FNAB are similar to those used in adults.[20] Given the good degree of specificity, FNAB may be considered a standard component of evaluation of thyroid nodules in children.[21]

Another relatively straight forward application and interpretation of fine-needle aspirate biopsy is in the verification of metastatic or recurrent disease in the setting of a previously characterized primary tumor.[22] In this context, the verification of the presence of malignant cells may be sufficient to guide further clinical decisions. This least invasive biopsy method is particularly appealing in these patients who may already be immunologically or physiologically compromised.

There is a limited body of literature on the use of FNAB in the diagnosis of sarcomas. Osteosarcoma has been diagnosed by the use of fine-needle aspirates, with definitive diagnosis being obtained in 65% to 92% of patients. The technique is as accurate in children as it is in adults.[23] The use of FNAB in soft tissue tumors has been facilitated by the recognition of cytogenetic abnormalities and fusion proteins that are specific to these tumor types.[17,19,24] However, caution should be exercised in the use of FNAB in this setting, because the reported series come from a limited number of institutions with extensive experience in cytologic interpretation. The use of FNAB in diagnosing sarcoma has not gained widespread use.

Fine-needle aspiration has not been widely used for the diagnosis of small, round, blue cell tumors of childhood. However, with the increasing availability of ancillary studies, such as electron microscopy, immunocytochemistry, DNA ploidy, cytogenetics, and fluorescent in situ hybridization, its use may become more common.[25] Use of FNAB for the evaluation of head and neck masses in children has been reported to have good sensitivity and specificity.[26,27] The results of these series, however, should be interpreted with caution, because the majority of aspirates diagnosed as reactive lymphadenopathy and the number of new malignant diagnoses was small. In addition, false-negative FNAB diagnosis occurred frequently in patients ultimately diagnosed with lymphoma in other series (not specifically isolated to the head and neck).[15]

## Core Needle Biopsy

The advantage of core needle biopsy versus fine-needle aspiration is that it provides a sample sufficient in size to allow histologic examination rather than only cytologic examination. In addition, it can provide sufficient tissue for molecular

evaluation. Despite the widespread use of this technique in adults, its application in children has not been as common.

Various core needle devices may be used. These typically range in size from 14 to 18 gauge. These needles are designed so that a cutting sheath advances over the core of the needle to obtain a biopsy that is protected within the sheath as the needle is withdrawn. This cutting sheath may be advanced either manually (e.g., Tru-Cut, Baxter Travenol, Deerfield, Ill.) or by a spring-loaded firing system (e.g., Biopty, Bard Urological, Murray Hill, NJ) (Fig. 29-1). There are no data directly comparing the quality of specimens obtained with these two systems in pediatric malignancies. The faster deployment of the spring-loaded systems may result in less crush artifact, which has been demonstrated in pediatric kidney biopsies. Regardless of the system used, visual inspection of the core biopsy is necessary to verify adequate sampling. The number of passes required with a core needle is dependent upon the purpose of the biopsy and the consistency of the tissue being biopsied. For primary tumor diagnosis, multiple cores are typically required to obtain sufficient tissue for biological studies. Alternatively, in pulmonary lesions evaluated for metastatic disease, a single pass was usually sufficient in most series.

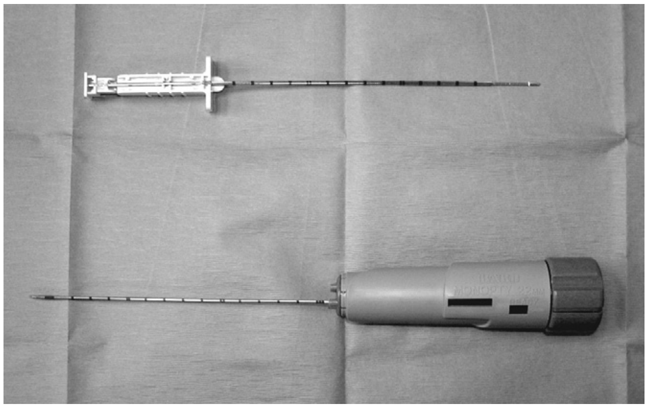

FIGURE 29-1 Two commonly used core needle biopsy devices. The upper device is a 14-gauge Tru-Cut needle (Allegiance, Cardinal Health). It is advanced into the region of interest, and then the inner needle is advanced. The outer sheath is manually advanced over the inner needle to obtain a core. The lower device is a 16-gauge Monopty biopsy device (Bard). It is spring-loaded and is activated after the tip is advanced into the region of interest. The spring-loaded mechanism automatically sequentially advances the obturator and the cannula.

Several large series have demonstrated the utility of core needle biopsies in children. The larger, more recent series are summarized on Table 29-1. The three most common scenarios for which percutaneous biopsies in children with malignancies are used are diagnosis of primary tumors, evaluation for possible recurrent disease, and evaluation of pulmonary lesions.

Success with core needle biopsy has been demonstrated in a wide variety of anatomic locations. These include neck, mediastinum, lung, peritoneal cavity, liver, retroperitoneum, kidney, adrenal, pelvis, and extremities.[1,2,12,13,28] Core needle biopsies have been demonstrated to be effective in obtaining adequate tissue for both primary diagnoses and confirmation of recurrence in these series. In the largest series of pediatric oncologic core needle biopsies, multiple passes were typically performed (median = 6 and maximum = 17). With this repetitive sampling, adequate diagnostic tissue was obtained for histologic and biological studies, obviating the need for operative biopsy in a wide variety of pediatric cancers. No patients in these series suffered procedure-related deaths or required operative therapy for procedural complications.[28]

The other common use of percutaneous core biopsies in pediatric oncology patients is in the evaluation of pulmonary nodules. Pulmonary nodules can be biopsied under either CT scan[29] or ultrasound guidance, often determined by the size and location of the lesions.[30] These procedures may be performed under either sedation or general anesthesia with

**TABLE 29-1**
**Series of Percutaneous Biopsies in Children**

| *Author (Year)* | *Number of Children* | *Number of Biopsies (Total/ Malignancy)* | *Method* | *Diagnostic Yield* | *Comments* |
|---|---|---|---|---|---|
| Skoldenberg (2002)[13] | 110 | 147/84 | US-guided core biopsies of wide range of tumors for initial diagnosis and evaluation for recurrence | 89% | |
| Hayes-Jordan (2003)[52] | 32 | 35/23 | US- or CT-guided core needle biopsies of pulmonary lesions under general anesthesia | 80% | Patients with nondiagnostic biopsy underwent repeat core needle or thoracoscopic biopsy; 10% small pneumothorax or hemothorax—none required drainage |
| Cahill (2004)[29] | 64 | 75/24 | CT-guided core or FNAB of pulmonary lesions with sedation or general anesthesia | 85% | One false negative for Ewing sarcoma; one tension pneumothorax required drainage |
| Fontalvo (2005)[30] | 33 | 38/32 | US-guided core needle of peripheral pulmonary lesions with general anesthesia and controlled ventilation | 84% | Included small lesions (24% $<$ 5 mm); 10% pneumothorax—none required drainage *(series partially overlaps with Hayes-Jordan, 2003)* |
| Garrett (2005)[28] | | 202/202 | US-/CT- or fluoroscopic-guided core needle biopsies of wide range of tumors for initial diagnosis and evaluation for recurrence | 93% overall 98% initial diagnosis 88% suspected recurrence | Multiple passes typically taken (median = 6); accomplished diagnosis, including biological studies without operative biopsies |

CT, computed tomography; FNAB, fine-needle aspiration biopsy; US, ultrasonography.

controlled ventilation. Typically, general anesthesia would be used in younger children or in children with smaller or deeper pulmonary lesions. Current series report success in more than 80% of lesions, including lesions less than 1 cm in size. Surprisingly, pneumothoraces are relatively uncommon, occurring in only 10% of children. The majority of these are managed without placement of a thoracostomy tube.

Needle tract recurrence represents an oncologic complication specific to this biopsy technique. Estimates of this complication in adults vary widely, ranging from 3.4% in hepatocellular carcinoma[31] to 1:8500 in thoracic tumors.[32] Obviously, the incidence of this complication is influenced by several factors. Immunologic, chemotherapeutic, and radiotherapeutic effects will decrease the likelihood of needle tract recurrence. The larger needles used for core needle biopsies are associated with a greater risk than the fine needles used for aspiration.[33] The cases series cited previously report no needle track recurrences in children.

# Minimal Access Surgery

Laparoscopy and thoracoscopy have become commonplace in general pediatric surgery, and both techniques are now used in cancer diagnosis and therapy. Gans and Berci first reported experience with multiple endoscopic techniques in children in 1971.[34] Interestingly, one of the chief applications for laparoscopy, which they advocated, was for guidance of biopsy of metastatic implants. Subsequently, the application of both laparoscopy and thoracoscopy has grown in the initial diagnostic technique for childhood malignancies and for the assessment of refractory or metastatic disease.

## LAPAROSCOPY

Laparoscopy affords several advantages for the evaluation of the abdominal cavity in children with childhood cancer. First, it provides the opportunity to completely examine the peritoneal cavity. A systematic examination of all peritoneal surfaces can be performed. The entire length of the bowel may be examined along with mesenteric lymph nodes. Multiple biopsies can easily be obtained. The second chief advantage of laparoscopy is decreased physiologic stress in children who may already be critically ill. Finally, as in all minimally invasive procedures, postoperative pain is reduced and recovery is hastened.[35] The main disadvantages of laparoscopy are the limited ability to assess retroperitoneal structures and the loss of tactile evaluation of deep lesions.

Diagnostic laparoscopy with biopsy has been used in several settings in the management of children with solid malignancies.[3,35] Biopsies obtained using laparoscopic techniques have a high rate of success in yielding diagnostic tissue.[3,36] Laparoscopy allows the surgeon to obtain larger tissue samples than may be obtained with core needle biopsy. This is particularly relevant if larger samples are required for biological studies. In the initial diagnosis, laparoscopy aids in the identification of site of origin of large abdominal masses. Laparoscopy has been shown to be superior to computerized tomography in assessing intraperitoneal neoplasms and for the evaluation of ascites. For example, laparoscopy allows direct assessment of whether a pelvic mass arises from the ovary or bladder neck, which may be difficult to distinguish by radiographic studies. Direct visualization with laparoscopy has been used to assess the resectability of hepatoblastoma. During the course of treatment, laparoscopy may be used to assess new metastatic disease or to assess initial tumor response as a second-look procedure.[3]

One area of concern with the use of laparoscopy in oncology has been the issue of port-site recurrence. There are relatively limited data on this issue in children. The Children's Cancer Group retrospective study of 85 children noted no port-site recurrences.[3] A survey of Japanese pediatric laparoscopic surgeons reported 85 laparoscopic and 44 thoracoscopic procedures with no port-site recurrences.[37] It should be noted, however, that 104 of these tumors were neuroblastomas, with many being detected by mass screening. The general applicability of this data may, therefore, be limited. A port-site metastasis has been reported in a child with Burkitt lymphoma.[38] Given the difference in tumor biology between adult adenocarcinomas and pediatric neoplasms, which often have a marked response to neoadjuvant therapy, it is difficult to draw conclusions from the adult literature. Certainly additional surveillance for this issue in pediatric tumors is merited.

Laparoscopy in children is typically performed under general anesthesia to facilitate tolerance of pneumoperitoneum. The only absolute contraindication to laparoscopic evaluation is cardiopulmonary instability, which would preclude safe insufflation of the peritoneal cavity. The supine position is used most commonly and affords a complete view of the peritoneal cavity. To facilitate visualization, a 30-degree laparoscope is used along with at least two additional ports for manipulation and retraction. Ascites should be collected for cytologic analysis and all peritoneal surfaces inspected. Incisional biopsies can be performed using laparoscopic scissors. Hemostasis is achieved with a combination of electrocautery and hemostatic agents (as discussed later in the section on open incisional biopsy) or by tissue approximation via laparoscopic suturing. Biopsy specimens are typically retrieved using a specimen bag. This reduces the chance of specimen destruction during retrieval and may decrease the risk of port-site recurrence. Cup biopsy forceps can be used to obtain specimens as well. Core needle biopsies can be directed by laparoscopy and be used to sample retroperitoneal, intraperitoneal, or hepatic masses. For deep-seated lesions, such as intrahepatic lesions, laparoscopic ultrasonography can be used to guide biopsy procedures and to compensate for the inability to palpate tissues.[39,40]

Complications associated with laparoscopic diagnosis and treatment of solid tumors in children are infrequent. The need for conversion to unplanned open operation has similarly been low.[3,35,41,42]

# Thoracoscopy

The initial experience with thoracoscopy in children was reported by Rodgers in 1976 and included two oncology patients (Ewing sarcoma and recurrent Hodgkin lymphoma).[43] Since this initial report, thoracoscopy has become widely used for the evaluation of thoracic lesions in children for several reasons. Postoperative pain associated with thoracoscopic biopsy or resection is markedly decreased compared with that seen with thoracotomy. Moreover, thoracoscopy allows near-complete visualization of all parietal and visceral pleural

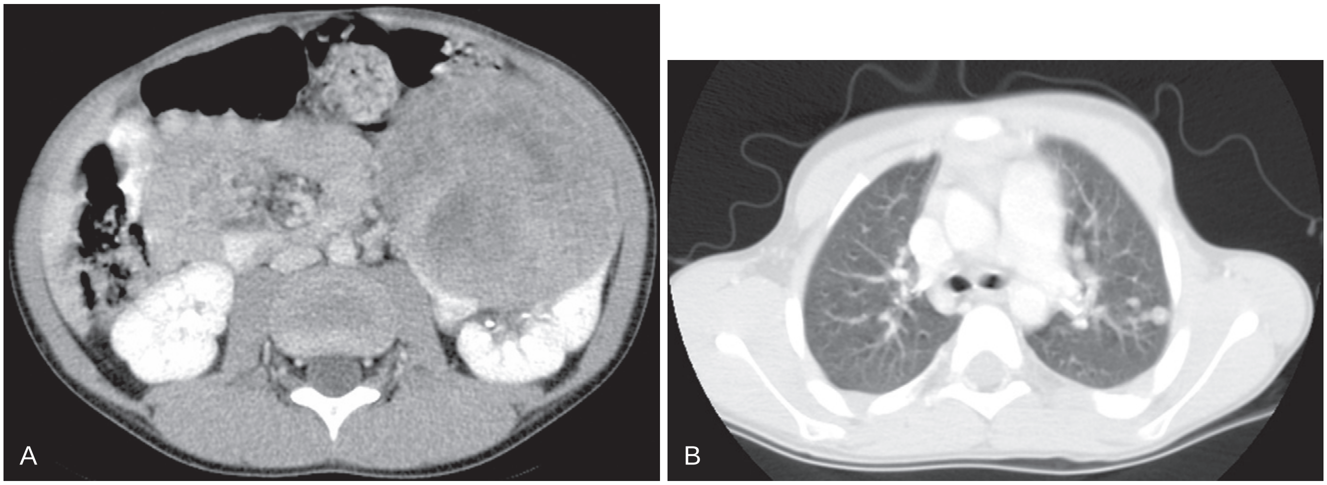

**FIGURE 29-2** Computed tomography (CT) scans obtained at the time of diagnosis of a new abdominal mass in a 5-year-old boy. **A,** Abdominal and pelvic CT scan shows a large left-sided renal mass. **B,** Chest CT scan demonstrates a single 8-mm pulmonary nodule in the left upper lobe. No other pulmonary lesions were identified. At the time of nephrectomy, a thoracoscopic excisional biopsy of the lung lesion was performed. Final pathology of the kidney demonstrated a stage II-favorable-histology Wilms' tumor, and the lung pathology showed a hyalinized granuloma.

surfaces, which cannot be accomplished with a thoracotomy. Additionally, in most children the mediastinum does not contain a significant amount of adipose tissue and, therefore, can be inspected thoracoscopically.

Although primary neoplasms of the lung are rare in children, pulmonary lesions are often a confounding issue in the treatment of children with cancer.[44] The most common tumor to have early pulmonary metastases is Wilms' tumor. Pulmonary metastases are also common with bone and soft tissue sarcomas, hepatic tumors, teratocarcinomas, and melanomas. Thoracoscopy is frequently used to evaluate for the presence of metastases either at the time of initial diagnosis or after follow-up imaging. Difficulty in distinguishing an opportunistic infection versus new metastatic disease is a common clinical scenario during the course of therapy. In areas with endemic granulomatous disease, thoracoscopy can also be helpful at the time of diagnosis (Fig. 29-2; case with histoplasmosis granuloma with new diagnosis of a Wilms' tumor). The diagnostic accuracy for thoracoscopic biopsies in this setting is very high.[41,44,45]

Mediastinal lesions may also be biopsied or resected using thoracoscopy.[46,47] Thoracoscopy provides clear visualization of both the anterior and posterior mediastinum, even in small children; therefore we prefer it rather than mediastinoscopy for evaluation of mediastinal lesions in children.

The only absolute contraindications to thoracoscopy are complete obliteration of the pleural space and the inability to tolerate single-lung ventilation when complete collapse of the lung is required.

Thoracoscopy in children is typically performed under general anesthesia with mechanical ventilation. Visualization is facilitated by single-lung ventilation if possible and supplemented with insufflation. In older children, this may be accomplished with a double-lumen endotracheal tube and, in smaller children, by mainstem intubation of the contralateral side. If selective ventilation is difficult to achieve or poorly tolerated by the patient, low-pressure insufflation (5 to 8 cm of water pressure) with carbon dioxide assists with visualization. The anesthesiologist must monitor for any adverse effects from this controlled tension pneumothorax. It can be evacuated rapidly if need be, but it is typically well tolerated. The child is positioned in the lateral thoracotomy position. Hyperextension of the chest increases the intercostal spaces and will facilitate movement of the thoracoscopy ports. This positioning should be adjusted for mediastinal lesions. For anterior lesions, a more supine position is used, and for posterior lesions the patient is positioned more prone. The initial port is placed in the midaxillary line using blunt dissection. Additional ports are placed under thoracoscopic guidance at sites based upon the location of the lesion of interest. A 30-degree thoracoscope is helpful to achieve complete visualization of all pleural surfaces. Complete inspection is also facilitated by the use of multiple port sites.

Careful correlation with cross-sectional imaging is essential to successful thoracoscopic sampling, particularly of smaller lesions. Pleural-based or subpleural pulmonary lesions are often apparent when the lung is deflated. These can be resected using endoscopic stapling devices and retrieved using specimen bags. Identification of deeper lesions is more challenging. Complete collapse of the lung allows identification of larger lesions. Biopsy of smaller lesions can be based on anatomic location if the location by CT scan is specific, such as apical, lingular, or basilar. CT-guided localization may be performed immediately before surgery to assure correct identification of the area of concern. The lesion may be marked by injection with methylene blue or, preferably, stained autologous blood, which is less prone to diffuse.[48,49] Lesions can be concomitantly marked with placement of a fine wire[50] or microcoils,[51] which can facilitate identification under intraoperative fluoroscopy. These localization techniques have been very effective in obtaining accurate biopsies in children.[48,49,52] Intrathoracic ultrasonography may be helpful in localizing deeper parenchymal lesions.[53] However, this technique is not widely used, and assessment of its efficacy in children is limited.

After sampling of tissues of interest is completed, the pneumothorax may be evacuated with a small catheter to

form a water seal. Unless extensive pulmonary biopsies are performed or the lung is otherwise diseased, a thoracostomy tube is often not required. Most children may be discharged the next day, and chemotherapy may be started promptly.[49]

Thoracoscopic techniques are highly effective in achieving diagnosis. Most pediatric series report a rate of success in obtaining accurate diagnostic tissue in almost all cases.[3,41,44,52] Complications during diagnostic thoracoscopy are rare. Pneumothorax or persistent air leakage may occur in children with underlying parenchymal lung disease or those requiring high-pressure ventilatory support.[52]

## Open Incisional Biopsy

Incisional biopsy remains the gold standard regarding the quality of tissue sampling if complete excision is not to be performed. Laparotomy or thoracotomy allows large samples to be obtained under direct vision, which can provide improved diagnosis compared with needle biopsies. For example, in the National Wilms' Tumor Study Group-4, open biopsy was more successful than core needle biopsies at identifying anaplasia in children with bilateral Wilms' tumor. Correlation with preoperative imaging allows multiple samples to be obtained if there is inhomogeneity within the tumor, which would raise concerns about sampling error.

The ability to obtain larger specimens is beneficial not only in providing tissue for molecular diagnosis and prognosis, but in providing samples for tissue banking and creation of cell lines. Samples obtained from these biopsies have provided the clinical material that allowed the development of the molecular diagnosis and prognosis techniques referred to earlier in this chapter. Further stratification of risk to allow more precise risk-based therapy remains a major focus for pediatric oncology trials. Finally, specimens that are tissue-banked from these larger specimens may be used for investigational therapies, such as tumor vaccines.

Several important factors should be considered in performing an open biopsy. The initial biopsy should consider the ultimate operative treatment of the tumor. For example, the incision for biopsy of an extremity mass should be oriented parallel to the axis of the limb, and care should be taken to avoid undermining subcutaneous or fascial planes. This allows subsequent wide local excision to be performed with minimal additional resection of tissue because of the biopsy. Likewise, testicular masses should only be biopsied through an inguinal approach, because a scrotal biopsy incision could require the addition of a hemiscrotectomy to the subsequent orchiectomy. Laparotomy for biopsy should be planned to allow subsequent resection through extension of the same incision.

Significant distortion of anatomic relations can occur with large retroperitoneal tumors and attention must be paid to avoid injury to structures, such as ureters or the bile duct, which may be distended over the mass. The most common intra-abdominal tumors in children tend to be vascular, and bleeding from the biopsy site is the most common serious complication. Strategies to reduce perioperative hemorrhage include normalization of coagulation parameters preoperatively and adequate operative exposure. Cauterization of the tumor capsule may help control bleeding, but we have found direct pressure after packing the biopsy site with oxidized cellulose combined with procoagulants, as described later, to be more efficient than generous cautery applied to the base of the biopsy site. If possible, closure of the tumor capsule can help with hemostasis.

Supplements to achieving hemostasis include topical agents and fibrin sealants. Commercially available topical products include gelatin foam pads, microfibrillar collagen, and oxidized cellulose, which is available as fabric and cottonoid. Fibrin sealants are composed of fibrinogen, thrombin, and calcium, which are mixed as they are delivered to the tissue to rapidly form a fibrin clot.

## Conclusion

Prior to performing a biopsy of a potential malignancy, the surgeon should consider the likely possible diagnoses. The biopsy should then be planned so that adequate tissue is obtained and preserved to determine not only diagnosis but also risk stratification. Percutaneous, minimal access surgical, and open surgical techniques each have an appropriate place in the evaluation of potential pediatric malignancies. The use of these techniques in a systematic, stepwise fashion is appropriate in some patients. The selection of the appropriate biopsy technique should be driven by both the specific question to be answered by the biopsy and individual institutional experience and resources. Planning an operative biopsy must account for the anticipated operative approach for definitive resection.

CHAPTER 30

# Wilms' Tumor

Peter F. Ehrlich and Robert C. Shamberger

Renal tumors account for 6.3% of cancer diagnoses for children younger than 15 years of age, with a reported incidence of 7.9 per million. Including adolescents younger than 20 years of age, this drops slightly to 4.4% of cancer diagnoses, with an incidence of 6.2 per million.[1] Renal tumors include Wilms' tumor (WT) (also referred to as nephroblastoma or renal embryoma), renal cell carcinoma (RCC), clear cell sarcoma of the kidney (CCSK), rhabdoid tumor of the kidney (RTK), congenital mesoblastic nephroma, cystic renal tumor, and angiomyolipoma.[2,3] WT is by far the most common, accounting for approximately 91% of all renal tumors in childhood. CCSK and RTK were originally considered subtypes of WT, but are now recognized as separate tumors. RCC comprises 5.9% of renal malignancies in children and adolescents.[1,4]

The treatment strategy for children with renal tumors evolved in conjunction with the definition of these pathologic subtypes. Treatment is based on traditional risk factors, stage and histology, and, more recently, on genetic markers. The goal of "risk-based management" is to maintain excellent outcomes but at the same time spare children with low-risk tumors intensive chemotherapy and radiation, with their long-term side-effects, and to intensify therapy for children with high-risk tumors in an effort to increase their survival. Despite these advances, children with rhabdoid, renal cell carcinoma, and anaplastic tumors still do poorly. This chapter reviews the most frequent renal tumors in children, including their biologic properties, multidisciplinary therapies, and future challenges.

## Wilms' Tumor

WT is the most common primary malignant renal tumor of childhood and comprises 6% of all pediatric tumors.[5,6] Outcomes for children with WT improved dramatically over the last 50 years, with long-term survival in both North American and European trials approaching 85% (Fig. 30-1). Survival rates for many of the low-stage tumors are 95% to 99%.[7,8] Current treatment protocols for children with WT were developed through a series of multidisciplinary cooperative group trials in both North America and Europe by the Children's Oncology Group (COG), formerly the National Wilms' Tumor Study Group (NWTSG), and the Société Internationale d'Oncologie Pédiatrique (SIOP). Their series of well-designed prospective randomized studies provide a large body of evidence-based knowledge to establish the optimal surgical, radiotherapy, and chemotherapy treatments for tumors based on the early studies on stage and histology and, more recently, also on cytogenetic and response-based factors. There are differences between the approaches of these two groups that affect staging and risk classification that are critical to understand when considering outcomes that will be discussed later in the chapter (Table 30-1).

## History

WT is named after Carl Max Wilhelm Wilms, a German pathologist and surgeon. He was one of the first to propose that tumor cells originate during the development of the embryo. He published his findings in 1897 and 1899 in an influential monograph titled "Die Mischgeschwülste der Niere," which described seven children with nephroblastoma as part of a monograph on "mixed tumors."[9,10] Although reports of successful excision of renal tumors in children appeared in the end of the 19th century, his name has been indelibly applied to them. Dr. Thomas Jessop (1837 to 1903), probably performed the first successful nephrectomy at the General Infirmary in Leeds, England, on June 7, 1877, on a 2-year-old child with hematuria and a tumor of the kidney.[11,12]

At the beginning of the 20th century, survival for a child with WT was 5%. Surgery was the first effective treatment for nephroblastoma and continues to be a critical component of successful multimodality therapy. Although surgery at that time was the only option for cure, it carried a significant operative mortality. In 1916, radiation therapy was added by Friedlander.[13] In the late 1930s, Ladd described removing renal tumors in selected children. His technique included a large transverse transabdominal approach with early ligation of the renal vessels and removal of the surrounding Gerota fat and fascia. This modification improved the outcome in children with nonmetastatic nephroblastoma to a 32.2% survival at 3 years, with an operative mortality reduced from 23% to 7%. The basic tenets of this operative procedure described by Ladd are used today, with the exception of early ligation of the renal vessels.[12–15]

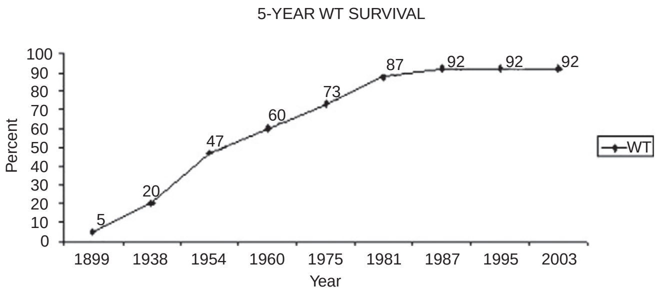

**FIGURE 30-1** This graph shows the improved survival of children with Wilms' tumor (WT) over time.

# Epidemiology

In the United States, there are 500 to 550 cases of WT per year. It is the second most common malignant abdominal tumor in childhood after neuroblastoma. The risk of developing WT in the general population is 1:10,000.[16] The incidence is slightly elevated for American and African blacks compared with whites and is significantly lower in Asians. The mean age at diagnosis is 36 months, with most children presenting between the ages of 12 and 48 months. Tumors tend to occur about 6 months later in girls than in boys. WT is rare at greater than 10 years and at less than 6 months of age. Tumors can be unilateral or bilateral (Figs. 30-2 and 30-3). Bilateral Wilms' tumors (BWT) occur in 4% to 13% of patients.[5,17–19] Children with congenital syndromes associated with WT, such as Beckwith-Wiedemann, have a higher risk of developing BWT.

Congenital anomalies, either isolated or as part of a congenital syndrome, occur in about 10% of children with WT.[20] WAGR syndrome (WT, aniridia, genitourinary malformation, mental retardation) is a rare genetic syndrome associated with a chromosomal defect in 11p13. Children with WAGR syndrome are at a 30% higher risk of developing WT than a normal child. Because of the presence of aniridia, most children with WAGR syndrome are diagnosed at birth. Children with WAGR account for about 0.75% of all children with WT.[21]

Beckwith-Wiedemann syndrome (BWS) is a congenital disorder of growth regulation, affecting 1 in 14,000 children. Children with BWS have visceromegaly, macroglossia, omphalocele, and hyperinsulinemic hypoglycemia at birth. They also have an increased risk of tumor development. The risk is greatest in the first decade of life and thereafter approaches that of the general population. Three large studies of children with BWS reported tumor frequencies of 7.1% (13/183), 7.5% (29/388), and 14% (22/159).[22–25] The most frequently observed tumors in BWS are WT and hepatoblastoma, which comprise 43% and 12% of reported cancers, respectively.[22,26] Denys-Drash syndrome (DDS) (nephropathy, renal failure, male pseudohermaphroditism, and WT) is also associated with an increased risk of WT. Some investigators have recommended prophylactic nephrectomy in children with this syndrome once they develop renal failure.[27,28] Other

**TABLE 30-1**
**Children's Oncology Group (COG) and Société Internationale d'Oncologie Pédiatrique (SIOP) Staging Systems**

**COG Wilms' Tumor Staging**

| *Stage* | *Criteria* |
|---|---|
| I | The tumor is limited to the kidney and has been completely resected.<br>The tumor was not ruptured or biopsied prior to removal.<br>There is no penetration of the renal capsule or involvement of renal sinus vessels. |
| II | The tumor extends beyond the capsule of the kidney but was completely resected with no evidence of tumor at or beyond the margins of resection.<br>There is penetration of the renal capsule or invasion of the renal sinus vessels. |
| III | Gross or microscopic residual tumor remains postoperatively, including inoperable tumor, positive surgical margins, tumor spillage surfaces, regional lymph node metastases, positive peritoneal cytology, or transected tumor thrombus.<br>The tumor was ruptured or biopsied prior to removal. |
| IV | Hematogenous metastases or lymph node metastases outside the abdomen (e.g., lung, liver, bone, brain). |
| V | Bilateral renal involvement is present at diagnosis, and each side may be considered to have a stage. |

**SIOP Staging**

| *Stage* | *Criteria* |
|---|---|
| I | The tumor is limited to the kidney or surrounded with a fibrous pseudocapsule, if outside the normal contours of the kidney. The renal capsule or pseudocapsule may be infiltrated with the tumor, but it does not reach the outer surface, and it is completely resected. The tumor may be protruding (bulging) into the pelvic system and dipping into the ureter, but it is not infiltrating the walls. The vessels of the renal sinus are not involved. Intrarenal vessels may be involved. |
| II | The tumor extends beyond the kidney or penetrates through the renal capsule and/or fibrous pseudocapsule into the perirenal fat, but it is completely resected. The tumor infiltrates the renal sinus and/or invades blood and lymphatic vessels outside the renal parenchyma, but it is completely resected. The tumor infiltrates adjacent organs or vena cava, but it is completely resected. The tumor has been surgically biopsied (wedge biopsy) prior to preoperative chemotherapy or surgery. |
| III | There is incomplete excision of the tumor, which extends beyond resection margins (gross or microscopic tumor remains postoperatively). Any positive lymph nodes are involved. Tumor ruptures before or during surgery (irrespective of other criteria for staging). The tumor has penetrated the peritoneal surface. Tumor implants are found on the peritoneal surface. The tumor thrombi present at resection, margins of vessels or ureter are transected or removed piecemeal by surgeon. |
| IV | Hematogenous metastases (lung, liver, bone, brain, etc.) or lymph node metastases are outside the abdominopelvic region. |
| V | Bilateral renal tumors present at diagnosis. Each side has to be substaged according to above classifications. |

**FIGURE 30-2** A computed tomography (CT) scan of a unilateral Wilms' tumor.

syndromes associated with WT include hemihypertrophy and Perlman syndrome. Urologic abnormalities, such as hypospadias, cryptorchidism, and nephromegaly, are also associated with WT.

# Molecular Biology and Genetics

A number of important advances in WT development have occurred since the early 1990s. A detailed description is beyond the scope of this chapter. Table 30-2 summarizes some of the key genes and more detailed references are cited.[29–56] There are several candidate genes that are been investigated and evaluated or are being evaluated in the clinical setting. These are described later.

## LOSS OF HETEROZYGOSITY AND DNA PLOIDY

Loss of heterozygosity (LOH) refers to loss of genetic material and allelic uniqueness. LOH was found initially in children with WT on chromosomes 11p (33% of tumors), 16q (20%), and 1p (11%). A major aim of the fifth National Wilms' Tumor Study (NWTS-5) was to determine if tumor-specific LOH for chromosomes 11p, 1p, or 16q was associated with an adverse prognosis for children with favorable-histology (FH) WT, a finding suggested in earlier retrospective studies.[34] Chromosomes 11p, 16q, and 1p were prospectively evaluated. Results demonstrated that outcomes for patients with LOH at 1p and 16q were at least 10% worse than those without LOH (Figs. 30-4 and 30-5). These findings are used as determinants of therapy on the current renal tumor studies of the COG.

A similar but smaller study was reported from the United Kingdom (United Kingdom Children Cancer Study Group Wilms Tumor trials 1 to 3) in which a comparable incidence of LOH for 16q (14%) and 1p (10%) was found, but in this study there was no association between poor outcomes and LOH at 1p.[42] The reasons for the different results are unclear; possible explanations include a smaller sample size of the British study or that the larger doses of doxorubicin used in the U.K. studies served to eliminate part of the adverse impact on prognosis.

Analyses from patients with WT have also identified recurrent deletions and translocations involving the short arm of chromosome 7.[43,48,55] Studies suggest a locus of interest between 7p13 and 7p21, perhaps the *POU6F2* gene at 7p14.[57–59] Clinical correlates of 7p LOH have not been published, and so the exact prognostic role of this possible Wilms' locus, if any, has yet to be determined.

Another aim of NWTS-5 was to determine whether DNA ploidy status is associated with worse outcome in children

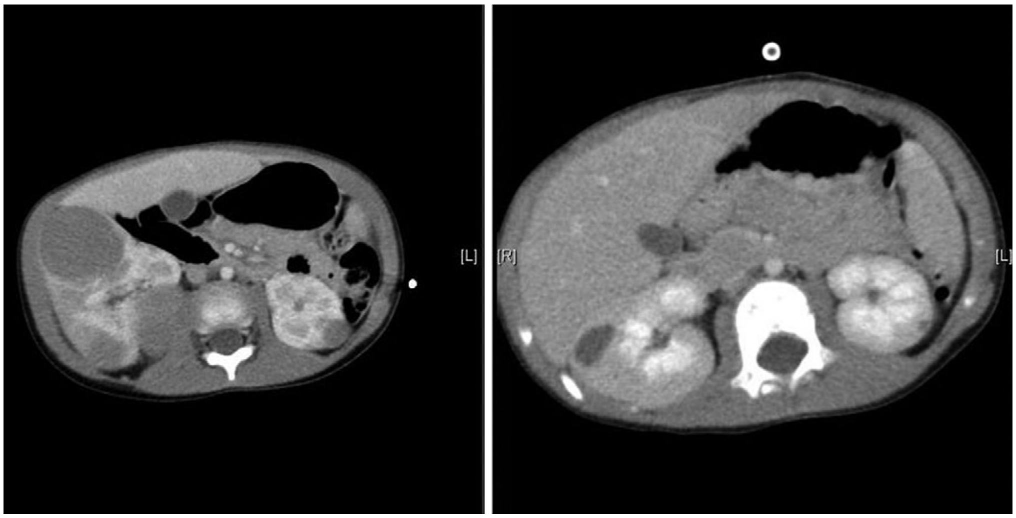

**FIGURE 30-3** Two computed tomography (CT) scans of bilateral Wilms' tumor at presentation and after 6 weeks of chemotherapy.

with favorable-histology DNA index as a prognostic marker: DNA index greater than 1.5 was strongly associated with anaplastic histology and predictive of poor outcome. However, DNA content was not predictive of outcome when stratified by stage and histology.[60]

## *TP53* GENE

The *TP53* gene is located on chromosome 17. The Tp53 protein is a negative regulator of cell proliferation and a positive regulator of apoptosis in response to DNA damaging agents. *TP53* is the most common mutated gene associated with human cancer. Li-Fraumeni syndrome is a multicancer predisposition syndrome that has constitutional *TP53* mutations.[61] However, WT rarely develops in Li-Fraumeni syndrome, and the majority of WT develop in the presence of wild-type *TP53*.[62] *TP53* mutations in WT are almost exclusively found in tumors with anaplastic histology. Seventy-five percent of anaplastic WT have *TP53* mutations. In the current COG study, one of the aims of the high-risk protocol is to study the incidence and association of *TP53* mutations.

# Clinical Presentation

Most children with WT present with an asymptomatic abdominal mass, often discovered by either a parent or pediatrician. Nonpalpable tumors are typically discovered by ultrasonography during evaluation for abdominal pain. Gross hematuria has been reported in 18.2% of patients and microscopic hematuria in 24.4%. Ten percent of children with WT have coagulopathy, and 20% to 25% present with hypertension because of activation of the renin-angiotensin system.[63] Fever, anorexia, and weight loss occur in 10%. Extension of tumor thrombus into the renal vein can obstruct the spermatic vein and result in a left varicocele and, in rare cases, tumor

extension into the atrium may produce cardiac malfunction. Tumor rupture and hemorrhage are also infrequent events that can present as an acute abdomen.

The differential diagnosis for an abdominal mass includes neuroblastoma, hepatoblastoma, rhabdomyosarcoma, and lymphoma. Neuroblastoma is the most common solid abdominal tumor in children. One clinical observation to help distinguish between WT and neuroblastoma is that children with neuroblastoma are often ill because of extensive metastatic disease at presentation. In contrast, children with WT are generally healthy toddlers with a palpable abdominal mass.

## Diagnosis

After an abdominal mass is identified, radiographic imaging is performed to determine the anatomic location and extent of the mass. Ultrasonography (US) is a good screening examination of a mass to determine its site of origin and to assess for possible intravascular or ureteral extension. About 4% of WT present with inferior vena cava (IVC) or atrial involvement and 11% with renal vein involvement.[5,6] Embolization of a caval thrombus to the pulmonary artery can be lethal, and the presence of a thrombus must be identified preoperatively to prevent this occurrence. US is a sensitive technique to identify vascular extension.[64,65] A computed tomography (CT) scan of the abdomen will confirm the renal origin of the mass and determine whether there are bilateral tumors. Early generations of CT scans missed 7% to 10% of bilateral lesions. Hence, contralateral exploration of the kidney was recommended in NWTSG protocols to assess for bilateral lesions.[66] A recent review of children with bilateral WT, however, demonstrated that only 0.25% of bilateral tumors were missed with modern helical CT scans, all of which were small.[67] Based on these results, bilateral exploration is not recommended in current protocols from the COG. Although magnetic resonance imaging (MRI) avoids radiation exposure, it has not been shown to be superior to CT scanning in standard assessments. MRI is currently being evaluated as a method to help distinguish nephrogenic rests from WT and may be the preferred method to follow children with bilateral WT after resection.

The common sites of metastatic spread are the lungs and the liver. Therefore, in addition to abdominal imaging, pulmonary imaging must be performed. In NWTS-4 and NWTS-5, 13% of patients (575 of 4,006) with unilateral favorable-histology tumors presented with pulmonary disease. Initially this was routinely evaluated based upon a chest radiograph. In current protocols, it is based upon CT scans.

$^{18}$F-fluorodeoxyglucose positron emission tomography (FDG PET) has not been fully delineated in pediatric cancers.[65] It is recognized that FDG PET has an established role in Hodgkin lymphoma and increasingly in sarcomas in children, but its role in WT is unclear.[68,69]

## Screening

Screening is reserved for children at risk for developing WT. This includes children with genetic syndromes such as BWS, idiopathic hemihypertrophy (IHH), WAGR, DDS, and Perlman syndrome. Renal ultrasound examination is the preferred modality to screen for WT. It is widely available, noninvasive, does not involve radiation exposure, and generally does not require use of sedation. It is recommended that children be scanned every 3 to 4 months. Debaun and colleagues assessed the cost effectiveness of screening for WT and hepatoblastoma in children with Beckwith-Wiedemann syndrome (BWS).[70] In this analysis, screening a child with BWS from birth until 4 years of age resulted in a cost per life-year saved of $9,642, while continuing until 7 years of age resulted in a cost per life-year saved of $14,740, although it is not truly established that the rate of cure or event-free survival (EFS) is higher based on this early monitoring protocol. Three retrospective studies have evaluated screening in children at risk for WT. One study from the United Kingdom of 41 children with WT and aniridia, BWS, or IHH showed no difference in outcome or stage distribution between screened and unscreened populations.[71] In a second study of BWS/IHH, Choyke and colleagues demonstrated that evaluation by US every 3 months until age 8 years in 12 children with BWS lowered the proportion of patients with late-stage tumors to 0%, which was significantly reduced compared with the 42% incidence of late-stage tumors in 59 unscreened patients with BWS/IHH.[72] A third study analyzed the impact of surveillance in children with aniridia, BWS, and IHH who had developed WT.[73] There was a higher proportion of stage I tumors identified in children who underwent routine screening than in those who did not. Although ultrasonography is easy, false-positive results have been reported and have led to unnecessary investigations and surgery in patients who had benign lesions, such as cysts, nephrogenic rests, or foci of renal dysplasia, supporting the use of either MRI or CT to further define the lesions before surgical intervention.[72–74] The U.K. Wilms' Tumor Surveillance Working Group suggests that surveillance should be offered to children who are at a greater than 5% risk of WT.[75]

Children with Perlman syndrome are at a significantly increased risk of WT; therefore surveillance specifically for WT is warranted. Based on a review by Tan and colleagues, there is currently insufficient evidence to justify tumor surveillance in Sotos, Weaver, Proteus, and Bannayan-Riley Ruvalcaba syndromes or the syndrome of macrocephaly-cutis marmorata telangiectatica congenita. Of interest, children with Klippel-Trenaunay syndrome (KTS) had been considered to be at increased risk for developing WT. In a 2004 study by Fishman and colleagues, the risk of developing WT in children was assessed using the NWTSG database.[76] The risk of WT in children with KTS was no different than in the general population, and thus routine ultrasonography surveillance is not recommended.

## Pathology

Tumor histology is a major determinant of therapeutic stratification for children with WT. The diagnostic classification of pediatric renal tumors has benefited from central review of tumors from patients treated in the cooperative group trials.[77] This success has enabled the introduction of disease-specific and risk-based therapy. For example, clear cell sarcoma of the kidney (CCSK) and malignant rhabdoid tumor (MRT) were initially considered to be variants of WT and were

managed with chemotherapeutic agents for WT, but they are now considered distinct entities with separate therapies.

WT are embryonal tumors containing components seen in normal developing kidneys. The classic WT consists of three elements: blastemal, stromal, and epithelial tubules. Tumors contain various proportions of each of these elements. Triphasic patterns containing blastemal, stromal, and epithelial cell types are the most characteristic, but biphasic and monophasic lesions occur.[78] Less frequently, abnormal mucinous or squamous epithelium, skeletal muscle, cartilage, osteoid, or fat are found in WT.[79]

When the tumors are monophasic, they can be very invasive and difficult to distinguish from other childhood tumors, such as primitive neuroectodermal tumor, neuroblastoma, and lymphoma. Monophasic undifferentiated stromal WT look like sarcomas, such as clear cell sarcoma of the kidney, congenital mesoblastic nephroma, or synovial sarcoma. Other WT may have differing amounts of skeletal-muscle differentiation, from well-differentiated (rhabdomyomatous) to poorly differentiated (rhabdomyoblastic) skeletal muscle. A WT that is entirely tubular and papillary can be difficult to distinguish from papillary renal cell carcinoma.[79]

WT are divided into two groups: those with “favorable” histology and those with “unfavorable” histology. Favorable-histology tumors comprise 90% of the unilateral and bilateral tumors.

Anaplastic histology is considered unfavorable histology along with the CCSK and rhabdoid tumors. Unfavorable histology is found in about 10% of childhood renal tumors. It is rare in the first 2 years of life (2%), then increases in patients older than 5 years to 13%. It is also more frequent in nonwhite (African-American and Latino populations) than in white patients.[80] In a report by Bonadio and colleagues, 30.1% of anaplastic tumors occurred in the nonwhite population. In a multivariate analysis, older age, being nonwhite, and lymph node positivity were the significant predictors of anaplastic WT histology. Finally, anaplasia has been strongly associated with the presence of *TP53* mutations.[81]

Different treatment protocols for children with anaplastic versus favorable-histology tumors were first used in NWTS-3. Anaplasia is defined by multipolar polyploid mitotic figures, marked nuclear enlargement (giant nuclei with diameters at least 3 times those of adjacent cells), and hyperchromasia.[82] Focal anaplasia is defined as the presence of one or a few sharply localized regions of anaplasia within a primary tumor, the majority of which contain no nuclear atypia. The cells must not be present in any sites outside of the kidney. Tumors with diffuse anaplasia must have at least one of the following four criteria. Anaplastic cells outside of the kidney, presence of anaplasia in a random kidney biopsy, anaplasia in more than one region of the kidney, and anaplasia in one region, with extreme nuclear pleomorphism in another site. The difference between focal and diffuse anaplasia has been demonstrated to have prognostic significance.[83] Anaplasia is a marker of resistance to therapy, not of tumor aggressiveness.[78,82,84] Although associations between histologic features and prognosis or responsiveness to therapy have been suggested, with the exception of anaplasia (unfavorable histology), none of these features have reached statistical significance and therefore have not been used to determine therapy.[78,84]

The classic WT is triphasic, but some tumors can have dominant blastemal, stromal, and epithelial elements. Stromal dominant tumors are associated with intralobar nephrogenic rests, and epithelial dominant tumors have been associated with perilobar nephrogenic rests.

## PRETREATED TUMORS AND PATHOLOGY

Tumors that have been treated with chemotherapy before resection differ in their histopathologic findings from tumors resected primarily. In the SIOP-9 study, the most common subtype of tumors resected without neoadjuvant chemotherapy was triphasic mixed histology (45.1%), followed by blastemal (39.4%) and epithelial dominant (15.5%), whereas in tumors that received preoperative chemotherapy, the most common histology was regressive (37.6%), followed by mixed (29.4%), stromal (14%), blastemal (9.3%), and epithelial predominant (3.1%); 6.6% of tumors were completely necrotic.[85,86] The SIOP risk classification uses these histologic findings as prognostic indicators to determine further therapies (Table 30-3). In addition, chemotherapy may produce tumor differentiation.[82,86,87] Anderson evaluated the histologic changes in tumors from 15 BWT patients that did not decrease in size radiographically following chemotherapy.[88] One had complete necrosis, 4 had rhabdomyomatous differentiation, and 10 had mature stromal differentiation. Despite their absence of regression in size, these patients had favorable outcomes, especially if there was rhabdomyomatous differentiation.

In SIOP-9, 10% of patients had postchemotherapy tumors that were completely necrotic. These patients had excellent outcomes. The SIOP-9 study also demonstrated that preoperative chemotherapy extensively ablates the blastemal component of WT.[87,89,90] The frequency of tumors with dominant blastemal components was markedly reduced (to 7.7%) by preoperative treatment compared with the no-treatment group (36%). Furthermore, this response is clearly an important prognostic factor. If predominant blastemal elements persist after initial therapy, the tumors were found to be highly aggressive. In SIOP-9, 5 of 16 (31%) of the postchemotherapy blastemal predominant tumors recurred, compared with none of the tumors that were predominantly epithelial or stromal after chemotherapy. Prior SIOP studies have also shown the prognosis for the purely blastemal group (after preoperative chemotherapy) to be inferior to that for the epithelial and stromal dominant tumors.

**TABLE 30-3**

**Revised International Société Internationale d'Oncologie Pédiatrique Working Classification of Renal Tumors of Childhood (2001)**

| *Stage* | *Risk* | *Histology* |
|---|---|---|
| I | Low | Mesoblastic nephroma<br>Cystic partially differentiated nephroblastoma |
| II | Intermediate | Nephroblastoma epithelial type<br>Nephroblastoma stromal type<br>Nephroblastoma mixed type<br>Nephroblastoma regressive type<br>Nephroblastoma focal anaplasia type |
| III | High | Nephroblastoma blastemal type<br>Nephroblastoma diffuse anaplasia type<br>Clear cell sarcoma of the kidney<br>Rhabdoid tumor of the kidney |

In the SIOP studies, postchemotherapy risk stratification and stage are used to determine additional therapy after resection. This categorization is different than the risk stratification used for tumors resected primarily in North America. *Low-risk* tumors are those that are completely necrotic following preoperative chemotherapy. *Intermediate-risk* tumors include all histologies other than completely necrotic, rhabdoid, anaplastic, or blastemal (less than 66%) dominant. *High-risk* tumors are those with diffuse anaplasia, rhabdoid, and blastemal dominance (greater than 66%) after chemotherapy (see Table 30-3).

### NEPHROGENIC RESTS AND NEPHROBLASTOMATOSIS

Nephrogenesis in the normal kidney is usually complete by 34 to 36 weeks' gestation. Nephrogenic rests (NR) are "areas of metanephric (embryonal tissue) persisting after the 36th week of life." The presence of multiple or diffuse nephrogenic rests is termed nephroblastomatosis.[91] Diffuse hyperplastic perilobar nephrogenic rests (DHPLNR) represent a unique category of nephroblastomatosis in which the rests form a thick rind around the kidney. The rests that cause the greatest diagnostic challenge are those that are actively proliferating or hyperplastic, and can be mistaken for WT. Hyperplastic NR can produce masses as large as conventional WT. Complicating things further is the fact that neoplastic induction of NR can occur. The diagnosis of DHPLNR is often made based on radiographs (Fig. 30-6). Histologically, a rest consists of predominantly small clusters of blastemal cells, but tubules and stromal components can be present. NRs are classified by their growth phase and location: perilobar or intralobar. Perilobar nephrogenic rests are limited to the periphery (subcapsular) of the lobes, while intralobar rests occur within the renal lobes and have an irregular margin. The growth phase of a rest is divided into (1) incipient or dormant nephrogenic rests that show few well-formed tubular structures but no evidence of proliferation and no mitoses, (2) hyperplastic nephrogenic rests that are composed of epithelial elements with nodular expansive growth, and (3) sclerosing rests that consist of stromal and epithelial elements with few blastemal nephrogenic elements (Fig. 30-7).

**FIGURE 30-6** Computed tomography (CT) scans showing diffuse hyperplastic perilobar nephrogenic rests.

NRs are considered precursor lesions to WT; however, only a small number develop clonal transformation into a WT. A child with a WT and NRs in the resected specimen is at increased risk of developing a metachronous tumor in the other kidney.[92] For a child less than 1 year of age, this risk is very significant, and these children need to be followed very carefully with sequential US examinations. A patient who has a unilateral tumor and a presumed nephrogenic rest is thought to be at increased risk of developing a metachronous tumor, but data to support that assumption does not exist. The prevalence of NRs in unilateral WT has been reported to be 28% to 41% in unilateral WT and close to 100% in bilateral WT.[93] Pathologic distinction between NR and WT can be very difficult. To make the diagnosis, it is critical to examine the juncture between the lesion and the surrounding renal parenchyma to distinguish between the two entities. Most hyperplastic NRs lack a pseudocapsule at the periphery, while most WT will have this feature. An incisional biopsy is of limited value, because it is uncommon for it to contain the interface between the lesion and the adjacent kidney. This is particularly true for patients with DHPLNR. In a study by Perlman and colleagues, pathology alone was insufficient to establish the diagnosis of DHPLNR in 21 of 33 cases that underwent biopsy at the time of initial diagnosis.[94] In addition, because rests are found within and adjacent to WT, a biopsy may result in the inadvertent pathologic diagnosis of WT. Alternatively, a small WT may be present within a large field of nephroblastomatosis, obscuring it for biopsy. Taken together, in these situations where a renal mass could be a tumor or a rest where a biopsy is performed, Perlman and colleagues suggest using the term "nephrogenic process, consistent with a WT or a nephrogenic rest."

## Staging

The COG/NWTS and SIOP staging systems are fundamentally different. In COG/NWTS protocols, initial surgical resection is recommended in most cases. Thus for unilateral tumors, the pathology of the tumor is established prior to administration of chemotherapy or radiotherapy. In contrast, SIOP protocols generally recommend chemotherapy followed by nephrectomy, and surgicopathologic staging is assessed at that time.

The COG/NWTS staging system has evolved as features associated with prognosis have been defined. A very important concept for this staging system is that there is a local stage and a disease stage. Local staging refers to the abdominal disease

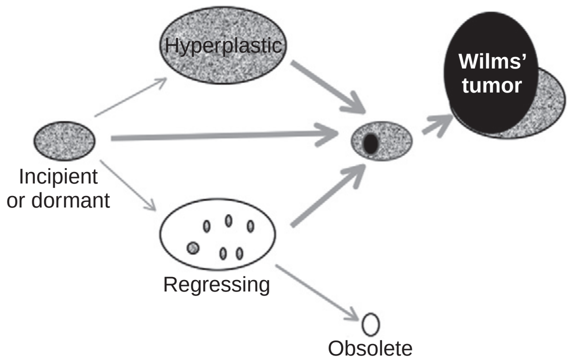

**FIGURE 30-7** Cartoon of growth phases and classification of nephrogenic rests.

only, whereas disease stage considers both the local and distant hematogenous metastatic disease. Both factors determine therapy; the use of local radiation therapy to the tumor bed is based on the local stage, and the use of additional chemotherapy is based on both stage III local disease or distant metastasis.[95] The current COG and SIOP staging systems are shown in Table 30-1.

# Treatment

The successful treatment for children with WT has been the direct result of prior multidisciplinary studies from cooperative group trials, including the NWTSG, SIOP, and the United Kingdom Children's Cancer Study Group (UKCCSG), that have defined the key components to therapy. These trials have identified several prognostic factors used for risk stratification in current protocols, including biologic markers. This section will review these prognostic factors, operative therapy, chemotherapy, and radiotherapy (with a focus on COG studies).

## PROGNOSTIC FACTORS

The current prognostic factors used in COG trials are histology, stage, age, tumor weight, response to therapy, and loss of heterozygosity at 1p and 16q. The two most important continue to be the histology and the stage of the tumor.[7,8,96]

*Histology:* The details and prognostic significance of tumor pathology have been previously discussed in the Pathology section.

*Stage:* The tumor stage is determined by the results of the imaging studies and both the surgical and pathologic findings at nephrectomy (see Table 30-1).

*Rapid response:* This is a prognostic category being evaluated in patients who have stage IV disease that is based on lung metastasis alone. The goal in these patients is to avoid lung radiation. Response to therapy is also being assessed in bilateral disease.

*Loss of heterozygosity:* LOH (described previously) at both 1p and 16q are now used as determinants of therapy on the current COG renal tumor studies.[96]

## OPERATIVE THERAPY

Surgical therapy is a primary component in the multidisciplinary treatment of WT or other neoplastic renal lesions. Irrespective of whether surgery is performed as a primary therapy or in a delayed fashion after chemotherapy, there are a number of fundamental tasks that are required of the surgeon. These are (1) safe resection of the tumor, (2) accurate staging of the tumor, (3) avoidance of complications that will "upstage the tumor" (rupture or unnecessary biopsy), and (4) accurate documentation of operative findings and details of the procedure in the operative note. Intraoperative events that negatively affect patient survival include tumor spill, failure to biopsy lymph nodes, incomplete tumor removal, failure to assess for extrarenal tumor extension and surgical complications.[97–99]

### Technical Concerns: Unilateral Tumors

Ladd and Gross established the basic principles for resection of a presumed malignant tumor of the kidney, including wide abdominal exposure, resection of the surrounding Gerota fat and fascia to remove potential sites of lymphatic spread and early control of the renal vessels.[12,100] Lymph node sampling is now established as crucial for accurate staging.[101] Understaging the extent of the tumor can increase a child's risk of relapse, and overstaging will result in increasing the intensity of chemotherapy or radiation. A transverse transabdominal or thoracoabdominal incision provide the best exposure and are associated with fewer complications than a flank incision.[98,102–104] The thoracoabdominal incision is best for large tumors, to optimize visualization of the plane between the tumor and the diaphragm to avoid rupture from excessive traction on the tumor. Intraoperative events that negatively affect patient survival include tumor spill and inadequate staging.[97–99]

Early examination for involvement of the liver, renal vein, or IVC or peritoneal surfaces is important, as is identification of preoperative rupture of the tumor. Routine exploration of the contralateral kidney for bilateral disease was mandated in NWTS-1 to NWTS-5. In 1995, Ritchey and colleagues reviewed the accuracy of imaging in assessing bilateral disease from NWTS-4 (1986 to 1994). He found that bilateral tumors were missed in 7% of children by using the preoperative imaging studies. Thus, for NWTS-5, routine contralateral exploration was mandated. In 2005, Ritchey and colleagues did a follow-up study to look at what happened in those patients whose lesions were missed by imaging on NWTS-4. The size of the missed lesions was less than 1 cm in six patients and 1 to 2 cm in three patients. Management of missed lesions included enucleation in two cases, biopsy in six, and no surgery in one. No patient underwent irradiation. The postoperative chemotherapy regimen consisted of doxorubicin, dactinomycin, and vincristine in six children, and dactinomycin and vincristine in three. Median follow-up was 9 years. There were no recurrences in any kidney with a missed lesion. All nine patients were alive and disease free at last follow-up. The results of this study in conjunction with the advances in imaging quality means that routine contralateral exploration in the presence of a negative CT is not mandated.[66,67] If a clear contralateral lesion is present, then the child should be treated on the bilateral protocol. If studies suggest a possible contralateral lesion on the kidney, the contralateral kidney should be formally explored prior to nephrectomy.

Ladd and Gross stressed the need for early vascular ligation prior to the development of chemotherapy. This is no longer practiced because of the risk of injury to the vessels, particularly to the superior mesenteric artery in large left-sided tumors. The tumor should be mobilized by opening the lateral peritoneal reflection and reflecting the colon and its mesentery off the anterior surface of the kidney. For right-sided tumors, a Kocher procedure is also helpful. When ligating the renal pedicle, it is best to ligate the renal artery first if it can be safely identified, to avoid increasing the venous pressure within the tumor, which can result in rupture of the capsule. Vascular control in most cases is best completed after the tumor is fully mobilized.[99,105,106] The renal vein should be palpated prior to ligation to be certain there is no venous extension of the tumor. The adrenal gland may be left in place if it is not abutting the tumor; but, if the mass arises in the upper pole of the kidney, the adrenal gland should be removed with the neoplasm. The ureter is ligated and divided as low as possible.[107] The tumor and kidney should be handled gently throughout the operation

to avoid rupture, which will increase the intensity of therapy and risk for local recurrence.[99,105,106]

Pathologic assessment of hilar and regional lymph nodes is critical to accurately stage a child with a renal tumor.[97,99] Routine lymph node sampling from the renal hilum, the pericaval, or para-aortic areas must be performed. Simply looking at the lymph nodes to determine whether they are positive is highly inaccurate.[108] Unfortunately, failure to sample lymph nodes (whether dealing with a unilateral or bilateral tumor) is the major technical error noted in WT surgery.[97] Furthermore, studies have demonstrated a higher risk of recurrence in children who did not have their lymph node status documented at the time of nephrectomy.[12,99,109]

WTs tend to displace rather than invade the surrounding vessels. This feature of WT has two implications. First, the surgeon must be certain of the identity of the vessels to ligate.[102] Second, most organs can be dissected away from the tumor, because actual invasion is rare. When actual invasion is identified, radical en bloc resection (e.g., partial hepatectomy or colectomy) is not warranted as primary therapy.[98,99] WTs are very chemosensitive, and, in these situations, prior adjuvant therapy will result in a lower rate of complications than a multiorgan resection.[98] A small section of diaphragm, psoas muscle, or tip of the pancreas, however, is acceptable.

Recent reports have suggested that hepatic metastasis should be resected at presentation.[110,111] To address this question, the COG renal tumor study group reviewed outcomes for patients with different sites of metastasis and found no significant difference in outcome for patients with liver versus lung metastasis. Primary resection of liver metastases prior to adjuvant therapy is not currently recommended.[112]

### Spill

"Spill" refers to a break in the tumor capsule during operative removal, whether accidental, unavoidable, or by design. Studies have shown a higher risk of recurrence in patients who had tumor spill or rupture, irrespective of the cause or extent of the soiling.[97–99] Spill is also considered to have occurred if the renal vein or ureter are transected where they contain tumor. In COG protocols, spill is also considered to have occurred if a preoperative or intraoperative needle/open biopsy was performed. This is not the case for those patients treated following Société Internationale d'Oncologie Pédiatrique protocols: Fine-needle or Tru-Cut needle biopsy is allowed in this study; however, incisional biopsies are considered as ruptures, automatically stage III, and are contraindicated. "Rupture" refers to either the spontaneous or post-traumatic rupture of the tumor preoperatively, with the result that tumor cells are disseminated throughout the peritoneal or retroperitoneal space.[101] Bloody peritoneal fluid may be a sign of rupture, and a thorough examination of the tumor surface is mandated. Rupture is also considered to have occurred if the tumor penetrates the kidney capsule, with open neoplastic tissue surface being in free communication with the peritoneal cavity. If found, all of these situations make the child stage III and must be carefully documented in the operative note.

### Unresectable Tumors

There are clinical situations where it is agreed that primary nephrectomy is contraindicated. These are when (1) there is extension of tumor thrombus above the level of the hepatic veins; (2) the tumor involves contiguous structures, whereby the only means of removing the kidney tumor requires removal of the other structures (e.g., spleen, pancreas, and colon but excluding the adrenal gland); (3) there are bilateral tumors; (4) the tumor is in a solitary kidney; or (5) there is pulmonary compromise resulting from extensive pulmonary metastases. Studies conducted by the cooperative groups have shown that pretreatment with chemotherapy almost always reduces the bulk of the tumor.[113–116] This makes tumor removal easier and may reduce the incidence of surgical complications.[117] Preoperative chemotherapy does not result in improved survival rates, and it may result in the loss of staging information and changes the histology of the tumor as noted previously.[118,119]

## SPECIAL CONSIDERATIONS

### Management of Tumor Extension in the Renal Vein, Inferior Vena Cava, and Atrium

WT patients may present with tumor extension through the renal vein to the IVC and even up to the right atrium. This is found in 4% to 11% of children. Surgical treatment is dependent on the extent of vascular invasion. Extension is usually asymptomatic, and many are detected preoperatively by US, CT, and/or MRI scans. However, those that extend just into the renal vein may only be detected at operation because of compression and distortion of the veins by the tumor, reinforcing the need to palpate the renal vein and IVC at the start of nephrectomy before any mobilization of the kidney that might dislodge the thrombus.[106,120,121] As noted previously, a primary resection when tumor thrombus extends into the inferior vena cava at the level of the liver or higher is discouraged. COG protocols recommend that these patients be managed initially with preoperative chemotherapy. This approach will often achieve significant shrinkage and regression of the intravascular thrombus, facilitating subsequent surgical removal.[106,122] The severity and number of operative complications are reduced with preoperative chemotherapy for those with vascular extension above the hepatic veins. Alternatively, if the tumor extends only into the renal vein or renal vein and IVC below the level of the liver, the tumor and thrombus can, in most cases, be removed en bloc with the kidney.

Control of renal veins and cava above and below the tumor with vessel loops is necessary, using standard vascular surgery techniques. The tumor should not be transected, if possible, because this will result in spill and upstaging of the patient. In some cases, the tumor may be adherent to the vessel wall. A similar technique used for removing plaque for a carotid endarterectomy is helpful to lift the tumor off the vein wall. It must be stated in the operative report if the intravascular tumor extension was removed en bloc or if tumor was transected, as well as if the tumor thrombus is removed completely and if there is evidence of either adherence to or invasion of the vein wall. If, after preoperative chemotherapy, the tumor still extends above the hepatic veins, cardiopulmonary bypass is generally needed to remove the vascular extension of the tumor.

### Management of Tumor Extension in the Ureter

Extension of WT into the ureter is a rare event.[107] In NWTS-5, the incidence of ureteral extension was 2%. Preoperative imaging detected ureteral extension in only 30% of these

patients; the rest were discovered at operation. Clinical presentations included gross hematuria, passage of tissue per urethra, hydronephrosis, and a urethral mass. The diagnosis should be suspected in these patients, and cystoscopy with retrograde ureterogram may aid in preoperative diagnosis. If extension of tumor into the ureter is detected or suspected, the ureter should be resected with clear margins.

### Horseshoe Kidney, Single Kidney, and Nonfunctioning Kidney

A WT in a horseshoe kidney presents unique challenges. Children with a tumor in a horseshoe kidney are treated as unilateral tumors, NOT as bilateral tumors. Children with horseshoe kidneys and WT must be carefully imaged prior to any surgery.[123] The blood supply to horseshoe kidneys is quite variable and must be carefully imaged prior to surgery.[123] At the time of operation, the blood supply to the kidney as well as the location of the ureters must be identified and isolated. Exposure and mobilization of the kidney on the side of the tumor is carried out as in unilateral resection. The side of the kidney containing the tumor, the isthmus, and the ipsilateral ureter are resected. As with other unilateral procedures, the lymph nodes are sampled for staging purposes. Children with a single kidney, or a situation where a tumor occurs in one kidney but the second kidney is nonfunctioning, should be managed using a renal-sparing approach, with preoperative chemotherapy to facilitate surgery and preserve more renal tissue.

### Patients with Wilms' Tumor Treated Only with Surgery

NWTS-5 evaluated a subset of very-low-risk patients with favorable-histology tumors who might be treated without chemotherapy. The criteria for this arm of the study was stage I FH in patients who had lymph nodes biopsied, had a specimen weight of less than 550 g, and who were less than 2 years of age. Seventy-five patients were enrolled before closure of the study, and 8 developed recurrent disease (lung involvement in 5 and the operative bed in 3). Three other patients developed metachronous contralateral WT. Stringent stopping rules for the study were designed to ensure closure of this arm of the study if the 2-year EFS was 90% or less based on the expectation that approximately 50% of the surgery-only children would be salvaged after recurrence, thus attaining the 95% predicted survival of these children treated with vincristine and dactinomycin (EE-4A). This limit was exceeded on June 14th, 1998, and this arm of the study was closed when the 2-year disease-free survival estimate reached 86.5%.[124] Subsequent patients were treated with EE-4A. A recent long-term follow-up study of the surgery-only cohort and the EE-4A group, with a median follow-up of 8.2 years, reported the estimated 5-year EFS for surgery only was 84% (95% confidence interval [CI]: 73% to 91%); for the EE-4A patients it was 97% (95% CI: 92% to 99%, $P = 0.002$). One death was observed in each treatment group. The estimated 5-year overall survival (OS) was 98% (95% CI: 87% to 99%) for surgery only and 99% (95% CI: 94% to 99%) for EE-4A ($P = 0.70$).[125] The surgery-only EFS was less than for EE-4A, consistent with the earlier report. The salvage rate for the surgery-only cohort, however, exceeded that seen with children who had received two-drug chemotherapy, which had been predicted to be 50%. Thus 85% of the infants avoided any chemotherapy, while those who did receive it for relapse were treated with three agents (DD-4A). A current study in the COG is assessing this cohort again and is evaluating biologic markers for this very-low-risk group.[126]

### Neonatal Tumors

Neoplastic renal lesions in the neonate are rare and include benign and malignant tumors.[127,128] Acute and long-term toxicity from therapy is a considerable concern in infants. The distribution of tumors is age dependent. In the perinatal period, congenital mesoblastic nephroma (CMN) is the leader, accounting for greater than 50% of the renal tumors, followed in rank by WT, RTK, and CCSK.[127–131] WT, CMN, and rhabdoid tumor of the kidney (RTK) are the principal neoplasms of the kidney occurring after 3 months, when CMN accounts for less than 10%. An international retrospective study of 750 neonatal renal tumors in children less than 7 months of age found that 63.4% were WT.[127] Eighty-two percent of these were stage I/II. In contrast, RTK presented with advanced disease (53% stage III/IV). RTK accounted for nine of eleven tumors presenting with metastases. Outcomes paralleled older children, with excellent results for neonates with WT (5-year OS of 93.4%) and poor for RTK (5-year OS of 16.4%).[127]

### Acquired von Willebrand Disease in Children with Wilms' Tumor

von Willebrand disease (vWD) is an inherited coagulation disorder characterized by mucocutaneous bleeding, a prolonged bleeding time (BT), and a reduced level of functional von Willebrand factor (vWF). Secondary laboratory abnormalities include a decreased level of procoagulant factor VIII (FVIII) and activity of ristocetin cofactor (FVIII:RCoF) activity.[132] Acquired vWD has been reported in patients with WT and other malignancies and has important implications for the surgeon.[133,134] A single prospective study of 50 WT patients found the incidence of acquired vWD was 8%.[134] However, the true incidence and prevalence in WT is unknown, because a full bleeding history and factor levels are rarely obtained. Until recently, the literature has suggested that, when identified, the bleeding has been clinically insignificant, characterized by epistaxis, hematuria, gingival bleeding, and easy bruising.[135] Recent reports of profuse intraoperative bleeding that only stopped after ligation of the renal vessels have contradicted this assumption.[136,137] Despite normalization of FVIII and vWF activity and antigen levels prior to surgery, during surgery profuse intraoperative bleeding occurred, requiring multiple transfusions with FVIII, FFP, cryoprecipitate, platelets, and packed red blood cells.[136] Immediately after ligation of the renal vessels, all abnormal bleeding stopped, with normalization of FVIII and vWF antigen activity.

The mechanism of acquired vWD in WT is unknown. Tumor adsorption of vWF has been reported in other malignancies; however, this was not seen in the WT cases where intraoperative bleeding was significant. vWF inhibitors, rapid abnormal clearance of vWF, and coagulopathy related to elevated levels of hyaluronic acid and consequent blood hyperviscosity have also been proposed.[138,139] Why some cases had intraoperative bleeding and others do not is also not known. Baxter[136] suggests that these tumors may be more hypervascular, but this is not proven. The risk of intraoperative bleeding highlights the importance of recognizing acquired vWD in children with WT. In all cases, the initial sign was a prolonged prothrombin time (PT) and partial thromboplastin

time (PTT). When found, this should mandate acquiring a further history for bleeding and factor analysis. Although correction of factor levels prior to surgery appears to help in most cases, it does not guarantee that significant intraoperative bleeding will not occur. In the case reports of profound intraoperative bleeding, it was observed that, once the renal vessels were ligated, the bleeding ceased. Thus preoperative embolization should be considered as a management strategy. Alternatively, preoperative chemotherapy may also be a safe option.

## BILATERAL WILMS' TUMOR

Bilateral Wilms' tumors BWT occur in 4% to 13% of patients (see Fig. 30-3).[5,17–19] Unfortunately, outcomes for children with bilateral tumors have not been as good as those of children with unilateral tumors. In NWTS-5, the 4-year OS was 80.8% for a child with favorable histology and 43.8% for a child with anaplastic histology.[84] In 1998, the United Kingdom Children's Cancer Study Group published their experience with BWT patients treated between 1980 and 1995.[140] In 57 patients, conservative surgical treatment with initial biopsy was followed by chemotherapy and delayed tumor resection, while 13 underwent initial surgical resection followed by chemotherapy. Overall survival was 69%, with similar survival in the patients with initial surgery versus neoadjuvant chemotherapy. BWT with an unfavorable histology was associated with a poor prognosis, with only one of seven patients surviving. Renal failure was seen in 6% of the survivors who were conservatively treated and in 20% of the survivors who underwent initial resection. In 2004, Weirich reported BWT outcomes from SIOP-9. Twenty-eight patients were evaluated. Although therapy was individualized, all 28 patients with BWT were treated with preoperative therapy. Overall survival at 5 years was 85.1% (95% CI: 71.6% to 98.6%; four deaths), and relapse-free survival was 80.5% (95% CI: 65.2% to 95.8%; five relapses).[141]

Renal failure is another concern of children with BWT (Figs. 30-8 and 30-9). The etiology of renal failure in WT patients is multifactorial.[142–144] Factors that contribute to renal failure include intrinsic progressive renal disease related to a genetic predisposition, inadequate renal parenchyma after one or more tumor resections, the nephrotoxic effects of chemotherapy and radiation, and the potential for hyperfiltration injury to the remaining renal parenchyma. Ritchey defined the incidence and etiology of renal failure in patients treated on NWTS-1 to NWTS-4. BWT was the greatest risk factor for renal failure (16.4% for NWTS-1 and NWTS-2, 9.9% for NWTS-3, and 3.8% for NWTS-4). Other risk factors identified were Denys-Drash syndrome, metachronous tumor, progressive disease in patients with bilateral tumors requiring bilateral nephrectomies and radiation nephritis.[144] Breslow reported the 20-year end-stage renal disease (ESRD) outcomes in children treated for WT (see Figs. 30-7 and 30-8).[142] The major risk factors he identified for renal failure were BWT and congenital syndromes—Denys-Drash, WAGR, and genital urinary anomalies (hypospadias or cryptorchidism). Thus preservation of renal tissue without sacrificing long-term survival is of particular importance for those with BWT.

Despite 40 years of clinical trials for WT, it was not until 2009 that a formal BWT trial was opened by COG. Several prior reports contributed to the development of this protocol. Shamberger and colleagues examined 38 of 188 patients with BWT with progressive or nonresponsive disease (PNRD).[145] The mean duration of chemotherapy was 7 months; 36 patients were treated with two regimens of chemotherapy, and 21 patients received three. Patients with PNRD fell into two categories: first, patients with anaplasia whose tumors were not sensitive to the therapy administered (4 patients); second, patients who had tumors with very mature rhabdomyomatous or differentiated stromal elements (14 patients) and 1 with complete necrosis. A second study from Anderson looked at the histologic changes in BWT patients who did not respond to chemotherapy and the relationship between these changes and prognosis.[146] Their results mirrored those of the NWTS study. Fifteen patients whose tumors did not respond were evaluated. One had complete necrosis, 4 had rhabdomyomatous differentiation, and 10 had mature stromal differentiation. Despite not radiographically responding to chemotherapy, these patients had favorable outcomes. Patients in these studies fell into two categories. First, there were patients with anaplasia whose tumors were not sensitive to the therapy administered. Anaplastic tumors respond poorly to chemotherapy and, once the diagnosis of anaplasia is made, a complete resection is needed.[84,140,147,148] Second,

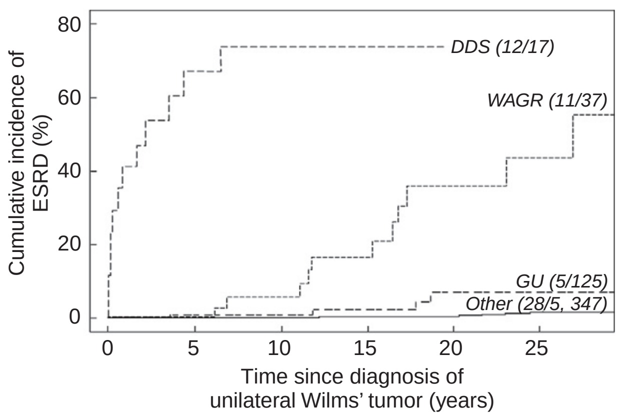

**FIGURE 30-8** Kaplan-Meier plot of renal failure rates at 20 years of age in children with a unilateral Wilms' tumor (WT). DDS, Denys-Drash syndrome; ESRD, end-stage renal disease; GU, genitourinary; WAGR (syndrome), Wilms' tumor, aniridia, genitourinary malformation, mental retardation.

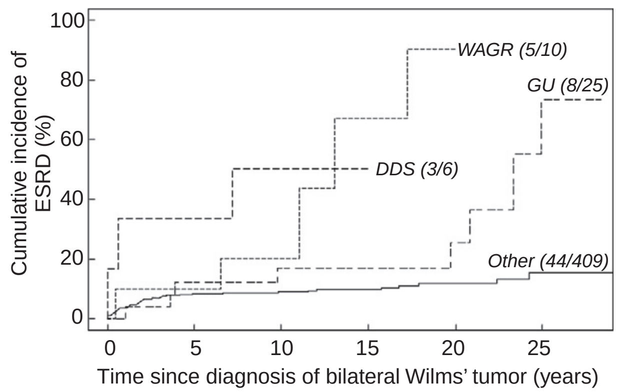

**FIGURE 30-9** Kaplan-Meier plot of renal failure rates at 20 years of age in children with bilateral Wilms' tumor (BWT). DDS, Denys-Drash syndrome; ESRD, end-stage renal disease; GU, genitourinary; WAGR (syndrome), Wilms' tumor, aniridia, genitourinary malformation, mental retardation.

there were patients who had tumors with very mature rhabdomyomatous or differentiated stromal elements and complete necrosis, all of whom had an excellent outcome. Again these patients are best served with resection.[146] Therefore if the bilateral lesions do not respond radiographically to therapy, it is critical to establish whether this is due to anaplasia or mature histology.

Hamilton and colleagues have demonstrated the difficulty in identifying anaplasia in patients with BWT.[148] Twenty-seven patients with anaplasia were reviewed from NWTS-4. Discordant pathology between the kidneys was seen in 20 patients, highlighting the importance of obtaining tissue from both kidneys. Seven children who were eventually found to have diffuse anaplasia had core needle biopsies, which failed to establish the diagnosis in all of these cases. Anaplasia was identified in only three of nine patients who had an open wedge biopsy and in seven of nine patients by partial or complete nephrectomy. Thus percutaneous biopsies rarely establish the diagnosis, and open biopsies were successful in only a third of the cases.

An important question is to determine how long to treat a child who has BWT with chemotherapy before intervening surgically. In SIOP-9, patients with unilateral tumors were randomized to receive either 4 or 8 weeks of dactinomycin and vincristine preoperatively. There was an average 48% reduction in tumor volume after 4 weeks that increased to 62% after 8 weeks of chemotherapy.[116,149] A review by the German Pediatric Hematology Group (GPOH) of their patients with BWT reported that maximum tumor shrinkage occurred in the first 12 weeks of chemotherapy.[150]

The two principal aims of the COG BWT study are to improve 4-year event-free survival and to prevent complete removal of at least one kidney in 50% of patients with BWT by using preoperative chemotherapy. This is a response-based protocol starting with chemotherapy, followed by evaluation at 6 and 12 weeks with definitive surgical therapy in all patients by 12 weeks (see Fig. 30-3). This protocol does not mandate an initial tissue diagnosis because bilateral renal tumors in children are invariably WT; biopsy does not change the therapy in most cases; anaplasia is hard to diagnose, and the biopsy will effectively increase the stage of the tumor and its risk for local recurrence.[148] In the current COG protocol, local spill of the tumor is designated as stage III. This classification was changed because of the finding of an increased incidence of abdominal recurrences in NWTS-4 patients with tumor spill.[99] First, for patients with BWT, the initial regimen will consist of regimen vincristine, actinomycin D, doxorubicin (VAD) (vincristine [VCR], dactinomycin [DACT], doxorubicin [DOX]), a more intensive combination of drugs based on regimens used with good results and minimal toxicities by both SIOP and the UKCCSG WT groups, which enables patients to receive two doses of DOX, in addition to six of VCR and two of DACT, during the first 6 weeks of therapy.[151] It differs from the standard three-drug regimen, DD-4A, in which the DOX and DACT are administered in separate cycles.[152] The three-drug chemotherapy regimen of VAD was chosen to give an enhanced therapy for possible stage III disease, because patients rarely have a lymph node biopsy before initiation of therapy. Second, it was elected to enhance the chemotherapy rather than administer radiotherapy, which might increase the occurrence of radiation nephritis in the remaining kidney. Third, a more intensive therapy was selected for treatment to avoid the use of a sequential regimen of increasing intensity, which was seen in the review of the prior cohort of NWTS-4 BWT patients.

## CHEMOTHERAPY

In 1963, Farber first reported that dactinomycin had activity against WT.[153] Today, dactinomycin continues to be part of the backbone of therapy for children with WT. Other active chemotherapeutic agents have been identified subsequently, including vincristine, doxorubicin, and cyclophosphamide. Clinical trials conducted by NWTSG and SIOP have evaluated, stage by stage, different chemotherapeutic protocols to assess the efficacy of various combinations and duration of therapy.[105,154–159] In NWTS-4, 4-year event-free survival and overall survival averaged 90% for patients with favorable histology.[154,159] Therefore NWTS-5 focused on evaluating biologic markers of prognosis, such as LOH, developing more effective therapy for recurrent disease, and reducing therapy in children with low-risk tumors.

Treatment on the current COG protocols for favorable-histology WT is determined by stage, histology, and LOH. For children with favorable-histology stage I and II tumors without LOH, 18 weeks of vincristine and dactinomycin (regimen EE-4A) is recommended. Results from NWTS-5 showed these children had an overall survival of 98.4% and 98.7%, respectively. For children with FH stage III and IV tumors without LOH, 24 weeks of vincristine, dactinomycin, and doxorubicin is recommended (regimen DD-4A). For those patients who have positive LOH at both loci (1p and 17q), treatment will be intensified. If they are stage I or II and LOH positive, they will receive DD-4A, and if they are stage III and IV LOH positive, they will receive vincristine, dactinomycin, and doxorubicin with alternating cycles of cyclophosphamide versus etoposide (regimen M). Dosing modifications are made for children less than 12 months of age.

Anaplastic tumors have been less successfully treated. NWTS-3 and NWTS-4 were the first studies to prospectively evaluate the benefit of additional/different chemotherapy therapy for these tumors. One randomized arm compared 15 months of vincristine, dactinomycin, and doxorubicin, with or without cyclophosphamide. For patients with stage II to IV diffuse anaplastic histology, the addition of cyclophosphamide resulted in a 4-year relapse-free survival estimate of 54.8% when treated with cyclophosphamide compared with 27.2% when treated without it ($P = 0.02$).[160] In NWTS-5, patients with focal anaplasia or diffuse stage I were treated with EE-4A. This was based on prior historical data, with a goal of reducing therapy. Unfortunately, the 4-year event-free and overall survival estimates for stage I (focal or diffuse) anaplastic WT were lower than previous studies (EFS 69.5% and OS 82.6%). Thus therapy with EE-4A is inadequate. Patients with focal anaplasia stage II to IV were treated with DD-4A. Children with stage II to IV diffuse anaplastic WT were treated with vincristine, doxorubicin, and cyclophosphamide (VDC) alternating with cyclophosphamide and etoposide (CyE) (regimen I). The 4-year event-free survival estimates for stage II to IV diffuse anaplastic WT on NWTS-5 were 82.6%, 64.7%, and 33.3%, respectively, with similar overall survival.[84] The current protocols and chemotherapy agents for unilateral tumors are shown in Table 30-4.

**TABLE 30-4**
**Current Children's Oncology Group Chemotherapy Regimens for Unilateral Wilms' Tumor**

| *Regimen* | *Agents* |
|---|---|
| EE-4A | Vincristine and dactinomycin |
| DD-4A | Vincristine, dactinomycin, doxorubicin, and radiation therapy (XRT) |
| Regimen I | Vincristine, dactinomycin, doxorubicin, cyclophosphamide (CPM1), and etoposide (ETOP), as well as radiation therapy (XRT) |
| Regimen M | Vincristine, dactinomycin, doxorubicin, cyclophosphamide, and etoposide; radiation therapy also to be administered as part of this regimen |
| Revised UH-1 | Vincristine, dactinomycin, doxorubicin, cyclophosphamide, carboplatin, etoposide, and radiation |
| Revised UH-2 | Vincristine, dactinomycin, doxorubicin, cyclophosphamide, carboplatin, etoposide, irinotecan, and radiation therapy (XRT) |
| Vincristine/irinotecan window therapy | Vincristine and irinotecan in conjunction with revised UH-1 or revised UH-2, depending on response |

### Recurrent Tumor

Treatment of recurrent disease in children with WT is challenging. Recurrence occurs in 15% of patients with favorable histology tumors and in 50% with anaplastic histology. Recurrence is most frequent within 2 years of the initial diagnosis and most common in the lungs, tumor bed, and liver.[161] Less common sites are bone, brain, and distant lymph nodes.

Recurrent disease is treated by chemotherapy, surgery, and radiotherapy. NWTS-5 evaluated two protocols for recurrent disease, avoiding use of agents included in the primary protocols. Stratum B was for patients with stage I and II disease initially treated with EE-4A. The chemotherapy for this relapse protocol was regimen I (alternating courses of vincristine/doxorubicin with cyclophosphamide), in addition to surgical resection and radiation therapy. Event-free survival at 4 years was 71.1%, and 4-year overall survival was 81.8% for all patients and was 67.8% and 81.0%, respectively, for those who relapsed only to their lungs.[162] Stratum C was for patients initially treated with DD-4A.[163] The chemotherapy protocol for this group was alternating cycles of cyclophosphamide versus etoposide and carboplatin versus etoposide. Four-year event-free survival and overall survival were 42.3% and 48.0%, respectively, for all patients and were 48.9% and 52.8% for those who relapsed in the lungs only. Bone marrow transplantations have been performed for patients with recurrent disease, with reported event-free or disease-free survival rates of 36% to 60% in these small series.[164–166] At present, there is no open relapsed study in SIOP or COG, because the groups are awaiting new and more effective agents for treatment of this disease.

## RADIOTHERAPY

Analogous to surgery and chemotherapy, the cooperative group trials have refined the indications for radiotherapy. In addition, technologic advances have helped to deliver irradiation with increased efficacy and less toxicity to surrounding tissues. The three principle fields for radiotherapy for renal tumors are whole abdominal, flank, and lung (metastatic lung disease). All five NWTSG studies and the current COG studies use radiotherapy as part of the multimodality treatment for advanced-stage tumors.

In 1950, Gross and colleagues demonstrated the efficacy of radiotherapy as an adjuvant therapy prior to the advent of chemotherapy. In this series, nephrectomy with postoperative radiation improved survival to 47%.[167] Favorable histology tumors are generally very radiosensitive. NWTS-1 to NWTS-3 helped define the indications, timing, and dose of radiotherapy. NWTS-1 established that irradiation provided no advantage in children younger than 24 months with stage I FH tumors who also received 15 months of dactinomycin.[168] That study also demonstrated that in stage III tumors with local tumor spill or previous biopsy, there was no need for irradiation of the whole abdomen, thus sparing patients the associated toxicity.[169] NWTS-2 showed that radiotherapy could be avoided in all children with stage I WT if they received vincristine and dactinomycin.[170] NWTS-3 established that radiotherapy could be avoided in children with stage II tumors given vincristine and dactinomycin and also demonstrated that children with stage III favorable-histology tumors who received 10.8 Gy radiotherapy and vincristine, dactinomycin, and doxorubicin had similar tumor control to those who received 20 Gy with vincristine and dactinomycin. This was an important finding, because it eliminated the need for an age-adjusted dose schedule and significantly reduced the recommended dose of radiation.[157]

Timing of radiation following nephrectomy was assessed on NWTS-2, where a delay of 10 days or more before initiation of radiotherapy was associated with a higher rate of abdominal relapse, particularly among patients with unfavorable-histology tumors and a small radiation field.[157,168,169] A recent review of this issue from NWTS-3 and NWTS-4 data confirmed this observation.[171] Thus, in the COG protocols, it is recommended that abdominal irradiation be delivered as soon as practical after nephrectomy and not later than 14 days after surgery. The current recommendation for radiation therapy for COG protocols is shown in Table 30-5.

In contrast to FH tumors, the ideal dose for patients with anaplastic tumors is unknown. Anaplastic tumors are more resistant to chemotherapy and seem to be more resistant to radiotherapy as well. Anaplastic tumors have not demonstrated a radiation dose response between 10 Gy and 40 Gy.[160]

The radiotherapy strategy for patients with anaplastic histology (AH) on NWTS-5 included no irradiation for stage I AH tumors and 10-Gy radiotherapy for AH stage II and III in conjunction with nephrectomy and regimen I. The outcomes for both of these treatment strategies were suboptimal. Stage 1 patients had a 4-year EFS and overall survival of only 69.5% and 82.6%, respectively. Stage II, III, and IV patients had a 4-year OS after immediate nephrectomy, irradiation, and regimen I chemotherapy of 82.6%, 64.7%, and 33.3%, respectively.[84] EFS was similar to OS in all groups. Fifty percent of stage III recurrences were local, suggesting that the dose of 10 Gy was not adequate. These results form the basis for the current COG study that recommends the addition of irradiation for patients with stage I anaplasia and augmentation of irradiation for patients with stage III anaplasia.

For liver metastases, only those that are unresectable at diagnosis are irradiated. The treatment portal includes that portion of the liver known to be involved as identified by CT or MRI studies. The whole liver is treated in children with diffuse metastases.

### Lung Radiotherapy

Historically, pulmonary metastases were diagnosed based on lesions found on routine chest radiographs and were treated with whole lung radiation. For COG studies, it is delivered in eight treatments of 12 Gy. From NWTS-5, the 5-year EFS (95% CI) for stage IV category was lung only 76% (72% to 80%) (513 patients) and liver and lung 70% (57% to 80%) (62 patients).[172] Advances in imaging have changed the assessment of lung disease from plain radiograph to widespread use of chest computed tomography. Lesions are detected on CT scan that are not found on standard radiographs.[173–175] Thus more lesions are being identified. Complicating the use of radiation therapy is the fact that it is a major cause of long-term morbidity, particularly to the lung and heart, producing congestive heart failure, pulmonary fibrosis, and second malignancy.[176–178] Recent studies suggest that the management for pulmonary nodules should be reexamined. In SIOP-9, by 70 days of therapy, resolution of pulmonary nodules on CT scan in children with FH tumors was a favorable prognostic indicator.[179] In SIOP-9, many of these patients were spared whole lung irradiation, if complete resolution of pulmonary metastases occurred after 6 weeks of prenephrectomy chemotherapy with vincristine, dactinomycin, and doxorubicin with or without surgical excision of residual metastases. The 5-year relapse-free survival (RFS) for stage IV patients receiving preoperative chemotherapy was 62.5%.[179] The results of this study have been controversial. The United Kingdom Children's Cancer Study Group (UKCCSG) Wilms Tumor Study 1 followed a similar protocol; yet, their 6-year EFS was only 50%.[180] In their second study, UKCCSG-Wilms Tumor Study (UKWT2), the majority of children with lung metastases received whole lung irradiation (WLI), and the 4-year survival rate improved to 75%.[181] A COG study of patients with pulmonary lesions detected by CT only (as opposed to CT and chest radiograph) and treated with only two chemotherapeutic agents showed an inferior outcome compared with those treated with three drugs *irrespective* of whether or not they received pulmonary radiation.[172] A fourth study examined the value of biopsy prior to treating patients with lesions detected only by CT.[175] Two thirds of the children had tumor on biopsy, suggesting that histologic evaluation may be valuable in directing therapy. The current COG study is evaluating the use of radiographic response to chemotherapy to predict the need for whole lung irradiation. Those patients with stage IV favorable-histology WT with pulmonary metastases who have complete CT resolution of the pulmonary lesions after 6 weeks of vincristine/dactinomycin/doxorubicin chemotherapy will continue the same chemotherapy without whole lung irradiation. Those who do not have resolution of pulmonary metastases by week 6 will have the addition of cyclophosphamide and etoposide to the other three drugs and will receive whole lung irradiation.

## LATE EFFECTS

The increasing numbers of survivors of WT have led to a better understanding of adverse medical conditions related to treatment of their disease that can develop over time.[182] Treatment for WT impacts renal function (discussed earlier), pregnancy, cardiac and pulmonary function, and second malignancies may develop.[178,183–187]

### Pregnancy

Treatment for WT impacts reproductive capacity and increases the risk of complications during pregnancy. The National Wilms' Tumor Long-Term Follow-Up Study evaluated 700 maternal/offspring pairs.[188] If a woman had received flank radiation for unilateral WT, the dose of radiation correlated with increased risk of hypertension, fetal malposition, and premature labor. The children were also more at risk for low birth weight and prematurity (birth before 37 weeks). Premature labor was seen in 10.2% of women who did not receive flank radiation and 22% of those who received 35Gy ($P = 0.001$). Radiation therapy to the abdomen has resulted in absent/abnormal function of the ovaries, a small uterus, and premature menopause.[189–193] Male infertility is not at risk unless alkylating agents were used.

### Secondary Malignancies

Patients who have been treated for pediatric cancer are known to have an increased risk of second malignancies. This is in part due to treatment with known carcinogens, such as alkylating agents and radiotherapy.[183,194,195] An international cohort of 13,351 children with WT diagnosed before 15 years of age, from 1960 to 2004, was established to determine the risk of second malignant neoplasms (SMN).[178] One hundred and seventy-four solid tumors and 28 leukemias were found in 195 people. Median survival after a secondary malignancy was diagnosed 5 years or more from WT was 11 years; it was 10 months for leukemia. Age-specific incidence of secondary solid tumors increased from approximately 1 case per 1,000 person-years at age 15 years to 5 cases per 1,000 person-years at age 40 years. The cumulative incidence of solid tumors at age 40 years was 6.7%. In those patients whose

WT was diagnosed after 1980, there was a lower age-specific incidence rate for second tumors compared with those treated before 1980. Paradoxically, the incidence of leukemia was higher in those diagnosed after 1990. This may be due to decreasing use of radiation therapy and increasing intensity of chemotherapy in modern protocols for treatment of WT.

### Congestive Heart Failure

Congestive heart failure has been identified as a significant morbidity in children treated with doxorubicin, and this is exacerbated in patients who receive thoracic radiation. The cumulative frequency of congestive heart failure in patients treated on NWTS-1 to NWTS-4 was 4.4% at 20 years for patients treated initially with doxorubicin, but that percentage is expected to be lower with current cumulative doses.[184,185,196] The relative risk of congestive heart failure was found to be increased in females (risk ratio [RR] = 4.5; $P = 0.004$), and by cumulative doxorubicin dose (RR = 3.2/100 mg/m$^2$; $P < 0.001$), lung irradiation (RR = 1.6 for every 10 Gy; $P = 0.037$), and left abdominal irradiation (RR = 1.8/10 Gy; $P = 0.013$).[185] Preliminary results suggest that cardiotoxicity is lower with current radiation doses, but patients still have a substantial lifetime risk of developing cardiac disease.[183,196]

### Thoracic

Radiotherapy (RT) has been implicated as a major contributor to late complications. Acute lung injury is relatively uncommon, occurring in a minority of children.[197] The late effects of pulmonary RT include pneumonitis and restrictive lung disease, scoliosis, kyphosis, reduced lung capacity, and secondary tumors. In girls, breast hypoplasia and cancer have been described.[176,177] Paulino and his colleagues reported on the late complications of pulmonary RT in 55 long-term survivors of WT.[176] Two thirds of the patients had at least one complication. Forty-three percent had scoliosis or kyphosis, and 10% developed benign chest tumors (osteochondromas). Secondary tumors were noted in three patients within the lung field (two osteogenic sarcomas of the rib and one breast cancer), and all succumbed to these tumors. Pulmonary function was examined by Attard-Montalto and colleagues.[177] Subjectively, 63% percent of patients had mild to moderate exercise intolerance, and objective measurement of vital capacity and total lung capacity was decreased compared with age and height predicted values in all. All of the females had breast hypoplasia. In another study of long-term survival of females, all developed breast hypoplasia and one had breast cancer.[198]

# Other Renal Tumors

## CLEAR CELL SARCOMA OF KIDNEY

CCSK accounts for 3% of renal tumors reported to the COG studies. Each year, approximately 20 new cases of CCSK are diagnosed in the United States. CCSK was recognized as a distinct clinicopathologic entity by Kidd in 1970.[199] CCSK has been described as nests of ovoid, epithelioid, or spindled cells separated by fibrovascular tissue with a "chicken wire" pattern of small blood vessels. Most tumors show evidence of this "classical" pattern, but other reported histologic patterns seen include myxoid, sclerosing, cellular, epithelioid, palisading, spindle-cell, storiform, and anaplastic patterns.[200] Immunohistochemistry is used to exclude other renal tumors. CCSK is nonspecifically vimentin and Bcl-2 positive. Gene-expression profiling studies demonstrate the expression of neural markers (e.g., nerve growth factor receptor), expression of member genes of the Sonic Hedgehog pathway and the phosphoinositide-3-kinase/Akt cell proliferation pathway.[201,202] Recently, a translocation t(10;17) and deletion 14q have also been described in CCSK, suggesting that they may play a role in its pathogenesis.[203] CCSK is characterized by bone and brain metastases and the increased tendency for late recurrences. Long-term follow-up of CCSK patients is needed because 30% of relapses occurred more than 3 years after diagnosis, and some occurred as late as 10 years after diagnosis.[204] The tumor is generally unilateral and unicentric, with solid and, occasionally, cystic areas. On NWTS-1 to NWTS-3, treatment for CCSK was the same as for WT, and the outcomes were poor. In NWTS-4, patients were treated with vincristine, dactinomycin, doxorubicin, and RFS, and overall survival was improved versus NWTS-3 (RFS 71.6% versus 60.2% at 8 years, $P = 0.11$; OS 83% versus 66.9% at 8 years, $P < 0.01$).[204] To further improve survival, patients on NWTS-5 with CCSK were treated using regimen I (see Table 30-2), because etoposide and cyclophosphamide were active against CCSK in preclinical models.[205] Four-year OS for stage I patients was 100%. Stage II, III, and IV had 4-year OS of 88.9%, 94.8%, and 41.7%, respectively. LOH was not found in most cases of children with CCSK and is not predictive of outcomes. In the current COG study, patients with CCSK are treated according to the high-risk study. Patients with stage I disease will continue to be treated with regimen I but will not receive radiation therapy. The need to minimize unnecessary therapy in patients with stage I CCSK is highlighted by the fact that treatment-related deaths in the Argani series outnumbered tumor-related deaths, two versus one.[200] In addition, none of the stage I patients from NWTS-5 have relapsed, with a median follow-up of more than 4 years. To improve survival for children with higher-stage disease, they will be treated with revised UH-1 (see Table 30-4).

## RHABDOID TUMOR OF THE KIDNEY

RTK was initially described in 1978 as a "rhabdomyosarcomatoid" variant of WT.[206] Haas used the term "rhabdoid tumor" in 1981, because of the absence of muscle differentiation.[207] RTKs have been reported to occur throughout the body, including the brain, liver, soft tissues, lung, skin, and heart. RTK accounts for 2% of all renal tumors, and it is the most aggressive and lethal of all pediatric renal tumors. Clinical features that help distinguish an RTK from WT clinically include the presence of hypercalcemia and diffuse lymphatic and hematogenous spread in a young infant. Tomlinson and her colleagues reviewed 142 patients with RTK from NWTS-1 to NWTS-5.[208] Age at diagnosis was found to be a highly significant prognostic factor for survival of children with RTK. Infants have a dismal prognosis, whereas older children have a slightly more favorable outcome. Higher tumor stage and presence of a central nervous system (CNS) lesion were also predictive of a poor rate of survival. Unfortunately, these tumors tend to present at an advanced stage and are resistant to chemotherapy.[209] RTK is associated with second primary tumors in the brain, including cerebellar medulloblastomas, pineoblastomas, neuroblastomas, and subependymal giant cell astrocytomas.[210]

Grossly, the tumors are solid, unencapsulated, and often have extensive hemorrhage and necrosis. The tumors are very invasive. Microscopically, they consist of sheets of cells showing nuclear pleomorphism and characteristic morphologic features of open vesicular nuclei, prominent nucleoli, and scattered hyaline eosinophilic cytoplasmic inclusions composed of intermediate filaments in a "whorled" pattern. At present, no single immunohistochemical stain or profile is considered to represent a diagnostic criterion. Recently, genetic abnormalities of the *hSNF5/INI1* tumor suppressor gene on chromosome 22 have been shown to be characteristic for both renal and extrarenal rhabdoid tumors; the gene is important for chromatin remodeling. For all other renal tumors, except RTK, immunohistochemical staining for the wild-type integrase interactor 1 (INI-1) protein shows nuclear positivity. In renal and extrarenal rhabdoid tumors, this is absent.[211] This antibody is being evaluated for its diagnostic utility in the current COG renal tumor study.

Both SIOP and COG/NWTSG have reported poor outcomes for children with RTK.[208,212] The outcomes by stage from NWTS-5 are stage I = 50.5%, stage II and III = 33.3%, stage IV = 21.4%, stage V = 0%. Children with RTK, on the current COG study, will be treated using revised UH-1 if they are stage I to IV and have no measurable disease after surgery. If they have measureable disease (stage III, IV), they will receive a vincristine/irinotecan "window," followed by revised UH-2 if they have a partial or complete response (see Table 30-2). The rationale for this treatment strategy was based on reviewing the outcomes from the intergroup rhabdomyosarcoma (IRS) studies and several case reports that documented the successful treatment of advanced or metastatic rhabdoid tumor of the kidney.[213–215]

## RENAL CELL CARCINOMA

RCC in childhood accounts for 5% to 8% of all pediatric and adolescent renal malignancies. They are more common than clear cell sarcoma of the kidney and malignant rhabdoid.[1] The median age at presentation in children is 9 years. By age 15, RCC becomes as common as WT (Fig. 30-10). In the pediatric population, there have been limited therapeutic studies with no randomized controlled trials. Similar to WT, children with RCC generally present with an asymptomatic abdominal mass, although hematuria is a frequent finding.[216] Imaging studies cannot differentiate RCC from other solid

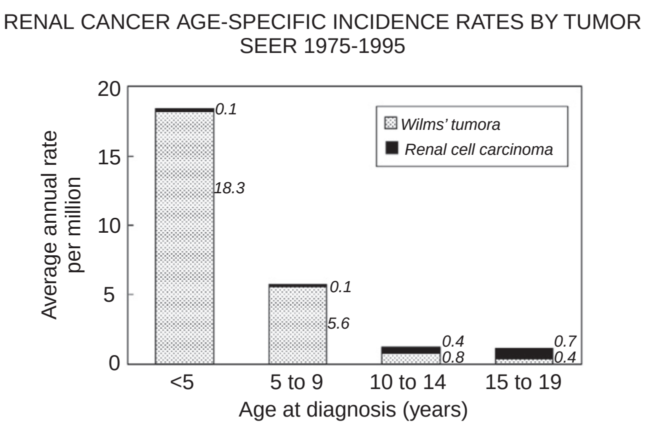

**FIGURE 30-10** Incidence of renal cell carcinoma and Wilms' tumor by age. SEER, Surveillance, Epidemiology, and End Results (Program).

renal tumors. RCC in children can be divided into two broad pathologic groups.[217] The first is the classical clear cell histology. This includes the adult-type RCC with 3p25 (VHL locus) genetic abnormalities and tumors in patients with tuberous sclerosis. In addition, there is a unique genetic subtype of clear cell that presents in adolescents and young adults, accounting for nearly one third of all cases. These tumors are characterized by the chromosomal translocations involving the *TFE3* gene on Xp11.2[217–219] or the *TFEB* gene on 6p21.[220,221] The abnormal gene fusions produce protein dysregulation and result in overexpression of either *TFE3* or *TFEB* transcription factors, which contribute to tumor pathogenesis. Immunohistochemistry can detect aberrant expression for TFE3 or TFEB and can thus be useful in establishing the diagnosis.[221,222] In addition, these translocation-positive RCCs have been described as second malignancies following previous chemotherapy.[223,224]

The second subgroup of pediatric RCCs are the papillary RCCs.[225–227] Papillary renal cell carcinoma appears more frequently than classical clear cell. Other RCC cell types include chromophobe or collecting duct types.[228] Renal medullary carcinomas are rare, but highly aggressive, malignancies that are associated with sickle cell hemoglobinopathy.[229,230] Approximately 25% of pediatric RCCs are not able to be classified because of atypical histologic features.[217]

Complete tumor resection is the most important determinant of outcome in RCC.[228] Younger age at diagnosis is also a favorable prognostic factor. It has been suggested that regional lymph node involvement does not portend the same grave prognosis as it does in adult renal cell carcinoma; however, because this impression was reached based on only 13 patients, further evaluation is required.[231] Data collected from RCC patients enrolled on NWTS-5 showed 5-year OS survival rates by stage: stage I 92.5%, stage II 73%, stage III 55%, and stage IV 9%. Similar to adult RCC, prognosis worsens with increasing stage, although direct comparisons of adult and pediatric data are confounded by the finding that most reviews of pediatric RCC used the modified Robson staging system rather than the tumor-node-metastasis (TNM) system. Neither chemotherapy nor radiation therapy have demonstrated activity in adult or pediatric patients with metastatic RCC. To address this lack of knowledge and experience, for the first time these tumors will be addressed in a COG protocol. To enable comparison with adult tumors, the staging system proposed by the World Health Organization will be used. The relatively good survival rate for children with localized RCC combined with the relative inefficacy of the known adjuvant therapies support treating children without adjuvant therapy. However, the provision of adjuvant chemotherapy is at the discretion of the local physicians. A major future thrust will be to identify novel agents with activity against RCC.

## CONGENITAL MESOBLASTIC NEPHROMA

Congenital mesoblastic nephroma (CMN) is the most frequent renal neoplasm of newborns and young infants, accounting for 5% of all renal tumors.[129,232–234] The median age at diagnosis is 2 months. In 1967, Bolande and colleagues were the first to describe the tumor as a separate entity from WT.[234] CMN are firm on gross examination, and the cut surface has the yellowish gray trabeculated appearance of a leiomyoma. To date,

three histologic subtypes have been described. The classical type, first identified by Bolande (24% of cases), cellular type (66% of cases), and mixed type (10% of cases) showing both classical and cellular patterns.[235] The classical variant is characterized by leiomyomatous histology, with spindle cells in bundles, rare mitoses, and the absence of necrosis. It is histologically similar to infantile myofibromatosis. The cellular variant consists of solid, cellular, sheetlike growth pattern of oval or round cells with little cytoplasm and frequent mitoses and necrosis, which resembles infantile fibrosarcoma. The mixed type of congenital mesoblastic nephroma features areas resembling both classical and cellular morphologies.[235–237] The relationship between mixed CMN and the two main histologic subtypes is not clear.[238]

The observation that classical CMN is similar to infantile myofibromatosis and cellular CMN resembles infantile fibrosarcoma suggests that these may be two distinct entities, and genetic studies provide evidence in support of this hypothesis. Cellular CMN is characterized by the t(12;15) translocation, resulting in the *ETV6-NTRK3* fusion gene, a genetic change that has not been identified in classical CMN, but is characteristic of infantile fibrosarcoma.[238,239] This led to the hypothesis that cellular CMN is an intrarenal occurrence of infantile fibrosarcoma, whereas classic CMN reflects intrarenal fibromatosis. The cloning of the resulting gene fusion has allowed the development of molecular detection assays for this subtype of congenital mesoblastic nephroma. The absence of the fusion product in classical congenital mesoblastic nephroma correlates with its demonstrated absence in infantile myofibromatosis. The challenge then is to explain the existence of the mixed lesions.

Clinically, most children with CMN have an excellent prognosis and are cured with a radical nephroureterectomy with lymph node sampling.[236,240] However, CMN tends to grow into the hilar and perirenal soft tissue, and recurrence or metastases are seen.[241,242] In 1973, the first reports of local recurrences in children with CMN appeared in the literature.[243–245] Since then, metastasis to the lung, liver, brain, and heart have been reported.[245–249] Recurrence and metastatic disease has lead to a debate concerning the need for adjuvant therapy to prevent these rare events in a subset of patients versus the risks of this therapy in infants.[237,241]

Subsequent investigations demonstrated that recurrences were seen preferentially in either the cellular or the mixed subtypes. Other suggested risk factors for recurrence included age (more than 3 months of age), stage (stage III resulting from incomplete surgical resection), and vascular invasion.[250,251] In 2006, the German Pediatric Oncology Group published their experience with 50 children with CMNs, suggesting that a subgroup of children more than 3 months of age with stage III cellular CMN tends to develop recurrences more often supporting the earlier findings.[252] Alternatively, Perlman and colleagues evaluated 396 cases of CMN from the database of the J.B. Beckwith Developmental Renal Tumor Collection.[253] Thirty CMNs were known to have recurred (7.6% overall recurrence rate and 9.3% recurrence rate for tumors with a cellular histologic component). Recurrences took place within 1 year of diagnosis (range, 2 to 11.5 months); 20 were local, 8 were metastatic, and 2 were both local and metastatic. None of the classical CMNs recurred, including 18 that were known or suspected to have residual disease. Recurrences were confined to tumors with a cellular component or cellular and mixed, which had the same risk of recurrence. Stage III disease was the second factor associated with recurrence. Intrarenal and renal sinus vascular invasion correlated with increased potential for recurrence; however, the correlation did not achieve independent statistical significance. Other clinical or pathologic features previously suggested as prognostic factors, including age at diagnosis, were not proven to be of additional prognostic significance. This study concluded that the most important risk factors for recurrence in CMNs are the presence of a cellular histologic component and stage III disease. However, in none of these reports has the efficacy of adjuvant therapy been established.

## SOLITARY MULTILOCULAR CYST AND CYSTIC PARTIALLY DIFFERENTIATED NEPHROBLASTOMA

Cystic renal tumors are a diagnostic and therapeutic challenge (Fig. 30-11). Cystic nephroma (CN), cystic partially differentiated nephroblastoma (CPDN), and cystic WT (CWT) are a spectrum with CN at the benign end, CWT at the malignant end (these must have both a solid and cystic component), and CPDN in the intermediate position. The three types cannot be differentiated using imaging techniques and can be confused with cystic clear cell sarcoma and cystic mesoblastic nephroma.[254] Multicystic dysplastic kidney can generally be distinguished radiographically from the other entities, because it lacks any normal renal parenchyma that the other lesions should contain.[255]

## CYSTIC NEPHROMA

CN is an uncommon benign renal lesion that occurs most commonly in children younger than 24 months of age, with a male to female ratio close to 2:1. A second peak incidence occurs in adults around 30 years of age, with an 8:1 female to male predominance.[255–258] Grossly, these masses are

FIGURE 30-11 A magnetic resonance scan of a cystic nephroma.

well-encapsulated multilocular tumors composed of various-sized cysts with thin septations that compress the normal kidney. Microscopically, the identifying feature is that of mature well-differentiated cell types within the septa of the cyst wall. There are no blastemal or embryonal elements.[254,255] Most cases are unilateral, but some are bilateral.[259] Although CN is benign, cases have been reported with pleuropulmonary blastoma as well. The relationship between these two entities is undefined.[260,261]

## CYSTIC PARTIALLY DIFFERENTIATED NEPHROBLASTOMA

Cystic partially differentiated nephroblastoma is a multilocular cystic WT composed entirely of cysts separated by delicate septa. The majority of these lesions occur in the first 2 years of life.[256,262,263] Cystic partially differentiated nephroblastoma is usually well circumscribed and sharply demarcated from the adjacent normal kidney. It can be large (up to 18 cm in diameter) and may produce visible abdominal distention. This neoplasm is composed entirely of variably sized cysts; unlike CN, the septal stroma contains small foci of blastema, primitive or immature epithelium, and/or immature-appearing stromal cells.[264,265] In addition, skeletal muscle fibers are commonly present in cystic partially differentiated nephroblastoma.

Both COG/NWTSG and SIOP have reported their experiences with CN and CPDN.[262,266,267] In the NWTSG study, 21 patients were evaluated.[262] Thirteen patients received chemotherapy, and 8 patients did not. In the chemotherapy group, the distribution by stage was 10 children with stage I, 2 children with stage II, and 1 child with stage V. The 8 no-chemotherapy patients were all stage I with a 100% survival. The SIOP evaluated 14 patients with diagnoses of cystic nephroma (7 patients) and cystic partially differentiated nephroblastoma (7 patients). Two patients received preoperative chemotherapy. Primary nephrectomy was performed in 12 patients. Two patients underwent partial nephrectomy. In 1 child, postoperative chemotherapy was administered. None of the patients had progression of disease or recurrence. Overall survival was also 100%.[267] There is some concern about doing partial nephrectomies because of recurrences after incomplete excision as well as distinguishing this tumor from other malignant lesions.[267,268]

CHAPTER 31

# Neuroblastoma

Barrie S. Rich and Michael P. La Quaglia

Neuroblastoma is one of the most common solid tumors in infancy and childhood. This is a neoplasm of neural crest origin, arising in the adrenal medulla and along the sympathetic ganglion chain from the neck to the pelvis. The clinical course is quite variable, because this highly malignant tumor demonstrates unusual behavior. Although instances of spontaneous regression and tumor maturation from a malignant to a benign histologic form have been observed,[1–7] the disease is progressive in many cases. Survival in children with other malignancies, such as Wilms' tumor, rhabdomyosarcoma, acute lymphocytic leukemia, germ cell tumors, Hodgkin disease, and non-Hodgkin lymphoma, has been significantly improved by the intensive use of combined treatment modalities, but the outlook for many children with advanced neuroblastoma remains dismal.[1,5,8–12] This neoplasm exhibits great heterogeneity in its behavior and represents a significant challenge to practitioners.

Primitive neuroblasts can be identified in the fetal adrenal gland in the 10th to 12th intrauterine week. The nodules increase in number by 20 weeks' gestation but gradually diminish in number toward the end of gestation. Neuroblastoma in situ in the adrenal gland is seen in 1 of every 260 neonates who die of congenital heart disease and in as many as 1 in 39 infants who die from other causes in the first 3 months of life. The clinical incidence of the tumor is approximately 1 in 7,500 to 10,000 children.[1,10,13,14] Neuroblastoma is responsible for 10% of all childhood tumors and 15% of all cancer deaths. There are 700 cases diagnosed annually in the United States. Approximately 40% of cases are diagnosed by 1 year of age, 75% by 7 years, and 98% by 10 years.[1] More than half the patients are younger than 2 years at the time of diagnosis.[15] Neuroblastoma is slightly more common in boys than in girls, with a male-to-female ratio of 1.2:1.0.[1,10] It is the most common intra-abdominal malignancy in newborns, and the most frequently diagnosed malignancy in children less than 1 year of age.[16]

The embryonal nature of neuroblastoma has been well documented by its identification on prenatal ultrasonography, and the tumor has been known to invade the placenta during the antenatal period, though this is a rare occurrence.[17–24] More than 55 cases of antenatally discovered neuroblastoma have been reported in the literature since the original description by Fénart and colleagues in 1983.[25] The masses are usually identified during ultrasound examinations performed after 32 weeks' gestation. The earliest reported instance was observed at 18 weeks' gestation.[26]

Mothers of infants with congenital neuroblastoma occasionally experience flushing and hypertension during pregnancy as a result of catecholamine released from the fetal tumor in utero.

Neuroblastoma has been described in twins on many occasions, and familial occurrences in both mother and child and father and son have been reported.[23,27,28] Concordance for neuroblastoma in twins during infancy indicates that hereditary factors may be predominant in this age group, whereas discordance in older twins suggests that a random mutation may be more important for this population. The median age for the occurrence of familial neuroblastoma is 9 months, in contrast to 18 months in the general population. Maris and colleagues[29] observed that 20% of patients with familial neuroblastoma have bilateral or multifocal tumors and reported evidence for a hereditary neuroblastoma predisposition locus on chromosome 16p12-13. Neuroblastoma has been observed in infants with Beckwith-Wiedemann syndrome, neurofibromatosis (von Recklinghausen disease), Hirschsprung disease, central hypoventilation syndrome (Ondine's curse), and fetal alcohol syndrome, and in offspring of mothers taking phenytoin (fetal hydantoin syndrome) for seizure disorders.[30–34] Mutations in the *PHOX2B* gene, which is often seen in congenital central hypoventilation disorder, have been documented in those with familial neuroblastoma, and in 2.3% of those with sporadic neuroblastomas.[35] Recently, it has been determined that genetic mutations in the anaplastic lymphoma kinase (*ALK*) gene explain most hereditary neuroblastoma. However, activating mutations of this gene can also be somatically acquired.[36] This discovery has initiated the development of therapy based on *ALK* inhibition.[37] Although it is unlikely that environmental factors play an important role in causing this tumor, neuroblastoma has been noted among infants of mothers receiving medical therapy for vaginal infection during pregnancy and with paternal occupational exposure to electromagnetic fields.[1]

Neuroblastoma may occur at any site where neural crest tissue is found in the embryo. The neuroblast is derived from primordial neural crest cells that migrate from the mantle layer of the developing spinal cord. Tumors may arise in the neck, posterior mediastinum, retroperitoneal (paraspinal) ganglia, adrenal medulla, and pelvic organ of Zuckerkandl.[5,10,14,38] In 75% of cases, the tumor is located in the retroperitoneum,

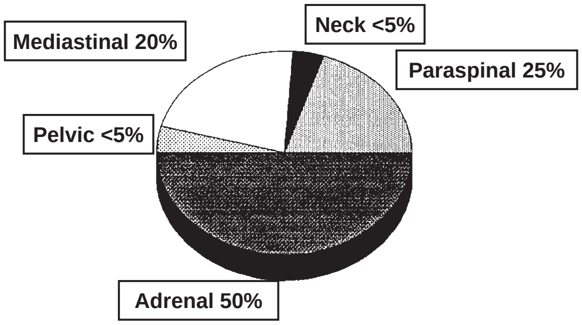

FIGURE 31-1 Distribution of cases of neuroblastoma at each of the primary tumor sites. Primary tumors most commonly occur in the adrenal gland.

in either the adrenal medulla (50%) or the paraspinal ganglia (25%). In 20% of cases, the primary tumor is in the posterior mediastinum. Less than 5% of tumors occur in the neck or pelvis (Fig. 31-1).[1,5,10,14] Primary intracranial cerebral neuroblastoma also occurs.[39,40] In addition, a teratoma in an infant may occasionally contain foci of neuroblastoma. Rare cases of neuroblastoma arising in the bladder have also been reported.[41]

The fate of the neuroblasts can follow 1 of 3 clinical pathways: (1) spontaneous regression, (2) maturation by differentiation from neuroblastoma to a benign ganglioneuroma, or most frequently, (3) rapid progression to a highly malignant tumor that is often resistant to treatment.

## Mass Screening

In an effort to identify early cases of neuroblastoma that were amenable to cure, mass screening programs were initiated in Japan in 1985, evaluating urinary vanillylmandelic acid (VMA) and homovanillic acid (HVA) levels in infants at 6 months of age. These studies identified a large number of infants with neuroblastoma. The survival in these cases was exceptionally high compared with the survival in patients who present with clinical disease diagnosed by conventional methods. The Japanese screening effort doubled the actual incidence of neuroblastoma in infants younger than 1 year of age, but neither decreased the number of cases observed in older children nor improved the survival of children older than 1 year of age.[1,42–44] Sawada and colleagues[43,44] reported a 96% survival rate in 170 cases of neuroblastoma identified by screening. These observations suggest that neuroblastomas identified by screening were most likely biologically favorable tumors that spontaneously regressed.[43] However, a small number of screened patients have had tumors with unfavorable biologic markers and a poor prognosis, and a few screened patients who tested negative at 6 months of age later (at 12 to 18 months of age) developed highly aggressive neuroblastomas.[45]

In general, mass screening has provided important information regarding the natural history of this enigmatic tumor and has identified a group of tumors that clearly regress and represent a biologically favorable form of tumor, in contrast to that noted in older children.[7] Prospective, population-based, controlled screening trials in Quebec minimized the rate of false-positive cases, but had an overall sensitivity of only 45%. The results were similar to the findings in Japan.[46] A German study offered screening to 2.6 million infants between 9 and 18 months of age. This effort identified 149 cases of neuroblastoma in 1,800 screened infants, demonstrating a predictive value of 8%.[47] The German investigators estimated that two thirds of the tumors detected by screening would have regressed spontaneously. The potential risks were highlighted by the fact that all 3 children who died in the group detected by screening had localized disease and succumbed from complications of treatment. These studies in North America, Japan, and Europe suggest that screening may result in an overdiagnosis of neuroblastoma and the performance of unnecessary therapies.[48] However, the results observed in screening studies are valuable and should help minimize treatment in the substantial subset of infants diagnosed with early-stage neuroblastoma that has an excellent chance of either maturing or spontaneously regressing.[49] Because of compelling medical and psychological reasons, especially among parents in false-positive cases, neuroblastoma screening was discontinued in many countries.[50,51] Following the cessation of screening elsewhere in the world, the Ministry of Health in Japan discontinued its mass screening program in April 2004.[52]

## Clinical Presentation

Neuroblastoma is a tumor with multiple clinical manifestations related to the site of the primary tumor, the presence of metastases, and the production of certain metabolic tumor byproducts. In 50% to 75% of reported cases, patients present with an abdominal mass. The tumor may be hard, nodular, fixed, and painful on palpation. Generalized symptoms include weight loss, failure to thrive, abdominal pain and distention, fever, and anemia.[1,5,10,14] Hypertension is found in 25% of cases and is related to the production of catecholamines by the tumor. Instances of hypercalcemia have been observed in association with neuroblastoma, and hemoperitoneum caused by sudden spontaneous rupture of the neoplasm has also been reported.[53,54]

Neoplasms arising in the upper mediastinum or neck may involve the stellate ganglion and cause Horner syndrome, which is characterized by ptosis, miosis, enophthalmos, anhydrosis, and heterochromia of the iris on the affected side.[5,10,14] Metastases to the bony orbit may produce proptosis or bilateral orbital ecchymosis—often referred to as "panda eyes" or "raccoon eyes" (Fig. 31-2). The latter finding in a child

FIGURE 31-2 Child with bilateral orbital ecchymoses ("panda eyes" or "raccoon eyes") resulting from orbital metastases from neuroblastoma.

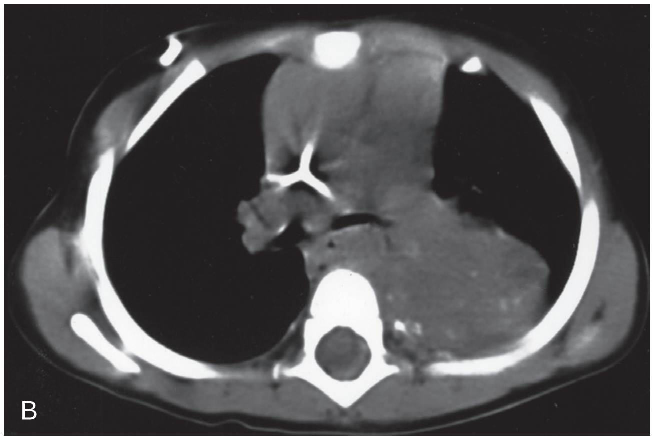

**FIGURE 31-3** **A,** Plain chest radiograph shows the presence of a left upper thoracic tumor. **B,** Computed tomography scan documents a mass in the posterior mediastinum that contains calcium, suggestive of a neuroblastoma.

without a history of trauma should always raise the index of suspicion for the presence of a malignancy. Mediastinal tumors may be associated with respiratory distress because of the tumor's interference with lung expansion and dysphagia caused by extrinsic pressure on the esophagus (Fig. 31-3).[10,55–57] Mediastinal and paraspinal retroperitoneal lesions may manifest with paraplegia related to tumor extension through an intervertebral foramen, resulting in a dumbbell- or hourglass-shaped lesion that may cause extradural compression of the spinal cord.[14,58–61] In a few patients, cauda equina syndrome has also been observed. Pelvic tumors may be associated with bladder and bowel dysfunction. They are usually palpable on rectal examination. They must be differentiated from presacral teratoma, yolk sac tumor, nonosseous Ewing tumor, and pelvic rhabdomyosarcoma.[5,10]

Anemia is often related to bone marrow invasion by the tumor. Excessive catecholamine production by the tumor may result in flushing, sweating, and irritability. Acute cerebellar ataxia, characterized by opsomyoclonus and nystagmus ("dancing eye syndrome"), has been observed.[62–66] This syndrome is seen more frequently (>60%) in patients with primary mediastinal tumors, in patients with stage I or II disease, and in infants younger than 1 year of age.[62,66] In addition, they are often more histologically mature. The involuntary muscular contractions and random eye movements are unrelated to metastases. The cause is suggested to be an autoimmune phenomenon related to an antigen–antibody complex involving antibodies that cross-react with Purkinje cells in the cerebellum.[62,64,66,67] Poor school performance and learning deficits may occur as sequelae.[64,65] The survival rate for patients who present with opsomyoclonus and nystagmus is approximately 90%. Presence of the dancing eye syndrome in patients who present with advanced tumors and N-myc overexpression, however, is associated with a poor outcome.[68] Despite tumor resection and adrenocorticotropic hormone treatment, the neurologic symptoms in survivors (including learning disabilities and attention deficits) may persist for many years.[63–65]

Infants with neuroblastoma, ganglioneuroblastoma, and, occasionally, benign ganglioneuroma may present with intractable diarrhea characterized by watery, explosive stools and hypokalemia.[69–71] The diarrhea is related to the production of vasoactive intestinal polypeptide (VIP) by the tumor.[10,69–71] Tumors associated with this syndrome often have somatostatin receptors and are differentiated, low-risk tumors. Serum VIP levels can serve as a tumor marker; the tumor often does not secrete catecholamines. These observations suggest that somatostatin receptor expression is a favorable prognostic factor.[72,73]

Children with advanced neuroblastoma frequently show evidence of protein-calorie malnutrition associated with immunoincompetence, based on anergy to a variety of skin test antigens.[74,75] Rickard and colleagues[74,75] demonstrated that patients with stage IV neuroblastoma who were malnourished at diagnosis had more treatment delays and a significantly worse outcome than adequately nourished counterparts with similar disease severity. These findings suggest that a nutritional assessment at diagnosis should be a component of the patient's staging.[74] In addition, Van Eys and colleagues[76] and Rickard and colleagues[74,75] showed that significant nutritional depletion occurs with multimodal cancer therapy and that total parenteral nutrition can replete and maintain the patient's nutritional status during intensive tumor therapy. In another study, Sala and colleagues[77] reported that the incidence of malnutrition in children with advanced neuroblastoma was 50%. They stressed the importance of nutritional status and its possible influence on the course of the disease and survival. Of interest is a study from Toronto, Canada, that implies that mandatory folic acid fortification of flour—initially intended to reduce the incidence of neural tube defects—was associated with a 60% decrease in the incidence of neuroblastoma in the province of Ontario.[78]

Neuroblastoma may spread by direct extension into surrounding structures, lymphatic infiltration, or hematogenous metastases. Regional and distant lymph nodes, liver, bone marrow, and bone cortex are frequently involved.[5,10,11,79–81] Patients with bone cortex metastases have an ominous prognosis. Bone metastases occur in sites containing red marrow and involve the metaphyseal areas of long bones in addition to the skull, vertebral column, pelvis, ribs, and sternum.[1,5,10,11] Bone lesions may cause extreme pain and may be first identified when a child refuses to walk because of leg pain. Hematogenous metastases to the brain, spinal cord, and heart are unusual. Brain metastases usually manifest in

older children with headaches and seizures.[8,82] Lung metastases are found on chest radiographs in only 4% of patients.[83] This may be the result of direct extension to the lung from mediastinal lymph nodes or diffuse hematogenous spread, presenting with a radiographic pattern that may be confused with pulmonary edema or interstitial pneumonia.[83] Lung involvement by intralymphatic metastases (not seen on chest radiographs) may be noted at autopsy. Occasionally, patients with advanced disease present with a bleeding diathesis related to thrombocytopenia from extensive involvement of bone marrow and interference with hepatic production of clotting factors by liver metastases. Multiple subcutaneous skin nodules and hepatomegaly may occur in infants with stage IV-S neuroblastoma.

# Diagnosis

Diagnosis of neuroblastoma is made through a variety of imaging and isotopic studies, serum and urine determinations, and histologic and genetic evaluation of tumor tissue. On the plain abdominal radiograph, approximately 50% of cases may show finely stippled tumor calcification.[10,11,14] Radiographs also may show displacement of bowel gas by a mass. Paraspinal widening is commonly found with celiac axis tumors. Chest radiographs may show a posterior mediastinal tumor, a paraspinal widening above the diaphragm from extension of an abdominal tumor, or a primary thoracic tumor. The diagnostic workup of patients with retroperitoneal tumors includes an initial upright radiograph of the abdomen, an ultrasound examination to distinguish a cystic from a solid lesion, and an evaluation for potential obstruction or compression of the inferior vena cava. As a rule, obstruction of the inferior vena cava in patients with neuroblastoma suggests the presence of an initially unresectable lesion.[10,84] Computed tomography (CT) can demonstrate tumor calcification in approximately 80% of cases (Fig. 31-4).[14,85] With CT studies using contrast enhancement, one can often distinguish kidney and liver from adrenal and paraspinal lesions and evaluate for intracranial extension of skull metastases.[10,85,86] Magnetic resonance imaging (MRI) is extremely useful in detecting intraspinal tumor extension and, in some instances, the tumor's relationship to major vascular structures. Helical (spiral) CT with three-dimensional reconstruction is also a useful method of evaluating this latter relationship. Abdominal CT is performed with intravenous contrast material, so that an intravenous urogram can be acquired during the same study.[84] In most instances, paraspinal or adrenal neuroblastoma causes lateral or downward displacement of the ipsilateral kidney or ureter (or both). A separate intravenous urogram is not necessary. Metaiodobenzylguanidine (MIBG) also images both soft tissue and bony disease. A recent study for the International Neuroblastoma Risk Group (INRG) task force proclaims MIBG the most sensitive and specific imaging modality for staging purposes for neuroblastoma, in addition to recognizing response to treatment, especially when a semiquantitative scoring method is used.[87] A long bone survey, isotopic bone scintigraphy (using the bone-seeking isotopes technetium and $^{131}$I-MIBG), and multiple bone marrow aspirates are also obtained.[10,11,84,85] Isotopic bone scans are also used to identify bone metastases; they show a close correlation with the radiographic skeletal survey and are occasionally more sensitive.[85] False-positive bone scans can occur in cases of recent bone trauma or inflammation. The bone-seeking isotopes are picked up by metastatic foci in the bone and by the punctate calcifications in the primary tumor (Fig. 31-5).[10,14] Demonstration of the bone-seeking isotope in a retroperitoneal or posterior mediastinal mass suggests that the lesion is a neuroblastoma. Although angiography was once performed to evaluate many childhood tumors, this test is rarely used today because vascular structures can be readily identified with less potential morbidity by other imaging studies such as helical CT or magnetic resonance angiography (Fig. 31-6).

Because neuroblastoma is a tumor derived from neural crest cells, it may secrete hormonal products and is likely a member of the amine precursor uptake and decarboxylation (APUD) family of tumors. More than 90% of children with neuroblastoma have tumors that produce high levels of catecholamines or their byproducts. Quantification of

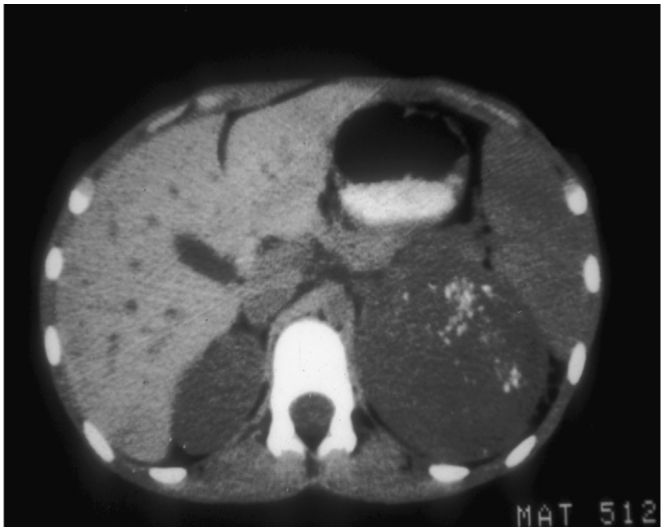

**FIGURE 31-4** Abdominal computed tomography shows a retroperitoneal mass with stippled calcification, consistent with neuroblastoma.

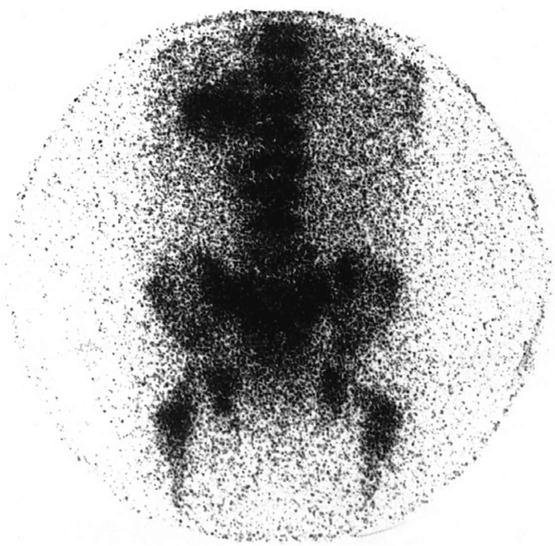

**FIGURE 31-5** $^{123}$I-MIBG scintiscan shows the presence of bone metastases and uptake of the isotope in a primary tumor in the adrenal gland.

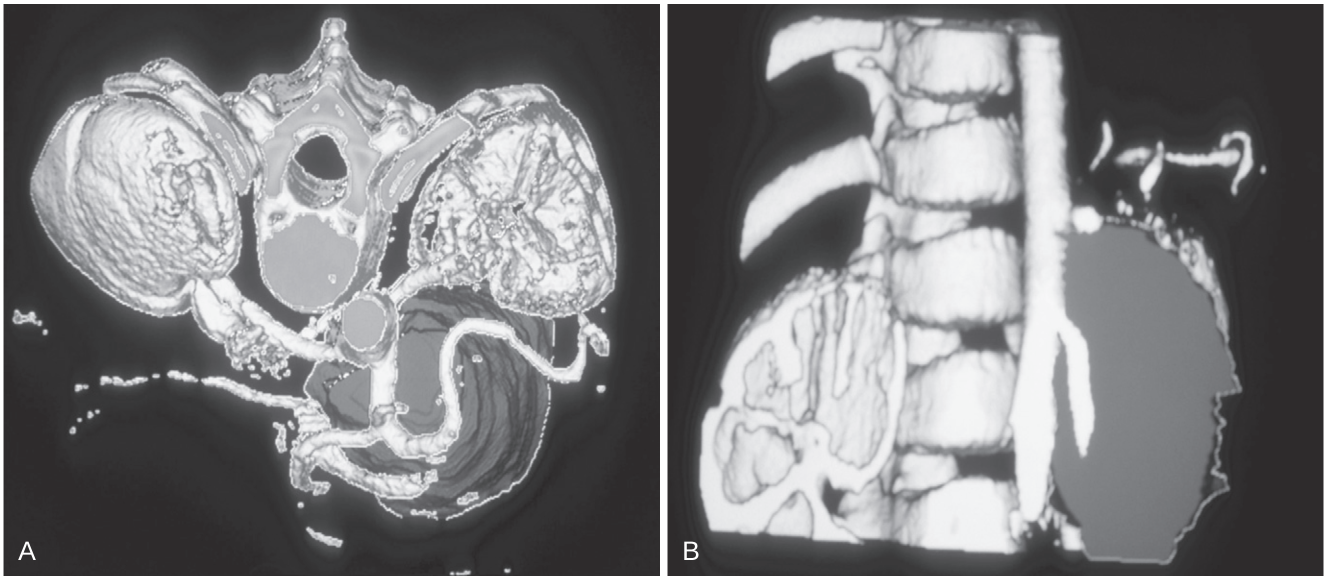

**FIGURE 31-6** Helical computed tomography scan with three-dimensional reconstruction of a neuroblastoma arising near the celiac axis. **A,** Anterior view indicates that the tumor does not involve the branches of the celiac axis. **B,** Lateral view demonstrates that the superior mesenteric artery passes through the tumor.

catecholamine byproduct secretion is best done by 24-hour urine collection.[86] Adrenaline, noradrenaline, dopamine, metanephrine, HVA, VMA, and vanillylglycolic acid levels are determined. Children with immature, more undifferentiated tumors tend to excrete higher levels of certain byproducts (e.g., HVA).[14] Patients with more mature tumors excrete more VMA. In rare instances, however, the tumor does not secrete excessive catecholamines. Prasad and colleagues[88] suggested that these are parasympathetic neuroblastomas that secrete increased levels of acetylcholine and fail to metabolize tyrosine to dopamine. Patients with advanced malignancy have elevated urine concentrations of cystathionine and homoserine; increased serum levels of neuron-specific enolase, ferritin, and lactic dehydrogenase; and, in 25% of cases, sera positive for carcinoembryonic antigen.[89–93] Hann and colleagues[89] reported that 63% of patients with stage IV disease had high serum ferritin levels, which was predictive of a poor prognosis, especially in girls older than 2 years. A number of studies showed that neuroblastic tumors produce increased serum levels of neuron-specific enolase.[90,92] Zeltzer and colleagues[93] documented that neuron-specific enolase levels are elevated in 96% of patients with metastatic disease and that high serum levels are associated with a poor prognosis, particularly in infants. Elevated serum lactic dehydrogenase levels are also associated with a poor prognosis in localized neuroblastoma.[91] Although these observations are of historical interest, none of these serum levels are independent prognostic factors, nor are they currently used to determine treatment. Although histologic examination of tissue is the key to the conclusive diagnosis of neuroblastoma, in advanced disease, rosettes of tumor cells in bone marrow aspirate and increased urinary excretion of VMA or other catecholamine byproducts are often considered indicative of the diagnosis. Immunologic analysis of bone marrow aspirate may be more sensitive than conventional analysis in detecting tumor cells.[94] Serial immunocytologic analysis of peripheral blood samples has also identified circulating neuroblasts, documenting tumor dissemination.

## Staging

Various staging schemes for neuroblastoma were used in the past. In 1988, an international staging system was devised, establishing a common set of criteria that could be used worldwide and would permit the accrual of large numbers of cases and allow valid comparisons of data (Table 31-1).[95] This system takes into account tumor size and location relative to the midline, in addition to the presence and degree of metastatic disease. It depends on the extent of surgical resection of the primary tumor in patients with nonmetastatic disease. Recently, the INRG developed a new staging system that takes into account pretreatment imaging of the tumor and bone marrow morphology, instead of surgical resection, which is dependent upon the approach of the surgeons and thus varies from institution to institution; this system appears in Table 31-2.[96] The aim of this system is to better evaluate pretreatment risk based on image-defined risk factors, and was developed to be used in tandem with the international system. In contrast to the International Neuroblastoma Staging System (INSS), infiltration across the midline is not included in this classification system.[96] Prospective analyses to validate this new system are ongoing.

## Pathology and Histology

The pathologic classification of neuroblastoma has been revised, and histologic features of the tumor that have important prognostic value have been established.[97–99] Previously, the Shimada classification system was used. The Shimada

**TABLE 31-1**
**International Neuroblastoma Staging System**

| Stage | Description |
|---|---|
| I | Localized tumor confined to area of origin; complete excision, with or without microscopic residual disease; ipsilateral and contralateral lymph nodes negative (nodes attached to primary tumor and removed en bloc with it may be positive) |
| IIA | Unilateral tumor with incomplete gross excision; ipsilateral and contralateral lymph nodes negative |
| IIB | Unilateral tumor with complete or incomplete excision; positive ipsilateral, nonadherent regional lymph nodes; contralateral lymph nodes negative |
| III | Tumor infiltrating across the midline with or without lymph node involvement; or unilateral tumor with contralateral lymph node involvement; or midline tumor with bilateral lymph node involvement or bilateral infiltration (unresectable) |
| IV | Dissemination of tumor to distant lymph nodes, bone, bone marrow, liver, or other organs |
| IV-S | Localized primary tumor as defined for stage I or II with dissemination limited to liver, skin, or bone marrow (limited to infants younger than 1 yr) |

**TABLE 31-2**
**The New International Neuroblastoma Risk Group Staging System**

| Stage | Description |
|---|---|
| L1 | Localized tumor not involving vital structures as defined by the list of image-defined risk factors and confined to one body compartment |
| L2 | Locoregional tumor with presence of one or more image-defined risk factors |
| M | Distant metastatic disease (except stage MS) |
| MS | Metastatic disease in children younger than 18 months with metastases confined to skin, liver, and/or bone marrow |

Note: Patients with multifocal primary tumors should be staged according to the greatest extent of disease as defined in the table.

system divided neuroblastic tumors into age-related favorable and unfavorable histologic categories, based on whether the tumor exhibited a stroma-rich or stroma-poor appearance (Table 31-3).[98] Stroma-rich tumors are characterized by extensive Schwannian stroma and signs of neuroblastic differentiation (i.e., developed nuclear and cytoplasmic features of ganglion cells). Stroma-poor tumors contain immature, undifferentiated neural crest cells and have a high mitotic karyorrhexis index (MKI). The MKI refers to nuclear fragmentation and is determined by the sum of the number of necrotic tumor cells; the number of cells with mitosis; and the number of cells with malformed, lobulated, or pyknotic nuclei per 5,000 cells examined. The MKI varies with age; a high MKI value in infants younger than 18 months is greater than 200/5,000 cells, and for those older than 18 months it is greater than 100/5,000 cells. All patients older than 5 years have unfavorable

**TABLE 31-3**
**Modified Shimada Pathologic Classification of Neuroblastic Tumors**

| | Age | *Favorable Histology* | *Unfavorable Histology* |
|---|---|---|---|
| Stroma-rich appearance | All | Well differentiated (ganglioneuroma) Ganglioneuro-blastoma, intermixed | Ganglioneuro-blastoma, nodular |
| Stroma-poor appearance (i.e., neuroblastoma) | Age $<$ 18 months | MKI $<$ 4% | MKI $>$ 4% or undifferentiated |
| | Age 18-60 months | MKI $<$ 2% and differentiating | MKI $>$ 2%, or undifferentiated or poorly differentiated |
| | Age $>$ 5 years | None | All |

histology. Stroma-poor tumors often have *MYCN* amplification, a high MKI, and a dismal outcome. A report by Shimada and colleagues[99] documented that both histology and *MYCN* amplification provided prognostic information that was independent of staging. Neuroblastomas with *MYCN* amplification have a characteristic histopathologic phenotype and a rapidly progressive clinical course.

The International Neuroblastoma Pathology Classification (INPC) adopted the Shimada classification with some minor modifications.[90,100–102] This age-linked classification is both prognostically significant and biologically relevant. The current system subdivides the undifferentiated subtype into undifferentiated and poorly differentiated tumors; changes the name of "stroma-rich, well-differentiated" tumors to "ganglioneuroma intermixed"; and adds a descriptive Schwannian, stroma-dominant character to ganglioneuroma.[103] There is also a ganglioneuroblastoma nodular (GNBn) group that is both Schwannian stroma rich/stroma dominant and stroma poor. Age remains a critical prognostic factor, and the grade of differentiation and MKI have different prognostic effects, depending on the patient's age at diagnosis. Favorable tumors are those that are poorly differentiated in children younger than 1.5 years of age, differentiating in children younger than 5 years of age, ganglioneuroblastoma intermixed, and ganglioneuroma. MKI is low (in those less than 5 years of age) or intermediate (in those less than 1.5 years of age) in this group as well. Unfavorable tumors are those that are undifferentiated or poorly differentiated in children older than 1.5 years, or any subtype of neuroblastoma in children older than 5 years. Patients with high MKI, or patients older than 1.5 years with an intermediate MKI, also have an unfavorable prognosis.[101] Although the presence of calcification was thought to favorably influence survival, further studies demonstrated that calcification does not have an independent prognostic impact.[97,103] Favorable Shimada histology was associated with an 85% survival rate, compared with 41% for unfavorable histologic

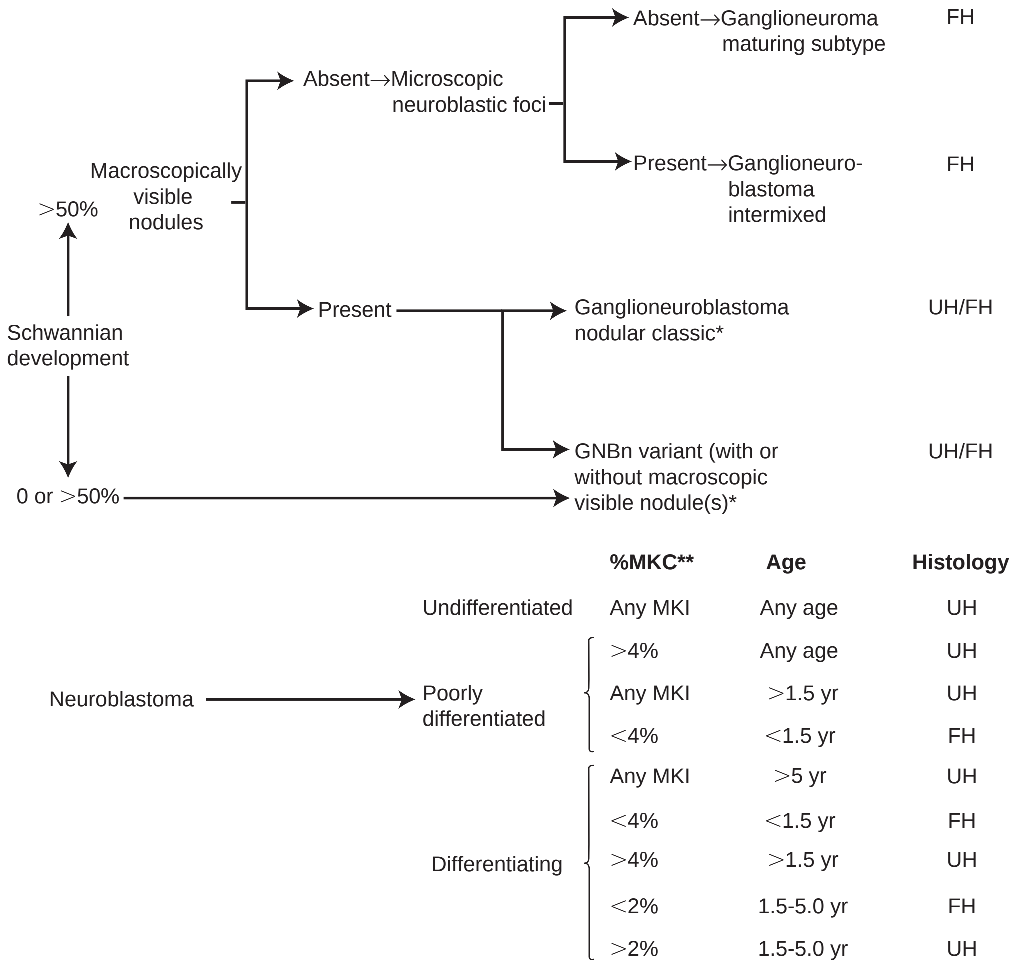

**FIGURE 31-7** International Neuroblastoma Pathology Classification. FH, favorable histology; GNBn, ganglioneuroblastoma nodular; MKI, mitotic karyorrhexis index; %MKC, mitotic and karyorrhectic cells; UH, unfavorable histology; *classic GNBn (single, macroscopically visible, usually hemorrhagic nodule in stroma-rich, stroma-dominant tissue background; **MKC 2%, 100 of 5,000 cells; MKC 4%, 200 of 5,000 cells. (From Peuchmaur M, d'Amore ES, Joshi VV, et al: Revision of the International Neuroblastoma Pathology Classification: Confirmation of favorable and unfavorable prognostic subsets in ganglioneuroblastoma, nodular. Cancer 2003;98:2274-2281.)

types. All GNBn cases were initially classified as unfavorable tumors. Umehara and colleagues[104] were the first to define subsets of these specific neoplasms that exhibit different behavior. Peuchmaur and colleagues[105] recently revised the INPC by dividing GNBn cases into two prognostic subsets—favorable and unfavorable. The favorable type was associated with an 86% event-free survival, whereas the unfavorable type (two thirds of cases) had only a 32% event-free survival. Children with the favorable subset of GNBn have an overall survival of greater than 90%, compared with 33.2% for those with the unfavorable GNBn subset (Fig. 31-7).[106] Large cell neuroblastoma has been identified as a distinct phenotype with aggressive clinical behavior.[107] These tumors have unfavorable histologic features, including monomorphous undifferentiated neuroblasts, a low incidence of calcification, and a high MKI. Immunohistochemical studies showed that large cell neuroblastoma cells stained positive for neuron-specific enolase, prodrug gene products, and tyrosine hydroxylase, and were negative for CD99.[107]

On gross examination, neuroblastoma usually appears as a highly vascular purple-gray mass that is often solid but occasionally cystic. The tumor has an easily ruptured, friable pseudocapsule that may lead to significant hemorrhage during operative manipulation. The tumor is often necrotic, especially the undifferentiated form. Mature tumors (ganglioneuromas) have a more solid consistency and frequently have a fleshy white color. The histologic pattern may be quite variable. Primitive stroma-poor neuroblastomas may be indistinguishable from other small, blue round cell tumors, such as Ewing tumor, rhabdomyosarcoma, or primitive neuroectodermal tumors. The neuroblast is a small round cell consisting predominantly of the nucleus without much cytoplasm. Immature, undifferentiated tumors are characterized by closely packed small spheroid cells without any special arrangement or differentiation.[108] Nuclei may appear cone shaped and are hyperchromic. Rosette formation may be observed and is considered a sign of early tumor differentiation (Fig. 31-8). The center of each rosette is formed by a tangle of fine nerve fibers. More mature-appearing, stroma-rich tumors may contain cells that resemble normal ganglion cells, with an admixture of histologic components characterized by abundant nerve filaments, neuroblastic rosettes, and ganglion cells all seen in a single microscopic field.[28,109] On electron microscopy, neurofibrils and electron-dense, membrane-bound neurosecretory granules may be observed. The neurosecretory granules may be the site of conversion of dopamine to norepinephrine.

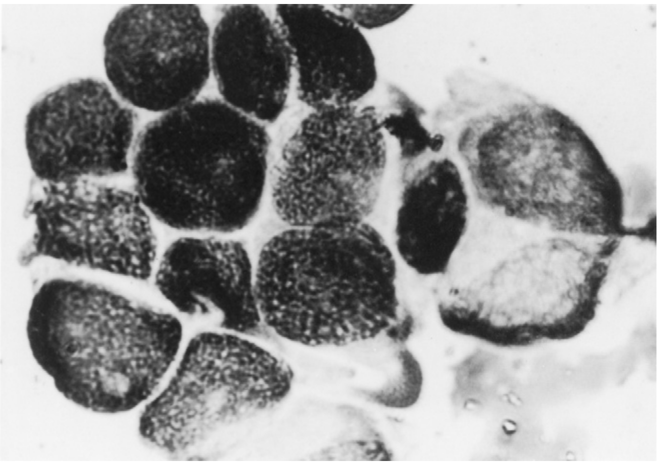

FIGURE 31-8 Histologic appearance of rosettes of neuroblastoma cells from a bone marrow aspirate, an early sign of tumor differentiation.

These ultrastructural findings and genetic identification of the tumor tissue can usually separate neuroblastoma from other small cell tumors. Segregation of neuroblastoma from other tumors can also be achieved by immunohistochemical staining that is positive for neurofilament proteins (S-100), synaptophysin, neuron-specific enolase, ganglioside GD2, chromogranin A, and tyrosine hydroxylase staining for these markers is negative in other small round cell tumors.[110]

Instances of spontaneous maturation from a highly malignant, undifferentiated neuroblastoma to a ganglioneuroblastoma, and subsequently to a benign ganglioneuroma, have been observed. Ambros and colleagues[111] reported that maturing neuroblastomas consist of both Schwann cells and neuronal cells, including ganglion cells. Schwann cells have normal numbers of chromosomes and triploid flow cytometry, in contrast to other neuronal cells, including ganglion cells.[102] These observations suggest that Schwann cells may be a reactive population of normal cells that invade a neuroblastoma, recruited or attracted by trophic factors, and may be responsible for tumor maturation and serve as an antineuroblastoma agent.[112,113] Schwann cells also produce angiogenesis inhibitors that induce endothelial cell apoptosis and may limit tumor growth by restricting angiogenesis.[1,114]

# Biologic and Genetic Alterations

Unique oncogenes are observed in tumors, such as *MYCN* and *RAS* oncogenes.[1,8] Amplification of *MYCN* (>10 copies) is associated with advanced disease, tumor progression, and a poor outcome, especially in children older than 1 year.[1,8,95,98,115,116] The *MYCN* proto-oncogene is located on the short arm of chromosome 2p24. Double minutes and long, nonbanding staining regions have been observed at this site and may represent amplified cellular genes. Studies have determined that the MycN protein binds DNA and leads to an increase in the level of endogenous Mdm2 mRNA and protein expression, with consequent p53 inhibition. This modification of Mdm2 levels by N-myc may partially explain its role in the aggressiveness of neuroblastoma.[117,118] Approximately 30% of patients with neuroblastoma have tumors with *MYCN* amplification. More than 90% of patients with *MYCN* amplification have rapidly progressive disease and are resistant to therapy.

Cellular DNA content is a predictor of response to chemotherapy in infants with unresectable neuroblastoma. DNA flow cytometry studies evaluating tumor ploidy indicate that children with diploid tumors have a worse outcome than those with aneuploid (hyperdiploidy or triploidy) tumors.[1,10] Similar to *MYCN* status, DNA ploidy is of prognostic value independent of stage and age, and the two factors (*MYCN* status, and ploidy) together provide important complementary prognostic information for infants.[1,111] DNA ploidy flow cytometry correlates well with response to chemotherapy and outcome. *MYCN* amplification is commonly associated with chromosome 1p deletion and diploidy.[119,120] Diploid tumors are commonly associated with an unbalanced gain of chromosome 17q, even in the absence of *MYCN*.[1,6,116,120] The most common cytogenetic abnormalities in neuroblastoma are 1p deletion and 17q gain.[119] Both abnormalities are poor prognostic factors and are associated with worse outcomes.[1,6,121–123] Allelic loss of 11q and 14q and gains of 4q, 6q, 11q, and 18q have also been observed (Table 31-4).[1]

**TABLE 31-4**
**Genetic Alterations in Neuroblastoma**

| *Genetic Feature* | *Associated Factor* | *Risk Group* |
|---|---|---|
| *MYCN* amplification | Diploidy or tetraploidy, allelic loss of 1p, high Trk-B, advanced stage (III, IV) | High |
| Allelic gain 17q | More aggressive tumor associated with *MYCN* amplification | High |
| Gain at 4q, 6p, 7q, 11q, 18q | Occurs concurrently with *MYCN* amplification | Risk related to *MYCN* status |
| Allelic loss 1p36 | Often associated with *MYCN* amplification | High |
| Allelic loss 11q | Few associated with *MCYN* amplification; correlates with LOH 14q | Intermediate decreased survival in patients without *MYCN* amplification |
| Allelic loss 14q | Correlates with LOH 11q, inverse relationship with allelic loss 1p and *MYCN* amplification | Intermediate |
| Predisposition of 16p12-13 | Familial neuroblastoma, multifocal and bilateral neuroblastoma | Low |
| Association with chromosome 10 (*RET*-oncogene) | Hirschsprung disease | Variable |
| Association with 11p15.5 | Beckwith-Weidemann syndrome | Low |

Note: This table does not include changes in the genetic expression of TRK-A, TRK-B, and TRK-C; the multidrug-resistant protein gene; telomerase; or others that are covered elsewhere in this chapter.
LOH, loss of heterozygosity.

High expression of the neurotropin Trk-A (a high-affinity nerve growth factor receptor) is associated with a good prognosis and is inversely related to N-myc.[116,124] Trk-A is observed in young infants and in those with stage I and stage IV-S tumors, and indicates a very favorable outcome.[116,124] Trk-A is associated with neural cell differentiation and tumor regression and may play a role in angiogenic inhibition. Trk-A downregulates angiogenic factor expression and decreases the number of microvessels in neuroblastoma tumor cell lines. Multivariate analysis, however, suggests that N-myc expression is a more important independent prognostic factor. The low-affinity nerve growth factor receptor gene is another proto-oncogene that has a prognostic effect similar to Trk-A and probably influences cellular maturation.[1,8,125] In contrast, high expression of Trk-B with its ligand BDNF may provide an autocrine survival pathway in unfavorable tumors, particularly those with *MYCN* amplification, possibly by providing a tumor cell survival or growth advantage.[1,126,127] The Trk-B–BDNF pathway also contributes to enhanced angiogenesis, tumorigenicity, cell survival, and drug resistance.[1,126] These patients have more advanced disease, are usually older than 1 year, and have a dismal outcome.[1,126,127] Trk-C expression has also been identified in neuroblastoma and is usually observed in lower-stage tumors that do not express N-myc.[1,128] A recent report identified targets of *TRK* gene expression, and recognized upregulation of proapoptotic factors and angiogenesis inhibitors. Conversely, Trk-B expression was associated with upregulation of genes related to invasion and therapy resistance. Its activation is associated with increased proliferation, migration, angiogenesis, and chemotherapy resistance of neuroblastoma cells.[126,129]

Another gene has been cloned, the multidrug resistance (MDR)-associated protein gene, that is associated with chemotherapy resistance, overexpression of N-myc, and a poor outcome.[130] The prognostic role of the *MDR* gene (*MDR-1*) in neuroblastoma is controversial.[130,131] High levels of the *MDR*-associated protein gene (located on chromosome 16), however, are associated with a poor outcome. This effect is independent of stage, N-myc expression, and Trk-A status.[130] Similarly, elevated P-glycoprotein levels are associated with progressive disease and a poor outcome.[132,133] Telomerase is increased in tumor cells and maintains cell viability by preserving the telomeres that protect the end of chromosomes.[1,134] There is an inverse relationship between telomerase levels and outcome in neuroblastoma and a direct correlation between telomerase levels and *MYCN* amplification.[1] CD44 is a glycoprotein found on the cell surface of a number of tumors, including neuroblastoma. High expression of CD44 is associated with a favorable outcome and is usually found in well-differentiated tumors. In contrast, Nm23 overexpression is observed in instances of advanced and aggressive neuroblastoma.[135] The ganglioside GD2 is found on human neuroblastoma cell membranes, and increased levels are associated with active disease and tumor progression. Gangliosides inhibit the tumor-specific immune response, and GD2 has become a target for immunotherapy.[136]

Evaluation of the relationship between tumor angiogenesis and outcome in infants with neuroblastoma demonstrates that increased tumor vascularity characterized by microvessel density correlates with advanced disseminated disease and the likelihood of metastases.[137–140] Angiogenesis is associated with *MYCN* amplification, unfavorable histology, and poor outcome. Neuroblastoma produces angiogenic factors that induce blood vessel growth, including vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF-A), stem cell factor, and their respective receptors—Flk-1, PDGFR, and c-Kit.[141] Komuro and colleagues[142] demonstrated that high VEGF-A expression correlated with stage IV disease and suggested that it could be a target for antiangiogenic therapy. Kaicker and colleagues[143] noted that vascular endothelial growth factor VEGF antagonists inhibit angiogenesis and tumor growth in experimental neuroblastoma in athymic mice with xenograft neuroblastoma cell line NGP. They also found that thalidomide suppressed angiogenesis and reduced microvessel density but not tumor growth. Kim and colleagues[144] and Rowe and colleagues[145] also demonstrated inhibition of tumor growth in experimental neuroblastoma models using antiangiogenic strategies. Imatinib mesylate, a compound used to treat patients with gastrointestinal stromal tumors, has been shown to decrease the growth of neuroblastoma in vivo and in vitro, decrease cell viability, and increase apoptosis (by ligand-stimulated phosphorylation of c-Kit and PDGFR) in a severe combined immunodeficiency (SCID) mouse model.[141] Davidoff and colleagues[138] demonstrated that gene therapy using in situ tumor cell transduction with retroviral vectors can deliver angiogenesis inhibitors for the Flk-1 receptor and restrict tumor-induced angiogenesis and tumor growth.

The Bcl-2 family of proteins is responsible for relaying apoptotic signals that influence tumor cell regression and is expressed in most neuroblastomas. The *BCL-2* gene produces a protein that prevents apoptosis. The level of Bcl-2 expression is high in advanced cases associated with a poor outcome and low in cases demonstrating tumor apoptosis (regression) and differentiation. High Bcl-2 expression may also play a role in acquired resistance to chemotherapy.[146] Subgroups of the Bcl family include Bcl-xL, which inhibits apoptosis, and Bcl-xS, which induces natural cell death. VEGF upregulates Bcl-2 expression and promotes neuroblastoma cell survival by altering apoptosis and its regulation proteins.[147] Elevated caspase levels (enzymes responsible for apoptotic signaling) are associated with an improved outcome in neuroblastomas that demonstrate favorable biologic features.[1] It has been shown that CpG–island hypermethylation inactivates caspase-8, TRAIL apoptosis receptors, the caspase-8 inhibitor, in addition to other proapoptotic factors.[148,149] In view of this finding that gene hypermethylation leads to resistance patterns, demethylating agents, including decitabine, are currently being investigated in preclinical studies.[150]

## Neuroblastoma in Infancy

For many years, the age of the patient and the stage of disease at the time of diagnosis were the two key independent variables determining prognosis in children with neuroblastoma. Evans and colleagues[3] and others found that infants younger than 1 year and those with stage I, II, or IV-S disease had a significantly better outcome.[5,11,34,151,152] Historically, patients older than 1 year and those with advanced disease (stages III and IV) did poorly. The worst survival data were observed in patients older than 1 year with stage IV disease and metastases to cortical bone.[1,5,11,14,153]

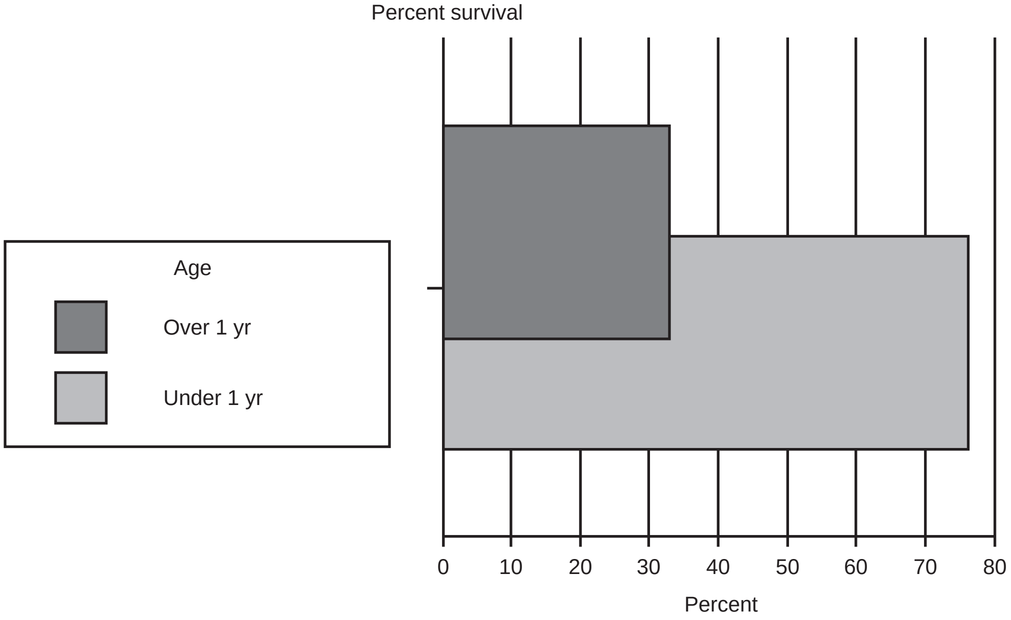

**FIGURE 31-9** Bar graph demonstrates the improved survival in infants with neuroblastoma who are younger than 1 year.

However, recent reviews have confirmed that 18 months serves as a better cutoff to predict outcome.[154–157]

Infants younger than 18 months at diagnosis have a significantly improved outcome. At the Riley Hospital for Children (Indianapolis, IN), the survival rate was 76% for infants younger than 1 year and only 32% for older patients (Fig. 31-9).[4] This favorable outlook for patients younger than 1 year extends across all stages, including infants with stage IV metastatic disease. The incidence of stage IV lesions in infants younger than 1 year is 30% compared with 60% to 70% in older patients.[4]

Infants with stage IV disease respond better to chemotherapy than do older children; 50% of infants have a complete response to treatment compared with 22% of older children.[158] This observation suggests that resolution of metastases may have a greater impact on length of survival than does the surgical excision. Further, this implies that surgical resection is beneficial in some infants and should be attempted when disseminated disease is controlled by chemotherapy. However, more intensive chemotherapy regimens and bone marrow transplantation (BMT) may be necessary to achieve a cure, especially in highly selected infants presenting with adverse biologic markers.

## Stage IV-S

The most unusual group of patients with neuroblastoma is those infants younger than 18 months with stage IV-S disease. This stage is characterized by hepatomegaly produced by extensive metastatic disease, subcutaneous metastases, and positive bone marrow with a primary tumor that would otherwise be classified as stage I or II. Stage IV-S cases account for approximately 30% of patients with neuroblastoma recognized in the first year of life.[4]

Some infants succumb from complications of their stage IV-S disease rather than progression of the tumor. Complications of severe hepatomegaly include respiratory insufficiency, caused by significant elevation of the diaphragm by the large, tumor-filled liver; coagulopathy; and renal compromise resulting from abdominal compartment syndrome produced by the mass (Fig. 31-10).[4,151,159–161] Vomiting may occur because of a change in the gastroesophageal angle related to the diaphragmatic elevation, resulting in gastroesophageal reflux, protein-calorie malnutrition, and aspiration pneumonia. Total parenteral nutrition may be a useful therapeutic adjunct.[74–76] Most fatalities in stage IV-S cases occur in infants younger than 2 months with severe symptoms related to hepatomegaly, who do not tolerate therapy as well as do older infants.[4,162] Symptomatic hepatomegaly caused by tumor infiltration may benefit from low-dose radiation to the liver in the range of 600 to 1,200 Gy, administered in doses of 100 to 150 Gy/day.[4,5,159] Although some early reduction in the size of the liver is seen, and peripheral edema may resolve in a few weeks, complete resolution may take 6 to 15 months.[4] Resolution of the liver mass is probably related more to the natural course of stage IV-S disease than to radiotherapy. Administration of low-dose cyclophosphamide 5 mg/kg per day is a reasonable treatment alternative. Although some investigators advocate the insertion of a Dacron-reinforced Silastic sheet to create a temporary ventral abdominal wall hernia to accommodate the enlarged liver and reduce intra-abdominal pressure, mortality resulting from septic complications has been observed.[4,159,163] To reduce the risk of infection, Lee and Applebaum[164] recommend the use of an internal polytetrafluorethylene patch to create a temporary ventral hernia. The graft can be removed in stages as the bulk of the hepatic mass regresses over time.

Survival of infants with remote metastases is greater than 80%, often without specific treatment. Most patients with stage IV-S disease (>90%) have favorable genetic and biologic factors, including high Trk-A expression, no *MYCN* amplification, favorable histology, and no evidence of allelic loss of chromosome 1p. This suggests that the majority of stage IV-S tumors undergo spontaneous regression. Although most patients with stage IV-S disease do well, Wilson and

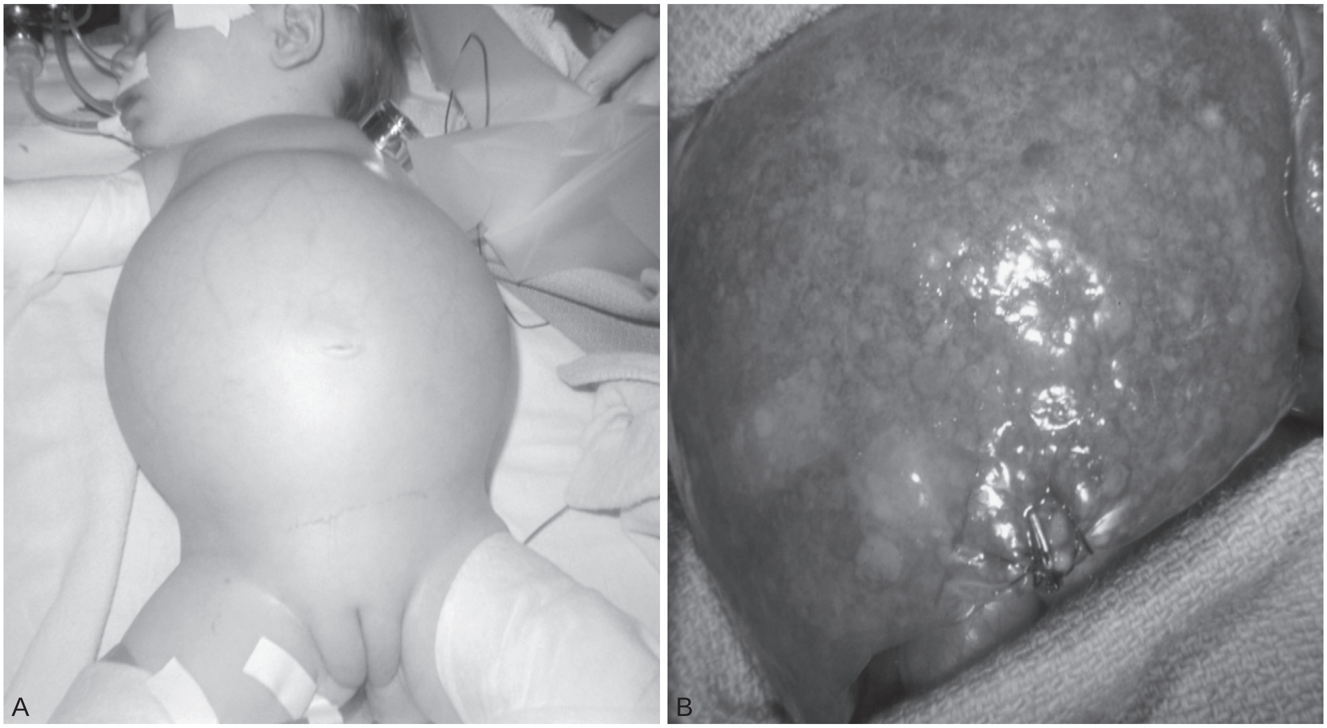

**FIGURE 31-10** **A,** Six-week-old infant presented with abdominal distention and hepatomegaly. **B,** Appearance of the liver at laparotomy. There were multiple metastatic nodules, and the biopsy confirmed the diagnosis of stage IV-S neuroblastoma.

colleagues[161] reported 18 cases with a heterogeneous tumor presentation and a survival rate of only 50%, including 3 patients with *MYCN* amplification. The presence of adverse genetic and biologic prognostic factors suggests that this subset of patients (<10%) requires more aggressive therapy. Of interest is that infants with multiple subcutaneous nodules seem to have the most favorable outlook. This may be because of increased immunologic activity as a result of tumor being present in multiple sites.[4] Increased uptake of major histocompatibility complex (MHC) class I antigen by neuroblastoma cells in vitro and in vivo may influence the outcome favorably.[165] Infants with stage IV-S disease have normal levels of MHC class I surface antigen expression, whereas those with stages I to IV have low levels.[165] Sugio and colleagues[166] reported that down-modulation of MHC class I antigen expression is associated with increased amplification of the *dMYCN* oncogene in patients with advanced disease.

In 2000, Nickerson and colleagues[162] described 80 infants with stage IV-S disease from the Children's Cancer Group (CCG). Fifty-eight cases were managed without specific therapy. All 44 asymptomatic patients survived without treatment. Symptomatic patients were treated with cyclophosphamide 5 mg/kg per day for 5 days and hepatic radiation at a dose of 4.5 Gy over 3 days. Five of six deaths occurred in symptomatic infants younger than 2 months. Event-free 5-year survival was 86%, and overall survival was 92%. Early intervention is imperative for stage IV-S patients with life-threatening complications (e.g., hepatosplenomegaly, coagulopathy, renal failure).[4,162] Surgical resection did not alter outcome. More aggressive chemotherapy is also required in those cases in which the tumor demonstrates more than 10 copies of *MYCN*, chromosome 1p deletion, or other adverse biologic markers.[4,162,167] Amplification of *MYCN* may be observed in 1 of 12 patients with stage IV-S tumors who develop progressive disease and die, despite having a favorable prognostic stage. In 2003, Schleiermacher and colleagues[167] reported on 94 infants with stage IV-S neuroblastoma in France; they observed an 88% overall survival and recommended a more intensive regimen using cisplatin and etoposide for those who require therapy. Some infants with stage IV-S disease have survived without resection of the primary tumor (in some, the primary tumor may not be identified).

## Cystic Neuroblastoma

Cystic neuroblastomas are relatively rare and are often identified on prenatal ultrasound examinations.[168] They characteristically occur in the adrenal gland, and almost all are diagnosed in early infancy (Fig. 31-11). Few are calcified, and only 10% are associated with elevation of urinary VMA and HVA levels.[169] They display a benign behavior and a favorable outcome. Some evidence suggests that they often regress and undergo spontaneous involution.[26] Some investigators have recommended observation alone, with close serial sonographic monitoring during the first few months of life. Operative resection should be reserved for tumors that fail to regress or that increase in size. Adjuvant chemotherapy is rarely required after resection. The Children's Oncology Group (COG) has performed a prospective study of observation alone for cases of perinatal neuroblastoma, with strict criteria for enrollment, including tumor volume (<16 mL, if solid, or <65 mL, if cystic). Results from the study are not yet available.

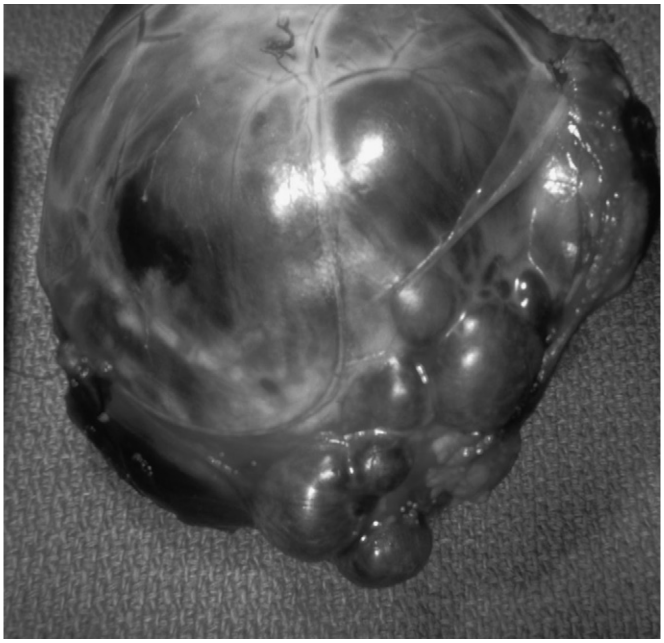

**FIGURE 31-11** Photograph of a cystic neuroblastoma of the adrenal gland in a 5-month-old baby who required complete excision. The patient was managed by surgery alone and is a long-term survivor.

# Multifocal and Bilateral Neuroblastoma

Bilateral neuroblastoma is relatively uncommon, occurring primarily in familial cases and young infants with alterations at the predisposition locus on chromosome 16p12-13.[29] Therapy has included observation alone; unilateral resection, with observation of the second (smaller) lesion or enucleation; and bilateral adrenalectomy, with postoperative hormonal replacement. Some bilateral tumors resolve spontaneously, while others persist and enlarge, requiring surgical intervention. The prognosis is generally good for these tumors, and most of the children survive. Occasionally these infants have other sites of multifocal disease. Tumor enucleation has been performed in cases with favorable biologic markers to preserve adrenal function. Hiyama and colleagues[170] described multifocal neuroblastoma in 8 of 106 cases (7.5%). Seven of eight cases had favorable histology, and all expressed Trk-A1 mRNA and the Ha-ras p21 protein. None of the tumors had *MYCN* amplification or elevated telomerase levels. Four had near-triploid DNA on flow cytometry, and all 8 had a proliferative index (percentage of cells in the S phase) of less than 25%. Four patients were treated with multistage resections. Five had bilateral neuroblastoma and were treated with tumor enucleation. All survived and are free of recurrence, and none require steroid replacement. The authors reviewed 53 additional cases of multifocal disease and noted that 18 had a family history of neuroblastoma and 25 were detected incidentally. Because of the excellent prognosis in patients with favorable biologic features, Hiyama's group recommended conservative surgical excision (enucleation) using minimally invasive surgical techniques.[170]

# Risk Stratification and Risk-Based Management

During the past 2 decades, a number of biologic and genetic factors have been identified that are important prognostic indicators and currently define therapy in North America. Based on the INSS, the use of the INPC, and the identification of numerous biologic and genetic characteristics as risk factors and predictors of outcome, a risk-based management system has been developed to determine treatment.[1,10,100–103] Newer treatment protocols individualize treatment using risk factors as predictors of outcome in an effort to maximize survival, minimize long-term morbidity, and improve the quality of life. Current protocols now categorize patients as low, intermediate, and high risk based on their prognostic factors (Table 31-5). Good outcomes are associated with stage I, II, and IV-S patients who are younger than 18 months and have hyperdiploid DNA flow cytometry, favorable histology, less than 1 copy of *MYCN*, high Trk-A expression, and absence of chromosome 1p abnormalities. In contrast, a poor prognosis is predicted in children older than 18 months with advanced tumors (stages III and IV), more than 10 copies of *MYCN*, low Trk-A expression, diploid DNA ploidy, allelic loss of 1p36, and unfavorable histology.

The site of the primary tumor was also considered predictive of survival by some investigators. Patients with tumors in cervical, pelvic, and mediastinal locations had an improved outlook compared with children with retroperitoneal (paraspinal or adrenal) tumors. Breslow and McCann[153] and Koop and Schnaufer,[152] however, suggested that the improved outlook in these cases can be explained by the patient's age and stage of disease. Despite these conflicting views, Filler and colleagues,[56] Young,[57] and Adams and colleagues[171] reported that site is a beneficial prognostic indicator for mediastinal lesions, and Haase and colleagues[5] noted the same for pelvic tumors, regardless of other factors.

Some early reports concerning neuroblastoma suggested that the more mature and differentiated the tumor, the better the prognosis.[108] Others noted that a more mature histology may be associated with the same dismal outcome as in patients with undifferentiated neuroblasts.[152] In patients with metastatic disease, the presence of more mature elements seemed to improve the outlook and was associated with increased survival.[9,11] Shimada and colleagues[101] subsequently classified the histopathology of neuroblastoma into favorable and unfavorable types, characterized by a stroma-rich appearance for the former and a stroma-poor appearance for the latter. The Shimada classification was also age related. The impact of Shimada histology class on prognosis proved to be important, especially when associated with other prognostic biologic variables, particularly amplification of the *MYCN* oncogene and allelic loss on the short arm of chromosome 1p (1p36).[99] The current INPC (which embraced and modified the Shimada classification) further divided cases into subsets of favorable and unfavorable histologic types and is a highly significant independent predictor of prognosis.[98,102,103,105,172] *MYCN* amplification is seen in approximately 30% of neuroblastoma cases and has an important role in modulating the malignant phenotype in neuroblastoma.[1,124,173] The prognostic value of *MYCN* status is independent of tumor stage and patient age. *MYCN* amplification is associated with a poor response to treatment,

**TABLE 31-5**
**Neuroblastoma Risk Groups***

| Risk Group | INSS Stage | Age | MYCN Amplification Status† | DNA Ploidy‡ | INPC (Modified Shimada) Histology |
|---|---|---|---|---|---|
| Low | 1 | Any | Any | Any | Any |
| Low | 2a/2b | Any | Not amplified | Any | Any |

rapidly progressive disease, and a dismal outcome. Although attempts to stimulate tumor maturation with nerve growth factor, adrenergic agonists, papaverine, prostaglandins, exogenous cyclic adenosine monophosphate, and hyperthermia were successful in the laboratory setting, there was minimal clinical evidence of their usefulness.[14,109,174–177] The use of retinoids as a promoter of differentiation, however, has rekindled interest in this concept and has been successful in prolonging survival in advanced cases during clinical trials.[174] The addition of cis-retinoic acid to the treatment protocol for high-risk cases of neuroblastoma following BMT or peripheral stem cell transplantation is now standard practice.[1]

A new pretreatment classification system based on 13 prognostic factors has recently been developed by the INRG, aiming to create international consensus for risk stratification. These factors include age, INRG stage, histology, DNA index, *MYCN* amplification status, and presence of 11q abnormality; they classify patients into 1 of 16 groups. Each group is categorized as very low, low, intermediate, and high risk, based on event-free survival rates of more than 85%, more than 75% to less than or equal to 85%, greater than or equal to 50% to less than or equal to 75%, or less than 50%, respectively.[178]

For low-risk patients, surgical excision of the tumor is usually curative and avoids the risks associated with chemotherapy. Intermediate-risk patients are usually treated with surgery and chemotherapy. Studies aimed at minimizing treatment regimens for this group of patients are ongoing. The poor prognosis in high-risk patients justifies a much more intense treatment regimen, including combination chemotherapy followed by complete surgical excision (if possible), radiotherapy to achieve local control, myeloablative treatments with bone marrow rescue, and biologic therapy.

## Operative Management

Initial surgery for extensive stage III and IV tumors should be limited to biopsy of tumor tissue, staging, and placement of a vascular access device. There is an increased rate of surgical complications when complete resection is attempted during initial surgery, with no improvement of survival.[179] After 4 or 5 cycles of chemotherapy, second-look surgery is performed. Although opinions vary regarding resection in high-risk patients, most investigators agree that complete gross resection, which is associated with excellent local control and improved outcome,[179,180] should be the goal of second-look procedures. Complete surgical removal of the primary tumor remains an essential component of treatment in the vast majority of cases.

During resection, adequate intravenous access is important because these tumors are quite vascular, and blood loss may be significant. Blood pressure must be carefully monitored intraoperatively to detect sudden hypertension caused by excessive catecholamine release from the tumor.

The surgical approach depends on the characteristics of the primary tumor. For upper abdominal lesions, particularly those involving major midline vessels, thoracoabdominal exposure is advantageous and well tolerated. The goal of resection is a complete dissection of the vasculature and should include the primary tumor site, in addition to all regional lymph nodes. Neuroblastoma often adheres to or surrounds the great vessels, and special care should be taken to identify and spare the blood supply to important visceral structures, such as the branches of the celiac axis and superior mesenteric artery.

In most children with localized disease, all or most of the tumor can be removed successfully. En-bloc contiguous resection of normal surrounding structures, such as the spleen,

stomach, pancreas, and colon, almost always can be avoided. In some cases, it is impossible to separate an adrenal or paraspinal neuroblastoma from the ipsilateral kidney, so nephrectomy may be necessary. It is important to excise any suspicious para-aortic and perirenal lymph nodes for staging purposes. A routine retroperitoneal lymph node dissection is usually not performed. The margins of the tumor resection are marked with titanium clips to guide the port if radiation is required and will reduce the scatter effect noted with other types of metal clips on follow-up CT scanning.

Because neuroblastoma may have a friable pseudocapsule, careful handling of the tumor during dissection is important to avoid tumor spill and hemorrhage. Primary adrenal tumors may be fed by a number of small arteries. The major venous drainage is usually constant, directly to the inferior vena cava on the right side, and into the left renal vein and subdiaphragmatic vessels on the left. Inferiorly located paraspinal and primary pelvic tumors often require careful dissection to separate the lesion from the bifurcation of the aorta and inferior vena cava. The tumor frequently extends into the intervertebral foramina (Fig. 31-12).

Minimally invasive surgical techniques have also been employed for selected cases of neuroblastoma.[180] Adrenal tumors initially detected by mass screening have been excised laparoscopically by a number of investigators.[181,182] Yamamoto and colleagues[49] described three cases of adrenal neuroblastoma in which the lesions were less than 20 mm in diameter. They used a 5-trocar technique and kept the intra-abdominal pressure for the pneumoperitoneum less than 4 mm Hg. The well-encapsulated tumors were completely excised; they were placed in a plastic bag and removed through the 10-mm trocar site. All had favorable

Note the vascular loops placed around the iliac arteries, right iliac vein, and ureter to facilitate a safe dissection.

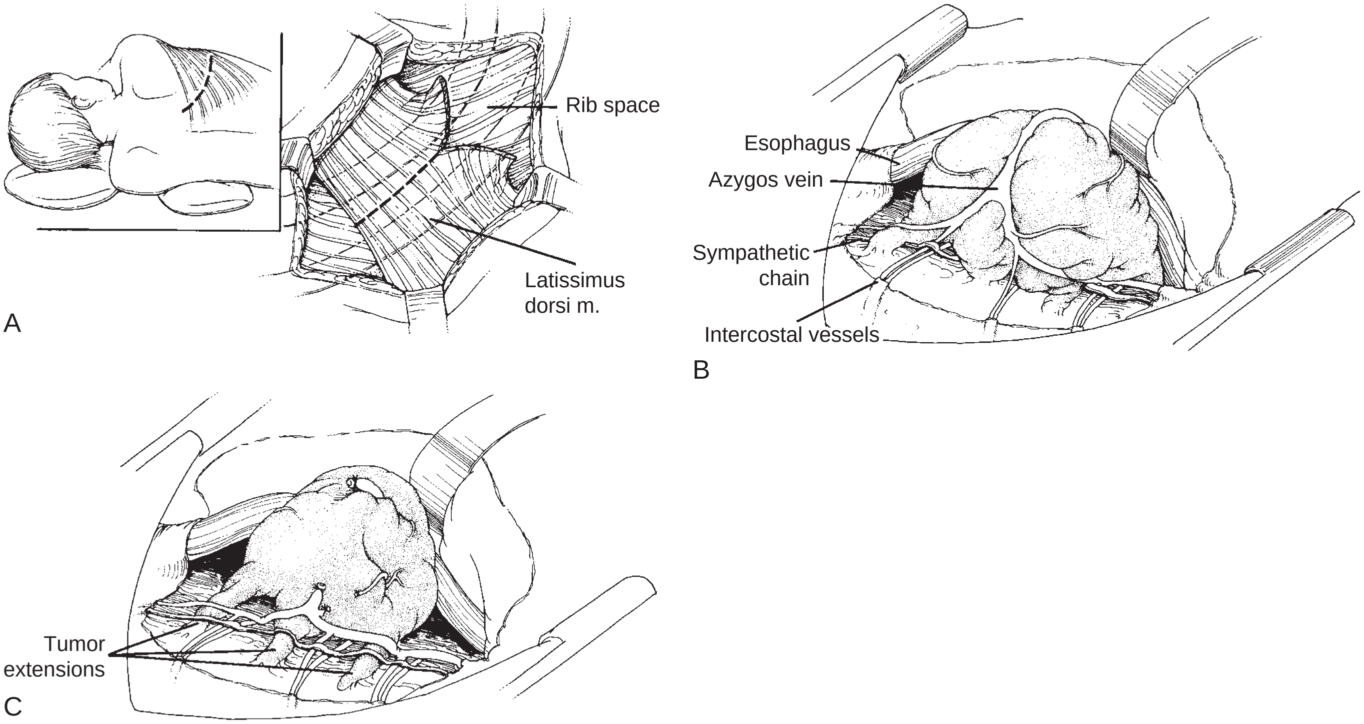

**FIGURE 31-13** **A,** Right posterolateral thoracotomy incision used for the excision of a posterior mediastinal neuroblastoma. **B,** Relationship of the tumor to surrounding tissues. **C,** The tumor is mobilized and retracted anteriorly, exposing numerous intervertebral extensions. The tumor extensions are divided at the vertebral foramina, leaving small remnants of residual tumor behind. This does not adversely influence the outcome.

histology, and none had *MYCN* amplification. No recurrences were observed. This and other reports suggest that, in selected cases, laparoscopic biopsy and tumor excision are both safe and effective.[181–183]

Mediastinal tumors are usually approached through a standard posterolateral thoracotomy incision. Excision of the pleura and the endothoracic fascia around the tumor usually allows entry into an appropriate plane of dissection. Mobilization of the tumor from the rib edges is accomplished with both sharp and blunt dissection. It is important to identify and either ligate or clip intercostal blood vessels feeding and draining the tumor. The tumor may be attached to a number of sympathetic ganglia and intercostal nerves and often extends, in one or more areas, into the intervertebral foramina (Fig. 31-13).[56,57,171,184] It may be impossible to remove every bit of tumor at the foraminal sites. Small primary tumors have been successfully removed by thoracoscopic techniques. Thoracoscopy is also useful in obtaining tissue for biopsy.

In patients with neurologic symptoms (including paraplegia) associated with dumbbell tumors, prompt MRI and an urgent laminotomy to excise extradural tumor and relieve cord compression are recommended before attempting intrathoracic resection of the tumor. The mediastinal resection can be delayed a short time to allow the patient's neurologic symptoms to improve. If extradural tumor is present on imaging studies but the patient is asymptomatic, chemotherapy is initiated and may shrink the tumor and avoid the need for laminotomy or laminectomy at the time of resection of the thoracic tumor. The choice of therapy for intraspinal tumor extension is still somewhat controversial. Plantaz and colleagues[59] reviewed 42 patients in France and recommended initial chemotherapy followed by surgical removal of residual disease. Yiin and colleagues[61] described 13 cases of neuroblastoma with symptomatic spinal cord compression and neurologic deficits. All the patients were treated initially with chemotherapy: 3 recovered, 4 improved, and 6 worsened and became paraplegic. Two of the six recovered after laminectomy. The authors recommended spinal cord decompression for patients who have neurologic deterioration on chemotherapy. Sandberg and colleagues[60] described the treatment of 46 patients with epidural or neural foraminal tumor involvement. Nine were low-risk patients with normal neurologic examinations who remained neurologically intact following operation or chemotherapy. Four low-risk patients with high-grade spinal cord compression improved or remained stable after surgical intervention, but 2 patients who were treated with chemotherapy had worsening deficits. Eleven of twelve high-risk patients with normal neurologic examinations and without radiographic high-grade spinal cord compression were treated with chemotherapy and had no neurologic deterioration. Of 16 high-risk patients with high-grade spinal cord compression, 7 of 10 were treated initially with chemotherapy, and all 6 who underwent initial surgery improved or remained stable. Spinal deformities occurred in 12.5% (2 of 16) treated nonsurgically and in 30% (9 of 30) who underwent surgery. The authors concluded that patients with high-risk tumors and spinal involvement but normal neurologic examinations should be offered chemotherapy, with the understanding that a small percentage may require operations for progressive neurologic deficits. Chemotherapy may be avoided in patients with low-risk tumors who can be offered a potentially curative procedure. Patients and their families should be made aware that operative intervention may be associated with subsequent spinal deformity in as many as 30% of cases.[60]

Cervical neuroblastoma is often localized and has a favorable outcome.[185] In a study of 43 cervical neuroblastomas,

Haddad and colleagues[186] identified four risk factors that were associated with increased operative morbidity: adherence to vascular structures, tumor size, friability, and dumbbell tumors. Imaging studies may show a solid mass with vascular displacement and narrowing.[187] Tumors arising in the neck or upper mediastinum often involve the stellate ganglion. If not present preoperatively, resection may result in postoperative Horner syndrome.[14,188] This is a relatively minor consequence outweighed by complete tumor excision and survival, but the patient's family should be made aware of this possible complication. Special attention should be given to protecting the brachial plexus and the phrenic, vagus, and recurrent laryngeal nerves.

Aggressive surgical management is occasionally associated with late complications in survivors, including ipsilateral atrophy of the kidney following adrenal resection and ejaculatory problems following pelvic tumor excision.[188] Of interest is the very favorable outlook noted in patients with stage III and IV tumors arising in the pelvis following complete tumor resection.[10]

# Chemotherapy

Although multiagent chemotherapy has significantly improved the survival rate of patients with many different types of tumors (e.g., Wilms' tumor), chemotherapy has no such effect in infants and children with resectable localized neuroblastoma with favorable biologic and genetic characteristics. For locoregional disease that does not have *MYCN* amplification, surgical resection alone is all that is necessary.[5,10,189] Patients with locoregional disease with poor prognostic biologic and genetic factors, however, are at higher risk and should be treated more aggressively with multiagent dose-intensive chemotherapy, in addition to a variety of therapies thereafter. Patients with stage IV disease who are younger than 18 months at diagnosis receive low-dose chemotherapy, in addition to surgery.[190]

Patients with stage IV disease who are *MYCN* amplified or older than 18 months at diagnosis remain the most difficult population to treat. Historically, these patients received cyclophosphamide, vincristine, and dacarbazine.[9,190,191] Patients in whom this treatment regimen failed received doxorubicin and teniposide (VM-26). Although these chemotherapy regimens did not effectively increase the cure rate of patients with stage IV disease, such treatment reduced the size of the primary tumor, often cleared the bone marrow of tumor cells, and was occasionally associated with histologic maturation from malignant neuroblastoma to benign ganglioneuroma.[9,11] Unfortunately, only 40% of patients with stage IV disease demonstrated a complete response to chemotherapy; 30% had a partial response; and 30% were unresponsive.[9] When the clinical estimation of response was subjected to confirmation by laparotomy, many patients thought to be responders to chemotherapy actually had persistent tumor not identified by preoperative testing.[15,76,172]

Numerous studies confirmed the limited effectiveness of chemotherapy regimens in patients with metastatic disease.[9,73] Using cell kinetic data, Hayes and colleagues[192] demonstrated that the proliferating fraction of the tumor cell population in neuroblastoma is exceedingly small. A large pool of nonproliferating resting cells is resistant to chemotherapy. Timed sequential administration of cell cycle–specific and nonspecific drugs (cyclophosphamide and doxorubicin, or cisplatin with teniposide or doxorubicin) was subsequently tested and resulted in improved response rates.[71,192] This improvement led to more aggressive, more intensive treatment protocols using multiple agents.

Currently, this patient population receives aggressive multimodality therapy, including induction chemotherapy to attain remission, followed by surgery and radiotherapy to further achieve local control. This treatment is followed by consolidation of remission with myeloablative therapy, autologous stem cell transplant, 13-cis-retinoic acid, and, possibly, the addition of immunotherapy.

The purpose of induction chemotherapy is to reduce tumor burden throughout the entire body, both at the primary site and at sites of systemic disease. Multiple agents are often used, including cyclophosphamide, ifosfamide, doxorubicin, cisplatin, carboplatin, etoposide, topotecan, and vincristine. These agents are now given as dose-intensive regimens.

# Radiotherapy

Neuroblastoma is a radiosensitive tumor, so radiotherapy remains an important part of the treatment regimen for patients with neuroblastoma. In general, in the management of neuroblastoma, radiotherapy is administered after both induction therapy and surgery, when minimal disease remains. It has also been used for bulky metastatic disease after a response is seen with chemotherapy, and for palliation in patients with refractory end-stage disease or painful metastases.[193–195] At our institution, a regimen that includes dose-intensive chemotherapy, surgery, and a dose of 2100 cGy of hyperfractionated radiotherapy to the primary site in patients with stage IV neuroblastoma resulted in a local control rate of greater than 90%.[46]

Although it is useful, external-beam radiotherapy is associated with considerable toxicity in growing children, resulting in growth disturbance, bony deformity, endocrine deficiency, hypoplastic soft tissue changes, skin atrophy, and, of greater concern, secondary malignancies in the radiation portal. Techniques used to decrease radiation-induced toxicity include hyperfractionation of the radiation dose, which usually does not reduce the desired antitumor effect, and avoiding the simultaneous administration of chemotherapy agents that may enhance the radiation effect. Brachytherapy and intraoperative radiotherapy can better confine the radiation effect to the target tissue and spare surrounding normal tissues.[196,197] Although early local control can be achieved, only 38% of patients with stage IV disease given intraoperative radiotherapy survived after 3 years. Some patients still require supplemental external-beam radiotherapy; postoperative ureteral stricture, renal artery stenosis, and neuropathies have been described.[5] Haas-Kogan and colleagues[196] described an experience using intraoperative radiotherapy in 23 cases of high-risk neuroblastoma and noted that this technique was effective only in patients who had gross total resection of the primary tumor.[196] All patients with partial tumor resection had recurrence, despite radiotherapy, and subsequently died. There are few data to support the efficacy of this therapy. Intraoperative radiotherapy is sometimes cumbersome to perform, especially in institutions that do not have an operative suite in the radiotherapy department or radiotherapy

equipment (including linear accelerators) in the operating room. Under these circumstances, after attempted tumor resection, the patient has to be transported under general anesthesia for the radiation treatment.

Children with refractory advanced neuroblastoma with widespread involvement often suffer severe pain due to metastases. Kang and colleagues[194] employed targeted radiotherapy using submyeloablative doses of $^{131}$I-MIBG to achieve disease palliation. The treatment stabilized disease, relieved pain, or improved performance status, with 31% of patients showing an objective response to treatment. They concluded that this modality is useful for treating end-stage neuroblastoma. Deutsch and Tersak[193] described the use of radiotherapy (300 to 1000 cGy) for palliative treatment of symptomatic metastases to bone. The most common treatment sites were the skull, spine, hip, and femur. In their study, 29% of patients survived 1 year or longer (range, 1 to 52 months); only 8% survived more than 3 years.

Targeted radiotherapy with MIBG has also been used in combination with myeloablative chemotherapy and proton therapy for recurrent and refractory neuroblastoma. Proton therapy has the advantage of delivering radiation more precisely than conventional radiotherapy. As it becomes more widely available, it may play a greater role in the management of children with neuroblastoma requiring radiation treatment.[1]

## Myeloablative Therapy

Myeloablative therapy, using near-lethal doses of phenylalanine mustard (melphalan) with autologous bone marrow rescue, has been shown to improve the tumor response rate. A combination of melphalan, doxorubicin, teniposide, and low-dose total-body irradiation followed by autologous BMT resulted in a relapse-free rate of 40% and, if deaths resulting from toxicity were excluded, there was a 2-year survival rate of 34% in patients with stage IV disease.[198] An alternative treatment was developed that relies on myeloablative chemotherapy using escalating doses of drugs given by constant infusion, followed by autologous (purged) bone marrow infusion but without total-body irradiation.[199]

Currently, stem cells are harvested during the induction phase of treatment, and stored for later use during the consolidation phase of treatment.[200] Chemotherapeutic agents used for this phase of treatment include carboplatin, etoposide, and melphalan. Peripheral blood stem cell infusion is used to reconstitute the marrow after myeloablative treatment. Immunoglobulin G levels are monitored and replaced with gamma globulin. Sulfamethoxazole and fluconazole are given prophylactically to avoid opportunistic *Pneumocystis carinii* and fungal infection.

The use of purged, peripheral blood hematopoietic stem cells has shown to have survival benefits over the use of allogeneic cells, mainly because of a higher toxic death rate and an increased incidence of graft-versus-host disease in the latter group.[94,201] Patients with high-risk stage IV disease have a better outcome with BMT, especially if they have amplification of the *MYCN* oncogene.[37,94,124] Preliminary reports are demonstrating improved event-free survival with rapid sequential tandem transplant consolidation therapy. This has initiated the ongoing COG phase III trial testing single versus tandem transplant as consolidation therapy.[201] However, to date, there are no prospective studies examining the use of myeloablative therapy in addition to dose-intensive induction therapy.[190] At our institution, the addition of myeloablative chemotherapy to dose-intensive chemotherapy did not decrease the rate of systemic or central nervous system recurrence.[202]

The addition of 13-cis-retinoic acid (isotretinoin), a biologic response modifier that causes tumor differentiation and decreases bone marrow tumor involvement, was shown to be useful.[199] Retinoids serve as multistep modulators of the MHC class I presentation pathway and sensitize neuroblastomas to cytotoxic lymphocytes.[202–204] In a phase III randomized trial in high-risk patients, Reynolds and colleagues[203,204] showed that high-dose pulse therapy with 13-cis-retinoic acid given after completion of intensive chemoradiation (with or without autologous BMT) significantly improved event-free survival. A CCG phase III randomized trial showed the use of 13-cis-retinoic acid after myeloablative chemotherapy had superior event-free survival in patients with remission, and this protocol is now commonly used for these particular patients.[199] A newly developed retinoid, fenretinide, has completed a COG phase I trial, and different oral formulations are being tested in the hopes of improving its bioavailability.[189,205]

## Immunotherapy

In the 1970s and 1980s, it was suggested that tumor regression in neuroblastoma involved an immunologic mechanism, resulting from an unusual tumor–host relationship.[206–208] Lymphocytes from children with neuroblastoma were observed to inhibit colonies of neuroblasts in culture but not cells from other tumors.[207] Sera from patients with progressive disease contain a blocking antibody that prevents a lymphocyte-mediated cytotoxic response and inhibits lymphocyte blastogenesis to phytohemagglutinins.[209,210] Lymphocytes from patients with neuroblastoma also have a decreased systemic and in situ natural killer activity.[211] In experimental studies, operative electrocoagulation and hyperthermia resulting from high-intensity focused ultrasonography induced immunity in mice with neuroblastoma.[206,207] A major problem is that advanced neuroblastoma cells are MHC class I deficient and evade immunorecognition.

The mainstay of current immunotherapy for neuroblastoma involves GD2. GD2 is a surface glycolipid antigen that is copiously found on all neuroblastoma cells. Raffaghello and colleagues[212] employed an anti-GD2 antibody in nude mice with neuroblastoma and noted increased long-term survival and decreased metastatic spread in a dose-dependent manner in treated mice compared with controls. Cheung and colleagues[213] suggested that immunotherapy using ganglioside GD2 monoclonal antibody should be directed at minimal disease and must be used in conjunction with dose-intensive chemotherapy to be effective. Kushner and colleagues[214] described the treatment of seven patients who relapsed with widespread disease after initial treatment with surgery alone for locoregional neuroblastoma. They received dose-intensive chemotherapy; anti-GD2 3F8 antibody; and targeted radiotherapy using $^{131}$I-labeled 3F8, if they had assessable disease, or 3F8, granulocyte-macrophage colony-stimulating factor, and 13-cis-retinoic acid, if they

were in remission. Five of the seven patients remained in remission between 4 and 8 years later.[214] The same group reported that high-dose cyclophosphamide, irinotecan, and topotecan were effective in achieving remission and inducing an immunologic state conducive to antibody-based passive immunotherapy (using 3F8 antibody) in resistant neuroblastoma.[215] Further studies have been completed that continue to show improved outcomes with the use of this antibody.

In contrast to 3F8, which is a mouse-derived monoclonal antibody, ch14.18 is a chimeric human/murine anti-GD2 antibody, and it has shown positive results in both phase I and II clinical trials (German NB90 and NB97 studies). Preliminary results from the COG randomized phase III trial using ch14.18 plus cytokines after autologous stem cell transplant versus control showed improved survival in the treatment group.[216]

Dendritic cells are potential targets for immunotherapy. They can enhance growth and differentiation of CD40-activated B lymphocytes, directly affect natural killer cell function, and act as antigen presenters.[217,218] Redlinger and colleagues[218] noted that advanced neuroblastoma impairs dendritic cell differentiation and function in adoptive immunotherapy. It has been shown that neuroblastoma-derived gangliosides inhibit dendritic cell function. Interleukin-12 (IL-12) is a potent proinflammatory cytokine that enhances the cytotoxic activity of T lymphocytes and resting natural killer cells.[217] In a murine model of neuroblastoma, Shimizu and colleagues[219] demonstrated that IL-12–transduced dendritic cell vaccine (with an adenoviral vector expressing IL-12) led to a complete and sustained antitumor response. Tumor regression was associated with a high infiltration of dendritic cells and viable T cells.

## Additional Therapies

$^{131}$I-MIBG infusion provides a way to specifically deliver radiotherapy to neuroblastoma cells, because it is taken up by more than 90% of neuroblastomas. The use of this treatment alone results in a response in 18% to 37% of patients with refractory or relapsed disease.[220] Rapamycin (mTOR) plays a significant role in cell growth and persistence of neuroblastomas, and phase II trials investigating rapamycin (mTOR) inhibitors are ongoing. Early results reveal a benefit in patients with recurrent neuroblastoma.[221] Additionally, trials are examining targeted therapies for the AKT pathway, as activation of AKT correlates with worse event-free and overall survival.[222–224] Biologic agents, such as histone deacetylase inhibitors, tyrosine kinase inhibitors, IGF-1 receptor inhibitors, N-myc inhibitors, ALK inhibitors, and various antiangiogenic agents, are also being investigated in ongoing clinical trials. The use of bisphosphonates is being explored as a possible treatment for bone metastases. Tumor vaccines and techniques of adoptive immunotherapy are also being evaluated in clinical trials.

## Summary and Future Directions

This common pediatric malignancy remains an enigma because of the high variability in tumor behavior. The primitive neuroblastic tumor may follow one of three possible pathways: spontaneous regression (apoptosis); differentiation and maturation to a benign ganglioneuroma; or, more commonly, tumor proliferation and rapid malignant progression. Fetal ultrasonography and infant screening programs have clearly demonstrated that some tumors spontaneously regress. Age-related histopathologic studies have clarified that some tumors (those with favorable histology) differentiate and mature, whereas others (those with unfavorable histology) are undifferentiated neoplasms that respond poorly to treatment and have a rapidly progressive course and fatal outcome.

Recognition of important biologic (and genetic) characteristics can help to categorize these tumors into risk groups (low, intermediate, and high) that determine future treatment protocols. Risk-based management permits individualized care for each patient based on age, INSS stage, INPC histology, and biologic and genetic characteristics that affect the behavior of each tumor.[1,10,102] This avoids unnecessary and potentially harmful treatment in patients categorized as having low-risk tumors and who may do well with surgery alone (and occasionally observation alone in highly selected cases). It allows the physician to reserve the most intensive treatment protocols for children with the highest-risk tumors and the most guarded prognosis. At present, the outlook is best in low-risk patients: infants younger than 18 months; patients with localized tumors that can be completely excised (stages I and II) with favorable INPC histology and low-risk biologic and genetic factors; and infants with stage IV-S disease. Infants with cystic or small solid neuroblastomas detected on prenatal sonograms also have a very favorable outcome. In patients with stage IV-S disease and those with cystic, multifocal, or bilateral tumors and favorable biologic characteristics, observation alone may be feasible. Close sonographic monitoring of these cases in the first year of life is important to ensure that the tumor shrinks and undergoes regression. Increase in tumor size is an indication for operative intervention.

Despite some improvements in outcome using high-intensity treatments, the outlook for patients with advanced neuroblastoma remains dismal, and less than half survive. A better understanding of factors influencing tumor regression and differentiation and tumor–host immune interactions is required. In children with high-risk tumors, identifying additional tumor markers and targeting effective monoclonal antibodies against the tumor, developing improved techniques to clear the bone marrow of tumor cells, using new and more effective chemotherapy regimens, and using growth factors (e.g., other biologic tumor modulators) to promote regression and differentiation may control disease progression and improve the outlook for this highly malignant tumor. Molecular profiling of the genetic changes that occur in neuroblastoma will likely permit a more precise classification system to predict outcome and further define the choice of specific therapy, which may include targeting the genes, proteins, and signaling pathways responsible for malignant progression of the tumor.[1] Also of concern are the long-term effects of neuroblastoma treatment, which include cardiac and renal toxicity, scoliosis, adverse effect on growth and development, delayed sexual maturation, learning disabilities, and occurrence of second neoplasms including renal tumors.[1,225,226]

CHAPTER 32

# Nonmalignant Tumors of the Liver

Wolfgang Stehr and Philip C. Guzzetta, Jr.

Primary liver tumors constitute less than 3% of tumors seen in the pediatric population, and only one third of those tumors are benign.[1] Benign tumors may be epithelial (focal nodular hyperplasia, hepatocellular adenoma), mesenchymal (hepatic hemangioma, mesenchymal hamartoma), or other (teratoma, inflammatory pseudotumor). Nonparasitic cysts, although not technically neoplasms, are also discussed in this chapter. One of the more interesting aspects of benign liver tumors in children is their predilection to occur in patients with other conditions, and this phenomenon will be discussed with each tumor type.

## Clinical Presentation

Most children with benign liver tumors present with a painless right upper quadrant abdominal mass or hepatomegaly. Symptoms of gastrointestinal compression, such as constipation, anorexia, or vomiting, may also be present. If the mass is painful, the pain is usually dull and aching and is caused by expansion of the liver capsule or compression of the normal surrounding structures. Jaundice and weight loss are uncommon except in infants with symptomatic hemangiomas, and those signs should raise the suspicion that the lesion is malignant. Acute abdominal pain may be caused by bleeding into the mass or into the peritoneum,[2] particularly in hepatocellular adenomas, although this problem is rarely seen in children. Children may present with congestive heart failure (CHF) and thrombocytopenia, which is known as Kasabach-Merritt syndrome when associated with a vascular anomaly such as a liver hemangioma.[3] Cutaneous hemangiomas are seen in about half the children with a liver hemangioma,[4,5] and the rapid enlargement of the liver with a diffuse liver hemangioma can cause abdominal compartment syndrome and respiratory distress.[4] CHF without significant thrombocytopenia can also be seen with liver arteriovenous malformation (AVM)[6] or mesenchymal hamartoma.[7] Fetal hydrops has been identified by prenatal ultrasonography in some fetuses with liver hemangiomas[8] or mesenchymal hamartoma.[9]

## Diagnosis

### LABORATORY TESTS

Serum alpha fetoprotein (AFP) is present in very high concentrations at birth (48,000 $\pm$ 35,000 ng/mL) and rapidly declines to adult levels of less than 10 ng/mL by 8 months of age (Table 32-1).[10] Thus in infants younger than 8 months, AFP levels must be interpreted in the context of this dramatic change. Markedly elevated AFP levels in a child with a liver mass almost certainly means that the mass is malignant, although milder elevation may be encountered with some benign lesions, such as mesenchymal hamartoma[11] or teratoma.[12] As mentioned previously, significant thrombocytopenia associated with a liver mass is usually part of the Kasabach-Merritt syndrome resulting from a liver hemangioma. Hypothyroidism may also occur in multiple or diffuse forms of liver hemangioma[13]; thyroid function tests should be done routinely in these children, because hypothyroidism significantly impacts their management.[14]

### IMAGING TECHNIQUES

The initial imaging study in a child presenting with an abdominal mass should be a supine radiograph of the abdomen, looking for calcifications within the mass. The next imaging study should be an abdominal ultrasonogram with Doppler spectral analysis, followed by computed tomography (CT) with intravenous contrast (Fig. 32-1).[15] Magnetic resonance imaging (MRI) may be indicated, depending on the sonogram and CT scan results, especially when surgical resection is planned and more detailed information about the vascular anatomy relative to the tumor is desired or in infants with hemangiomas in whom another diagnosis is being considered because the MRI appearance may be diagnostic. Arteriography is reserved for children with a liver hemangioma, an AVM, or, rarely, a mesenchymal hamartoma with CHF, when embolization of the blood supply to the tumor is needed for treatment. The use of percutaneous biopsy under sonogram or CT guidance in children with benign tumors is generally discouraged, unless excision of the tumor would pose a major risk to the child, because establishing a diagnosis on the basis of a small sample may be problematic for the pathologist and because resection is the proper

**TABLE 32-1**
**Normal Serum Alpha Fetoprotein (AFP) Levels of Infants by Age**

| *Age* | *No. of Patients* | *AFP Level* ± *SD (ng/mL)* |
|---|---|---|
| Premature | 11 | 138,734 ± 41,444 |
| Newborn | 55 | 48,406 ± 34,718 |
| Newborn to 2 weeks | 16 | 33,113 ± 32,503 |
| 2 weeks to 1 month | 43 | 9452 ± 12,610 |
| 1 month | 12 | 2645 ± 3080 |
| 2 months | 40 | 323 ± 278 |
| 3 months | 5 | 88 ± 87 |
| 4 months | 31 | 74 ± 56 |

therapy for most of these tumors, with the exception of liver hemangiomas. The findings on imaging studies are discussed in the sections on each individual tumor.

# Hepatic Hemangioma

Hepatic hemangiomas are the most common benign liver tumor in children and are more common than all other benign liver tumors combined. Most of these lesions are identified in the newborn period or during prenatal ultrasound screening.[8] To facilitate discussion about treatment and prognosis, a new subtype classification was delineated in 2007.[4] This classification designates the hemangioma as either focal, multiple, or diffuse and eliminates confusing terms such as infantile hepatic hemangioendothelioma.

## FOCAL LIVER HEMANGIOMA

Focal lesions vary in size but can be as large as 8 cm in diameter.[5] They are usually asymptomatic. Some of the children will have cutaneous hemangiomas as well. On MRI, there is a solitary liver lesion that is hypodense on T1-weighted sequences and hyperintense on T2-weighted sequences compared with normal liver. CT scan similarly shows contrast enhancing in the periphery of the mass with little contrast in the center (see Fig. 32-1). These lesions seldom need treatment, may be a hepatic form of hemangioma similar to the cutaneous rapidly involuting congenital hemangioma (RICH), and have generally regressed spontaneously by 1 year of age.[4,5]

## MULTIFOCAL LIVER HEMANGIOMA

Multifocal lesions are generally widely dispersed, spherical, and homogeneously enhancing lesions on MRI. Flow voids may be present in the lesions and may indicate the presence of arteriovenous shunts that may lead to congestive heart failure (CHF).[15] Cutaneous hemangiomas are almost always present in these children.[5] Treatment by corticosteroids of patients with CHF is highly successful,[4,5] but if steroids fail to control CHF, embolization of the shunts may be necessary.[6,16] Children with this lesion may have evidence of hypothyroidism, and thyroid function tests (TFT) should be obtained in all children with multifocal lesions. Prognosis is excellent with 100% survival in one series.[5]

## DIFFUSE LESIONS

Diffuse lesions frequently replace nearly all of the liver with lesions showing centripetal enhancement on MRI or CT. The clinical course is more complicated and potentially lethal. Massive hepatomegaly may lead to abdominal compartment syndrome, multisystem organ failure, and death. Severe hypothyroidism may develop because of overproduction of type III iodothyronine deiodinase; therefore TFT must be obtained.[13] Despite the large tumor burden, CHF is rare. If corticosteroid therapy does not result in rapid improvement, then liver transplantation should be considered early,[17] because the prognosis is otherwise poor.[4] Medical therapy with vincristine has shown some success,[18] but this option is often limited by the rapid clinical deterioration of children with diffuse lesions. Interferon therapy has been abandoned because of the risk of spastic diplegia in infants.[19] Survival for all children with the diffuse form of liver hemangioma is approximately 75%.[5,13]

## ARTERIOVENOUS MALFORMATION

An AVM may occur within the liver parenchyma or outside the liver between the hepatic artery and the portal venous system. Similar to patients with diffuse liver hemangiomas, patients with hepatoportal AVMs usually present before 6 months of age, many in the newborn period, with hepatomegaly, CHF, and a bruit over the liver.[21] In older children and adults, hepatic AVM may occur as part of hereditary hemorrhagic telangiectasia, also known as Osler-Weber-Rendu disease.[15,22] Angiography is diagnostic, and embolization is therapeutic in some patients, but it is necessary to eliminate the extensive collaterals for successful closure of the AVM.[15,21] Fatal complications from the embolization of liver

AVMs have been reported in adults.[23] Steroids have no place in the management of these lesions, and AVMs not managed successfully with embolization may be controlled with ligation of the hepatic artery.[24,25]

## MESENCHYMAL HAMARTOMA

Mesenchymal hamartoma (MH) usually presents as a painless right upper quadrant abdominal mass in a child younger than 2 years.[20,26,27] Some patients may have evidence of CHF,[7] and, similar to liver hemangiomas, MH has been diagnosed prenatally.[20,9] Edmondson[28] proposed that MH arises from a mesenchymal rest that becomes isolated from the normal portal triad architecture and differentiates independently. The tumor grows along bile ducts and may incorporate normal liver tissue. Because the blood vessels and bile ducts are components of the mesenchymal rest, the biologic behavior of the tumor varies with the relative predominance of these tissues within the loose connective tissue stroma (mesenchyma) that surrounds them. Thus the tumor may present as a predominantly cystic structure (Fig. 32-2) that enlarges rapidly because of fluid accumulation,[29] or it may be predominantly vascular and present with CHF.[7] Von Schweinitz and colleagues[30] suggested that fat-storing (Ito) cells of the immature liver may be involved in the development of MH. There are reports of chromosomal translocations within mesenchymal hamartomas.[31]

Serum AFP levels are usually normal in children with MH, but they may be mildly elevated.[20,11,32] The radiographic features of these tumors are consistent and distinguishing; abdominal sonography and CT demonstrate a single, usually large, fluid-filled mass with fine internal septations and no calcifications.[33]

Management must be tempered by the understanding that MH usually follows a benign course,[34] although there have been reports of malignant transformation.[35,36] In general, complete operative resection is the procedure of choice, if it can be accomplished safely. Huge lesions or those that involve both lobes may be treated by unroofing and marsupializing the cysts, although the lesion may recur after incomplete resection.

**FIGURE 32-2** Cross section of a pathology specimen of a left hepatic lobectomy for mesenchymal hamartoma in a 10-month-old male infant.

MH is an entity distinct from the liver hamartomas associated with tuberous sclerosis. The latter are smaller, multifocal lesions that may be associated with angiomyolipomas in other locations, such as the kidney; they are rarely symptomatic and usually present in children older than 2 or 3 years. These hamartomas have little clinical significance, but their presence may be helpful in diagnosing tuberous sclerosis.[37]

## HEPATOCELLULAR ADENOMA

Although isolated lesions are encountered in childhood, hepatocellular adenoma (HCA) is most commonly observed in adults in association with the use of anabolic corticosteroids or estrogen. HCA has been described in children treated with anabolic steroids and multiple blood transfusions for chronic anemia,[38] and it is expected in children with type I glycogen storage disease.[39] Bianchi[40] proposed several mechanisms for the development of HCA in patients with type I glycogen storage disease, including (1) regional imbalance in insulin and glucagon metabolism, because these hormones are important in the regulation of hepatocyte proliferation and regeneration; (2) response to glycogen overload; and (3) oncogene activation. A giant hepatocellular adenoma has also been reported in a child treated with oxcarbazepine for a seizure disorder.[41]

Microscopic examination of adenomas reveals hepatocytes in sheets and cords oriented along sinusoids without a ductal component. The cells have glycogen-filled cytoplasm and small nuclei without mitoses. Adjacent liver and vessels are compressed but not invaded. Children usually do not have coexisting cirrhosis.[38] The histologic pattern is similar to that of a well-differentiated hepatocellular carcinoma, and development of hepatocellular carcinoma within an unresected HCA has been reported.[42,43]

In children, HCA generally presents as an asymptomatic hepatic mass. The mass is solid on ultrasonography and CT. Liver enzyme and AFP levels are normal. A feature unique to this lesion is its propensity for intraperitoneal hemorrhage from spontaneous rupture. In adults, intraperitoneal bleeding is almost always seen in patients receiving estrogen therapy, and tumor regression may occur with the cessation of hormone administration. In patients with glycogen storage disease and HCA, tumor regression may occur with the correction of metabolic disturbances.[40] Because of the known association between HCA and hepatocellular carcinoma, resection of HCA is recommended when it occurs in a child who is not receiving steroids and does not have glycogen storage disease. If resection cannot be accomplished without substantial risk, observation of the lesion while monitoring the serum AFP level may be appropriate. If the AFP level begins to increase or the lesion is significantly symptomatic, and if the risk of resection is unacceptably high, liver transplantation may be the best alternative.

## FOCAL NODULAR HYPERPLASIA

Focal nodular hyperplasia (FNH) in children presents as an irregularly shaped, nontender liver mass. It is frequently found incidentally at laparotomy for another cause or on radiographic studies performed for another indication. The female-to-male

FIGURE 32-3 Surgical view of focal nodular hyperplasia within the left lobe of the liver in a 2-year-old child treated by left lateral lobectomy.

ratio for FNH is approximately 4:1.[44] FNH is occasionally seen with vascular malformations and hemangiomas in the liver,[45] as well as in children with type 1 glycogen storage disease,[46] and it has been postulated that the lesions represent an unusual response to injury or ischemia.[28] On abdominal sonography, the lesions may be isoechoic, hypoechoic, or hyperechoic compared with normal liver parenchyma, and multiple lesions may occur in 10% to 15% of patients. The classic central scar may not be seen on ultrasonography. CT typically shows a hypervascular lesion with a dense stellate central scar. Conventional arteriography or magnetic resonance angiography show a hypervascular mass with feeding arteries entering the periphery and converging on the central portion of the tumor. Some cases of fibrolamellar hepatocellular carcinoma are radiographically indistinguishable from FNH, which is a cause for concern if the diagnosis is being made without a biopsy.[47] There are reports of adult patients who have FNH and hepatocellular carcinoma simultaneously.[48]

On gross examination, the lesions are nonencapsulated, occasionally pedunculated, and quite firm (Fig. 32-3). Microscopic examination shows proliferation of hepatocytes and bile ducts and the pathognomonic central fibrosis. These lesions rarely become malignant or hemorrhage. Therefore expectant therapy is appropriate when removal might be associated with significant morbidity, the child is asymptomatic, and the diagnosis has been made conclusively by radiographic studies, normal AFP levels, and biopsy.[49]

## TERATOMA

There have been fewer than 25 case reports of hepatic teratoma in children invariably younger than 1 year.[12,50] Calcification is usually present within the teratoma, helping to differentiate it from other tumors. Some have met the criteria for an intrahepatic fetus in fetu.[51] Serum AFP levels may be elevated with a teratoma, but only mildly elevated in comparison with the levels seen with hepatoblastoma. Resection is the procedure of choice for a teratoma because of the risk of malignancy in any immature elements of the tumor.

## INFLAMMATORY PSEUDOTUMOR

Inflammatory pseudotumor of the liver is rare and generally seen in children older than 3 years but has been reported in younger children as well. Because this lesion is predominantly solid, it is difficult to differentiate it from other benign or malignant tumors by imaging studies. Invariably, the serum AFP level is normal. Fever, leukocytosis, and high C-reactive protein level in a child with a solid liver mass and normal AFP level are suggestive of an inflammatory pseudotumor of the liver thought to be an inflammatory reaction to some insult, although the instigating cause is usually unknown. It is difficult to diagnose this lesion without a large biopsy. Most children undergo resection, which is curative.[52,53]

## NONPARASITIC CYSTS

Nonparasitic cysts of the liver are rare and occur more commonly in adults than in children. Although they may be present and symptomatic at birth, most are asymptomatic and are identified incidentally at autopsy or laparotomy. Symptoms are related to abdominal distention or displacement of adjacent structures. Nonparasitic cysts occur with equal frequency in males and females[54] and are generally unilocular lined by cuboidal or columnar epithelium characteristic of bile ducts. The cyst fluid is typically clear or brown, and bile is rarely present. Pathologic studies suggest that nonparasitic cysts arise from congenital or secondary obstruction of peribiliary glands. These glands normally arise from the ductal plate at the hepatic hilum around the 7th week of gestation and continue to proliferate until adolescence.[54] Symptomatic cysts can be effectively treated by simple unroofing, marsupialization,[55] or sclerotherapy.[56] If biliary communication is suspected, cholangiography may identify the source and allow the communicating ductule to be oversewn.

Cystic dilatation of the intrahepatic ducts may also present as a mass, although jaundice and cholangitis are often associated with this problem. Resection of the affected lobe is the preferred therapy.[57] If mesenchymal hamartoma appears to be completely cystic on imaging, it may be misdiagnosed as a nonparasitic cyst. Post-traumatic bile cysts result from ductal disruption and intrahepatic accumulation of bile. These lesions can be treated by percutaneous drainage or, in some cases, by biliary sphincterotomy to reduce the bile duct pressure and lessen the biliary leak.[58] Resection is rarely necessary for post-traumatic cysts. Multiple parenchymal cysts associated with hereditary polycystic kidney disease are generally asymptomatic and so small that they do not require intervention.

Epidermoid cysts differ from other nonparasitic cysts, in that the lining epithelium is squamous rather than cuboidal. This histologic characteristic has led to the theory that these lesions may be foregut bud anomalies trapped in the hepatic substance. Although they are rare, there has been a report of malignant degeneration. Thus resection is the appropriate management.[59]

CHAPTER 33

# Malignant Liver Tumors

Rebecka L. Meyers, Daniel C. Aronson, and Arthur Zimmermann

## Historical Context

One hundred and thirteen years ago, the first case report of a hepatoblastoma (HB) was published in the English literature in 1898 by Misick in Prague.[1] He reports "A Case of Teratoma Hepatis" in a 6-week-old boy who died of respiratory problems. Autopsy showed a large tumor that occupied the lower half of the right liver lobe. Cysts, cartilaginous, and bony deposits were seen, as well as venous tumor infiltration. It was therefore not surprising that the tumor was described as a teratoma, with tissue representatives of the three embryonic germ cell layers. More than 60 years later in 1962, Willis introduced the term hepatoblastoma for this type of tumor that he defined as "an embryonic tumor that contains hepatic epithelial parenchyma."[2] At that time, hepatoblastoma usually was not distinguished from hepatocellular carcinoma (HCC). Through the work of Ishak and Glunz in 1967, morphologic criteria were defined for HB and HCC that were refined in the decennia that followed.[3,4]

Modern treatment dates to 1975 when Exelby published a landmark paper that has been cited in most reviews dealing with liver tumors in children. He reports the results of a survey of the American Academy of Pediatrics Surgical Section documenting the 1974 treatment practices and outcomes for liver tumors in children.[5] Through questionnaires sent to the members of the Surgical Section of the American Academy of Pediatrics (AAP), data on liver tumors in children operated upon during the previous 10 years were requested. From 110 replies, 375 liver tumors were reported, of which 252 were malignant (129 HB, 98 HCC), and 123 were benign. All patients with HB underwent primary surgical exploration, with biopsy only in 43 children and a subsequent attempt at definitive resection in 86. Seventy-eight of the 86 children in whom resection was attempted had complete excision of the tumor and 45 (60% of those resected) survived. Excessive blood loss was the most common complication during and immediately after operation, after which cardiac arrest occurred in 9 patients. There were 8 deaths in the operating room and 17 deaths in the immediate postoperative period attributable to the operation. Fifteen HB patients had irradiation of the liver; 53 patients had chemotherapy using a wide variety of agents. It was apparent that no cures were obtained from irradiation and/or chemotherapy in the absence of complete surgical resection. The overall survival for HB was 35%; for HCC it was 13%. With incomplete surgical excision no patient survived. There was no evidence that radiation therapy or chemotherapy controlled disease that could not be completely excised surgically. At this time, before the introduction of cisplatin-based chemotherapy and modern surgical techniques, it seemed that complete operative excision carried a high risk of morbidity, even mortality, but offered the only chance of cure.

The field has progressed considerably since Exelby's 1975 survey. With the introduction of cisplatin-based chemotherapy regimens in the 1980s, overall survival for HB increased from 35% to 70%[6] and has increased further to nearly 80% in the most recent trials.[7] Although our sophistication with chemotherapy and antiangiogenic regimens for both HB and HCC continues to evolve, the primary advantage of chemotherapy has been in a neoadjuvant setting to shrink the tumor and enable surgical resection. Although pediatric HCC is more likely to respond to chemotherapy than its adult counterpart, most HCC remains largely chemoresistant, and treatment efforts often focus on slowing tumor progression with the newest antiangiogenic agents. Complete surgical excision remains the cornerstone for cure in both HB and HCC as evidenced by the recent improvements in survival achieved with complete hepatectomy and liver transplantation.[8–10]

## Diagnosis

### CLINICAL PRESENTATION

Most liver tumors present with an asymptomatic abdominal mass palpated either by a parent or pediatrician.[11] In the youngest children (infants and toddlers) the most common malignant tumor is hepatoblastoma, which presents as an asymptomatic right upper quadrant or epigastric abdominal mass. Some children may have fatigue, fever, pain, anorexia, and weight loss. Rarely, HB may present with abdominal pain and hemorrhage after post-traumatic or "spontaneous" rupture of a previously occult tumor. Hepatocellular carcinoma and hepatic sarcomas are more common in older children and are more likely to present at an advanced stage. Nonspecific symptoms of inanition or respiratory failure may appear insidiously. As the cancer grows, the pain in the abdomen may

progress to shoulder or back pain and becomes more pronounced. The child may develop progressive anorexia and vomiting and appear thin and sickly. Tumor growth may compress or obstruct the normal hepatic architecture causing (1) ascites secondary to occlusion of the portal or hepatic veins, (2) gastrointestinal (GI) bleeding or splenomegaly from the portal hypertension of portal vein occlusion, or (3) jaundice, scleral icterus, and pruritus from obstruction of the biliary tree.[12] Symptoms of biliary obstruction are most common with biliary rhabdomyosarcoma.[13]

## DIFFERENTIAL DIAGNOSIS

Differential diagnosis of a pediatric liver mass includes malignant tumors, benign tumors, and a wide assortment of congenital and acquired lesions of the liver, listed as "other masses" in Table 33-1. For many of the "other masses" listed in Table 33-1, the key to the diagnosis might lie in the underlying medical condition. For example, one might expect to see a bacterial hepatic abscess in a child with chronic granulomatous disease, a fatty deposit in the liver of a child with hyperlipidemia, or perhaps an inspissated bile lake in a child with biliary atresia as shown in Figure 33-1. Organizing intrahepatic hematoma should be suspected in any child with a history of hepatic trauma or in newborns with sepsis and coagulopathy, especially if there is a history of perinatal birth trauma or hemodynamic collapse requiring cardiopulmonary resuscitation. Congenital liver cysts are rare and represent a spectrum ranging from large simple cysts, intrahepatic choledochal cyst, and ciliated hepatic foregut cyst. Acquired cysts might be due to a bacterial, hydatid, or amoebic abscess. A simple, asymptomatic congenital liver cyst may be safely observed.[14] If infectious or large and symptomatic, cyst drainage, marsupialization, or excision may be needed to relieve pain and prevent risk of rupture. Recent literature suggests a risk of squamous cell carcinoma arising later in life in those congenital hepatic cysts with a ciliated epithelial lining (ciliated hepatic foregut cyst), and therefore these should probably be excised rather than observed or marsupialized.[15,16]

Neoplastic liver masses, including benign and malignant tumors, account for about 1.0% to 1.5% of all pediatric tumors.[17] Age at presentation is often the key to differential diagnosis (Table 33-2).[18] In newborns, the most common tumor is infantile hepatic hemangioma.[19] Infantile hepatic hemangioma is to be distinguished from the much rarer kaposiform hemangioendothelioma that may present in the extremities, chest, or retroperitoneum. Kaposiform hemangioendothelioma of the retroperitoneum may present with Kasabach-Merritt phenomenon and progress to obstruct the porta hepatis.[20] Hepatoblastoma is most commonly diagnosed between 4 months and 4 years of age. Benign tumors in toddlers are mesenchymal hamartoma and focal nodular hyperplasia. Hepatocellular carcinoma and hepatic adenoma are seen in older children. The other tumors listed in Table 33-2 are rare. Although the most common benign tumors often show classical distinguishing features on computed tomography, imaging is *not* usually a reliable way to differentiate benign from malignant tumors.[21]

## LABORATORY EVALUATION

Routine laboratory investigation should include complete blood count; many children with a malignant liver tumor will exhibit some degree of anemia and thrombocytosis.[22] In HB, the thrombocytosis is thought to be caused by tumor production of thrombopoietin, interleukin-6, and interleukin-1B.[23–25] Additional laboratory tests include a liver panel (albumin, transaminases, glutamyl transferase, alkaline phosphatase, total and conjugated bilirubin), lactate dehydrogenase, tumor markers (alpha-fetoprotein [AFP], beta-human chorionic gonadotropin [beta-HCG], ferritin, carcinoembryonic antigen [CEA], catecholamines), and viral titers (hepatitis A, B, and C, Epstein-Barr virus).[18]

The most important tumor marker is the serum AFP. AFP will be elevated in 90% of children with hepatoblastoma and in 50% of children with HCC.[26] Although AFP is elevated in most children with hepatoblastoma, increased AFP is *not* pathognomonic for a malignant liver tumor. European, German, and American multicenter trials have all concluded that hepatoblastomas that fail to express AFP at diagnosis (diagnosis AFP level less than 100) are biologically more aggressive with a worse prognosis.[27–31] Rarely, the opposite has been reported—a case of well-differentiated, fetal-type, favorable prognosis hepatoblastoma that did not express AFP.[32] AFP levels must be interpreted with caution in neonates, because AFP is the major protein produced by the fetal liver

**TABLE 33-1**
**Differential Diagnosis of Pediatric Liver Masses**

| *Malignant Tumors* | *Benign Tumors* | *Other Masses* |
|---|---|---|
| Hepatoblastoma | Mesenchymal hamartoma | Vascular malformations |
| Hepatocellular carcinoma | Biliary cystadenoma | Arteriovenous malformation |
| Sarcoma | Focal nodular hyperplasia | Blue rubber nevus syndrome |
| Biliary rhabdomyosarcoma | Infantile hemangioma | Congenital/acquired cysts |
| Angiosarcoma | Hepatic adenoma | Simple |
| Rhabdoid | Nodular regenerative hyperplasia | Ciliated foregut cyst |
| Undifferentiated | Teratoma | Polycystic liver disease |
| Metastatic/other | Inflammatory myofibroblastic tumor | Choledochal cyst |
| Wilms' tumor | | Inspissated bile lake/biliary atresia |
| Neuroblastoma | | Parasitic cysts |
| Colorectal | | Amoebic |
| Carcinoid tumor | | Abscess |
| Kaposiform hemangioendothelioma | | Bacterial |
| Hemophagocytic lymphohistiocytosis | | Chronic granulomatous disease |
| Langerhans' cell histiocytosis | | Hematoma |
| Megakaryoblastic leukemia | | Fatty liver |

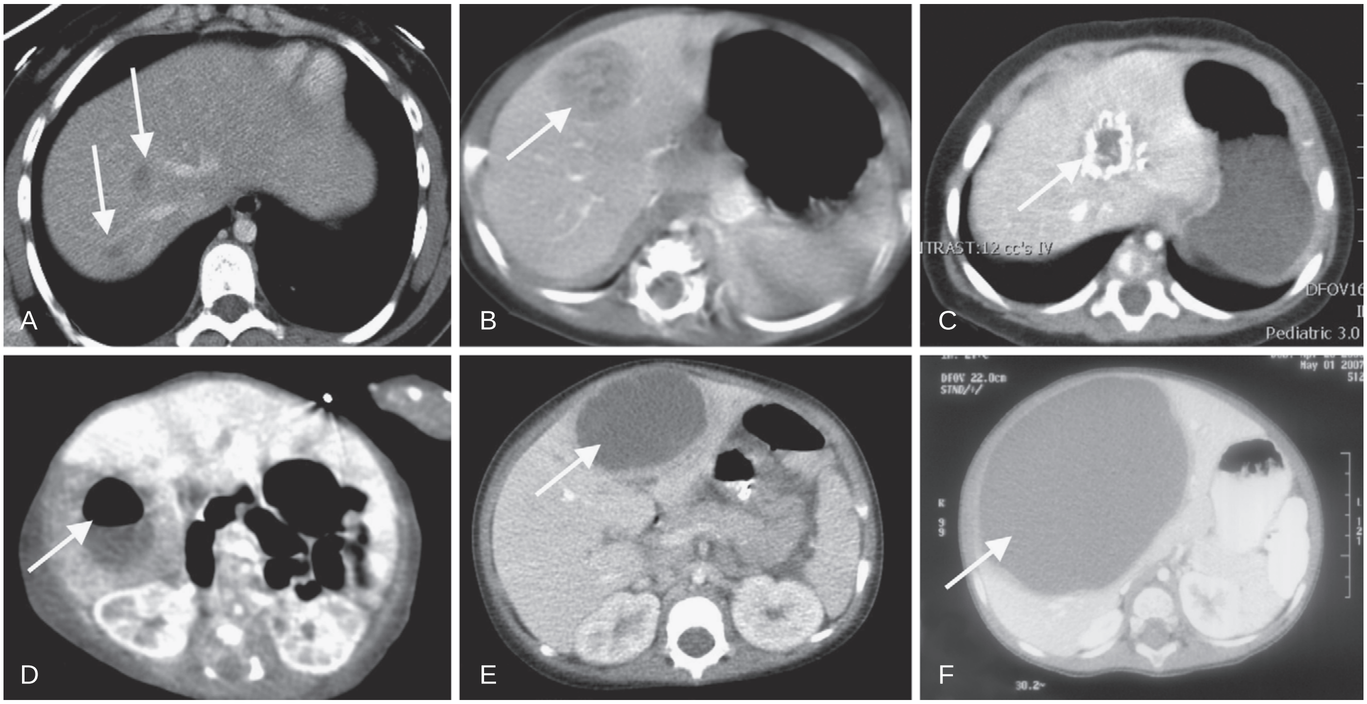

**FIGURE 33-1** Differential diagnosis: examples of non-neoplastic liver masses and cysts. **A,** Multiple small bacterial abscesses in a child with chronic granulomatous disease. **B,** Inspissated bile lake in a child with biliary atresia and cholangitis. **C,** Organizing hematoma in a newborn with sepsis and coagulopathy. **D,** Infarction of right lobe liver and hepatic abscess (with air fluid level) in a premature baby with necrotizing enterocolitis. **E,** Acquired cyst is an amoebic abscess in a toddler with fever. **F,** Congenital cyst is a ciliated foregut cyst in an infant with abdominal distension and feeding difficulties.

**TABLE 33-2**
**Age at Presentation, Most Common Liver Tumors of Childhood**

| *Age Group* | *Malignant* | *Benign* |
|---|---|---|
| Infant/toddler | Hepatoblastoma 43%<br>Rhabdoid tumor 1%<br>Malignant germ cell 1% | Hemangioma/vascular 14%<br>Mesenchymal hamartoma 6%<br>Teratoma 1% |
| School age/adolescent | Hepatocellular (including transitional cell tumors) 23%<br>Sarcomas 7% | Focal nodular hyperplasia 3%<br>Hepatic adenoma 1% |

From Von Schweinitz D: Management of liver tumors in childhood. Semin Pediatr Surg 2006;15:17-24.

and is thus produced in high amounts in the normal newborn. AFP may be especially high in neonates after hepatic damage and during regeneration of liver parenchyma. The half-life of AFP is 5 to 7 days, and levels fall throughout the first several months of life so that by 1 year of age the AFP should be less than 10 ng/mL.[33] Moreover, there are many reports of benign tumors, especially infantile hemangioma and mesenchymal hamartoma, in children presenting with high AFP levels.[34–36]

The other tumor markers useful in differential diagnosis are beta-HCG elevated in germ cell tumors, ferritin elevated in HCC and metastatic neuroblastoma; CEA elevated in HCC and metastatic colorectal, lactate dehydrogenase elevated in many malignant tumors, catecholamines elevated in metastatic neuroblastoma, hepatitis C in HCC, and Epstein-Barr viral titers in lymphoproliferative disease or lymphoma.

## RADIOLOGY

The radiographic appearance of the most common benign and malignant liver tumors is shown in Figure 33-2. Mesenchymal hamartoma is classically multicystic with the complex cysts separated by thick vascular septae. Focal nodular hyperplasia is generally well demarcated with a characteristic central stellate scar. Infantile hemangioma classically will demonstrate bright peripheral contrast enhancement. Infantile hepatic hemangioma may be focal, multifocal, or diffuse, as shown in Figure 33-2 in its diffuse form. Hepatoblastoma appears as a large multinodular expansile mass, usually unifocal, but occasionally multifocal. The tumor is generally well demarcated from the normal liver but is not encapsulated. HB may invade hepatic veins, disseminate to the lungs, or penetrate the liver capsule to reach contiguous tissues. An initial ultrasonogram will identify the liver as the organ of origin; additional testing, usually a contrast-enhanced abdominal computed tomography (CT) scan, is aimed at determining the extent of involved parenchyma and the presence or absence of macrovascular compression, displacement, or invasion. Metastatic liver tumors compared with primary malignant liver tumors have been reported to be more hypoechogenic on ultrasonography (US) and have less vessel invasion and contrast enhancement on abdominal CT.[37]

In hepatoblastoma and hepatocellular carcinoma, contrast-enhanced abdominal CT or magnetic resonance imaging

(MRI) outlines the anatomic extent of the tumor, clarifies its relationship to the central venous structures, and evaluates for multicentricity.[38] The radiographic appearance of the tumor at diagnosis is used to assign the tumor *Pre*treatment *Ext*ent of tumor (PRETEXT) (Fig. 33-3). The radiographic appearance of the tumor after preoperative (neoadjuvant) chemotherapy has been called *Post*-treatment *Ext*ent of tumor (POST-TEXT).[39] A chest CT scan is an essential part of the initial radiographic evaluation, to rule out metastatic pulmonary disease. In children with HB, about 20% present with metastatic disease in the lungs. In HCC, the number of children who present with advanced disease is quite high and pulmonary metastases at diagnosis have been reported as high as 50% in some series.[40]

# Malignant Liver Tumors

After neuroblastoma and Wilms' tumor, primary tumors of the liver are the third most common intra-abdominal neoplasms in children.[41] HB is the most frequent liver tumor in children in Western countries, whereas in Asia and Africa, hepatocellular carcinoma (HCC) occurs more frequently than HB, probably as a consequence of the higher prevalence of hepatitis B infection on those continents.[42,43] Other less common malignant pediatric liver tumors are listed in Table 33-1.

## HEPATOBLASTOMA

### Epidemiology, Biology, and Genetics

Hepatoblastoma accounts for about 80% of the malignant liver tumors in children.[12,44] In the United States, the incidence of HB has increased from 0.6 to 1.2 cases per million population in the last 2 decades.[44] It comprises 1% of all pediatric malignancies and affects mostly young children between 6 months and 3 years old, but cases in neonates and school-age children are also seen.

Researchers at the University of Minnesota are conducting a large epidemiologic study, termed the "HOPE" study, aimed at elucidating possible environmental and genetic risk factors that might account for the increasing incidence of HB seen over the past 2 decades.[45] The HOPE study (hepatoblastoma origins and pediatric epidemiology) can be reached at www.cancer.umn.edu/hopestudy. A leading theory is that the increased incidence is due to the growing prevalence of premature birth and very-low-birth-weight (VLBW) babies. Both prematurity and very low birth weight have been associated with an increased risk for HB. The association between HB and prematurity or VLBW was first shown in Japan and has since been confirmed in multiple studies.[45–49] No association has yet been found between prematurity as a risk factor and the age at which the tumor diagnosis is eventually made or the histologic subtype of the tumor. Unproven, but postulated, environmental risk factors include occupational exposure of the father to metals, such as welding and soldering fumes, petroleum products, and paint.[50] The list of possible iatrogenic exposures of the premature or VLBW baby in the neonatal care unit includes light, oxygen, irradiation, electromagnetic fields, plasticizers, medications, and total parenteral nutrition.[51]

HB is also associated with fetal alcohol syndrome and hemihyperplasia (formerly termed hemihypertrophy).[52] Hemihyperplasia is associated with an increased risk of embryonal tumors, primarily Wilms' tumor and HB. Curiously, although there is clinical overlap between hemihyperplasia and Beckwith-Weidemann syndrome, the genetic abnormalities seen in HB patients with Beckwith-Weidemann syndrome are not

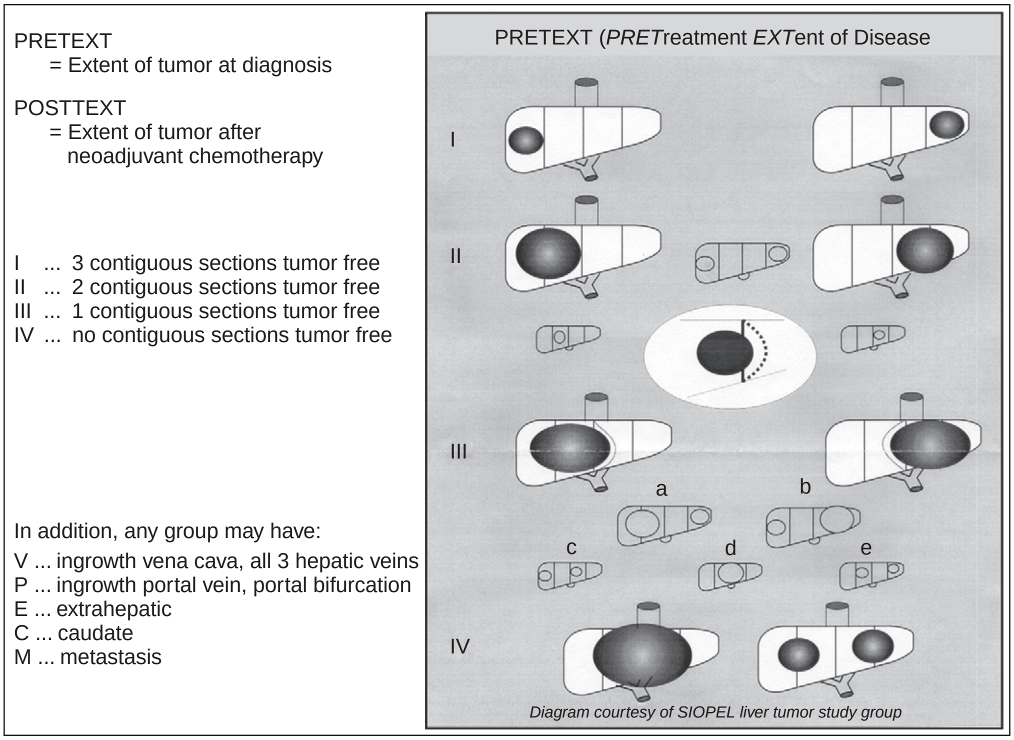

**FIGURE 33-3** PRETEXT.

seen in those with hemihyperplasia.[53] In addition to Beckwith-Weidemann syndrome, a number of other genetic syndromes have been associated with an increased risk of HB, including familial adenomatous polyposis (FAP), Li-Fraumeni syndrome, trisomy 18, and others as shown in Table 33-3.[54–68] Familial case reports of HB with familial adenomatous polyposis are striking and suggest a role in the pathogenesis of HB for chromosomes 5 and 11.[56,69] Additional screening for cases in familial adenomatous polyposis kindred families is recommended by testing for germline mutations in the adenomatous polyposis coli (APC) tumor suppressor gene.[55,70] Germline APC mutations are not commonly seen in children with sporadic HB.[71] The association between Beckwith-Weidemann syndrome and HB is so strong that experts recommend that children with Beckwith-Weidemann syndrome be screened with abdominal ultrasonography and AFP at regular intervals until they reach the age of 7 years.[72] The genetic abnormality in HB patients with Beckwith-Weidemann syndrome is mapped to the 11p15.15 locus and suggests the presence of a tumor suppressor gene at this location.[73] Additional biological markers may include trisomy 2, 8, 18, 20, and translocation of the *NOTCH2* gene on chromosome 1q12-21.[61] Up-regulation of insulin-like growth factor 2 may be mediated by overexpression of *PLGA1* oncogene, a transcriptional activator on the 8q chromosome.[74]

One of the most provocative genetic findings has been the association between HB and mutations of beta-catenin and activation of the WNT/beta-catenin signaling.[75–77] Microarray analysis of WNT/beta-catenin and MYC signaling has defined two tumor subclasses resembling distinct phases of liver development and characterized by a discriminating 16-gene signature. The highly proliferating tumor subclass showed gains of chromosome 8q and 2p and up-regulated MYC signaling.[78,79] Histologic subtypes of hepatoblastoma have also been characterized by different patterns of WNT and NOTCH pathway activation in DLK+ precursors.[80] The authors speculate that HB may arise from proliferating bipotential precursors with WNT activation most prevalent in embryonal and mixed histologic subtypes and NOTCH activation more prevalent in the differentiated pure fetal subtype.[80] In addition, deregulation of MAPK signaling pathway and antiapoptotic signaling is preferentially up-regulated in aggressive epithelial HB with a small cell undifferentiated component.[81] These gene expression signatures may provide prognostic and diagnostic markers, perhaps even therapeutic targets, in the future.[80,81]

Other genetic markers that have been associated with biological behavior include multidrug-resistance genes and the Hedgehog pathway.[82–85] Increased expression of multidrug-resistance genes is seen in response to chemotherapy in many childhood tumors, and this seems to be particularly true in HB.[82] Chemotherapy has been shown to induce overexpression of the multidrug-resistance gene *MDR1*, MDR-associated protein MRP1, and lung-related protein (LRP).[84]

## Pathology

According to the World Health Organization (WHO) Tumor Classification, hepatoblastoma is defined as a malignant tumor with divergent patterns of differentiation, ranging from cells resembling fetal epithelial hepatocytes, to embryonal cells, and with differentiated tissues, including osteoid-like material, fibrous connective tissue, and striated muscle fibers. In fact, the morphology of HB seems to reflect distinctive phases of hepatogenesis, recapitulating cell lineages derived from endoderm fated to become mature liver cells.[86] The neoplastic offspring of these cell systems is present in HB in a variety

HB, hepatoblastoma; HCC, hepatocellular carcinoma.

of proportions, used as the basis of HB classifications, of which the current International Society of Pediatric Oncology (epithelial) liver tumor study group (SIOPEL) classification is shown in Table 33-4. Untreated HB presents as a lobulated mass up to more than 20 cm in diameter, being solitary tumors in 80% of the patients and located to the right lobe of the liver in about 60%. The lesions usually show an expanding growth pattern, but conglomerated masses with satellite nodules are also observed. The color of the cut surfaces is variegated in many HB, partly caused by necrosis and hemorrhage, with the exception of fetal HB, which has the tan color of normal liver. The gross presentation of HB postchemotherapy is characterized by firm and well-delineated and sometimes multinodular masses with whitish fibrotic areas and calcifications.

Histologically, the epithelial components range in their differentiation from a small cell undifferentiated (previously termed anaplastic) phenotype, resembling other cellular blue tumors, to cells that are close to mature hepatocytes (the fetal phenotype). The current, histology-based classification is not consistent regarding cellular differentiation, because one subtype (macrotrabecular) reflects a growth pattern rather than a distinct differentiation step. The fetal subtype, occurring in a purely fetal and a so-called crowded fetal variant, displays the highest level of differentiation. Pure fetal histology HB is associated with both a diploid DNA complement and a low proliferative activity. About 20% of epithelial HB shows a mixture of fetal and less differentiated, embryonal-type cells, with a more pronounced mitotic activity. The macrotrabecular subtype (less than 5% of the tumors) reveals a growth pattern with large cell plates consisting either of fetal-embryonal or hepatocyte-like cells. The latter variant, macrotrabecular type 1 (MT-1) is difficult to distinguish from hepatocellular carcinoma and may have an unfavorable biology.[18] Undifferentiated HB mostly occurs as a small cell neoplasm not associated with elevated serum AFP (small cell undifferentiated [SCU] HB), but variants with larger cells also occur. HB-SCU forms a complex group of tumors in that at least part of the lesions seem to have a relation to rhabdoid tumors and are INI1 protein negative.[87,88]

A large proportion of HB (about 45% when examined after chemotherapy) reveal a mixed epithelial and mesenchymal (MEM) phenotype (HB-MEM; see Table 33-4). Osteoid-like bone tissue is a common mesenchymal (heterologous) component. The same epithelial components as found in the wholly epithelial HB subtypes occur in variable expression. The relative proportions of the components in HB-MEM undergo marked changes subsequent to chemotherapy. After exposure to chemotherapy, often the osteoid dominates the histologic pattern. A small proportion of HB-MEM exhibit unusual tissues, such as glianeuronal, enteric, or melanocytic tissues. These tumors are termed HB-MEM with teratoid features. It has to be emphasized that this term is descriptive and does not imply that these neoplasms are germ cell tumors. The prognostic significance of these histologic types and subtypes is currently under study in large trials.

**TABLE 33-4**

| |
|---|
| Hepatoblastoma, Wholly Epithelial Type |
| Fetal |
| Embryonal/mixed fetal and embryonal |
| Macrotrabecular (MT) |
| Small cell undifferentiated (SCU; formerly anaplastic) |
| Hepatoblastoma Mixed Epithelial and Mesenchymal Type (HB-MEM) |
| Without teratoid features |
| With teratoid features |
| Hepatoblastoma, Not Otherwise Specified (HB-NOS) |

*This is the classification used by the SIOPEL (International Society of Pediatric Oncology [epithelial] liver tumor study group). Classification systems used by American, German, and Japanese study groups vary.

So far, a prognostic relevance has been worked out for the fetal subtype (favorable)[89] and for HB-SCU (unfavorable).[30,31,90] An unfavorable histology of HB-SCU is also present in cases where the SCU feature is expressed in a focal pattern only.[91] In addition to the lesions listed in Table 33-4, an increased number of variants of HB, or lesions thought to be related to HB, have been described, leading to the concept of *tumor families*.[92]

## PRETEXT, STAGING, AND RISK GROUP STRATIFICATION

"Risk Group" stratification determines treatment for hepatoblastoma (HB) in current multicenter group trials. As shown in Table 33-5, The Children's Oncology Group (COG) has low, intermediate, and high-risk treatment groups, whereas SIOPEL defines a standard-risk and a high-risk group. COG continues to use traditional COG (Evans) stage I to IV, and prognostic factors (pure fetal and small cell undifferentiated histology and AFP < 100) to assign risk groups. Although COG does not currently use PRETEXT to assign risk group, it does use PRETEXT to define surgical guidelines, where it determines whether or not a tumor should be resected at diagnosis. The timing of resection will determine the tumor stage for all nonmetastatic tumors. In contrast, SIOPEL uses PRETEXT and prognostic factors to define risk groups.

PRETEXT (see Fig. 33-3) was devised by SIOPEL 1.[93] Subsequent SIOPEL trials (SIOPEL 2, and SIOPEL 3) have used PRETEXT as a tool to stratify treatment, define risk categories, and report outcomes in HB. Although the risk stratification schema differs somewhat between groups, the three other major multicenter pediatric liver tumor study groups, Children's Oncology Group (COG), German Pediatric Oncology Hematology (GPOH), and the Japanese Pediatric Liver Tumor (JPLT) have all chosen to adopt PRETEXT in their current and future protocols. Although PRETEXT has been found to have a slight tendency to overstage patients, it is postulated to show good interobserver agreement (reproducibility.) PRETEXT may also be used to monitor the effect of preoperative therapy when it is applied serially to assess tumor response to neoadjuvant chemotherapy.[28] In North America, COG uses PRETEXT to define surgical resectability (i.e., surgical resection guidelines) in its current HB protocol (AHEP 0731). Building upon the Couinaud 8–segment anatomic structure of the liver, the PRETEXT system divides the liver into four parts, called "sections" (Fig. 33-4). The left lobe of the liver consists of a lateral (Couinaud segments II and III) and medial section (segment IV), whereas the right lobe is divided into an anterior (segments V and VIII) and posterior section (segments VI and VII). Couinaud segment I is the caudate lobe and when involved is shown in PRETEXT with the annotation "C."

As shown by the examples in Figure 33-5, the tumor is classified into one of the following four PRETEXT groups depending on the number of liver sections that are free of tumor: PRETEXT I, three adjacent sections free of tumor; PRETEXT II, two adjacent sections free of tumor (or one section in each hemiliver); PRETEXT III, one section free of tumor (or two sections in one hemiliver and one nonadjacent section in the other hemiliver); and PRETEXT IV, no tumor free sections. Extrahepatic growth and gross vascular involvement is

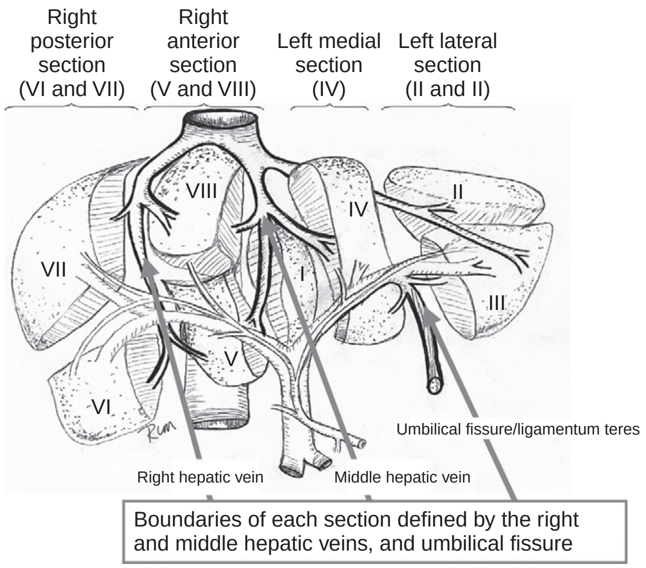

**FIGURE 33-4** PRETEXT is distinct from Couinaud 8–segments (I to VIII) anatomic division of the liver. PRETEXT defines four "sections." Boundaries of each section defined by the right and middle hepatic veins, and umbilical fissure.

**TABLE 33-5**
**Hepatoblastoma Staging and Risk Stratification**

| *Traditional COG (Evans) Staging System* | *Current COG Risk Stratification* | *Current SIOPEL Risk Stratification* |
|---|---|---|
| Stage I: complete gross resection at diagnosis with clear margins | Very low risk: pure fetal histology, resected at diagnosis (stage I/II); see resection guidelines below* | |
| Stage II: complete gross resection at diagnosis with microscopic residual disease at the margins of resection | Low risk: any histology resected at diagnosis (stage I/II); see resection guidelines below* | Standard risk: PRETEXT I, II, III |
| Stage III: biopsy only at diagnosis, or gross total resection with nodal involvement or tumor spill or incomplete resection with gross intrahepatic disease | Intermediate risk: stage III tumors (includes SCU histology) | |
| Stage IV: metastatic disease at diagnosis | High risk: stage IV tumors, AFP < 100 at diagnosis | High risk: PRETEXT IV, metastasis at diagnosis, SCU histology, AFP < 100 at diagnosis |

*COG surgical guidelines recommend resection of tumors at diagnosis (stage I/II) based upon PRETEXT. PRETEXT I and PRETEXT II resected at diagnosis if there is an anticipated greater than 1-cm surgical margin based upon preoperative imaging.

AFP, alpha-fetoprotein; COG, Children's Oncology Group; PRETEXT, pretreatment extent (of tumor) staging system; SCU, small cell undifferentiated; SIOPEL, International Society of Pediatric Oncology (epithelial) liver tumor study group.

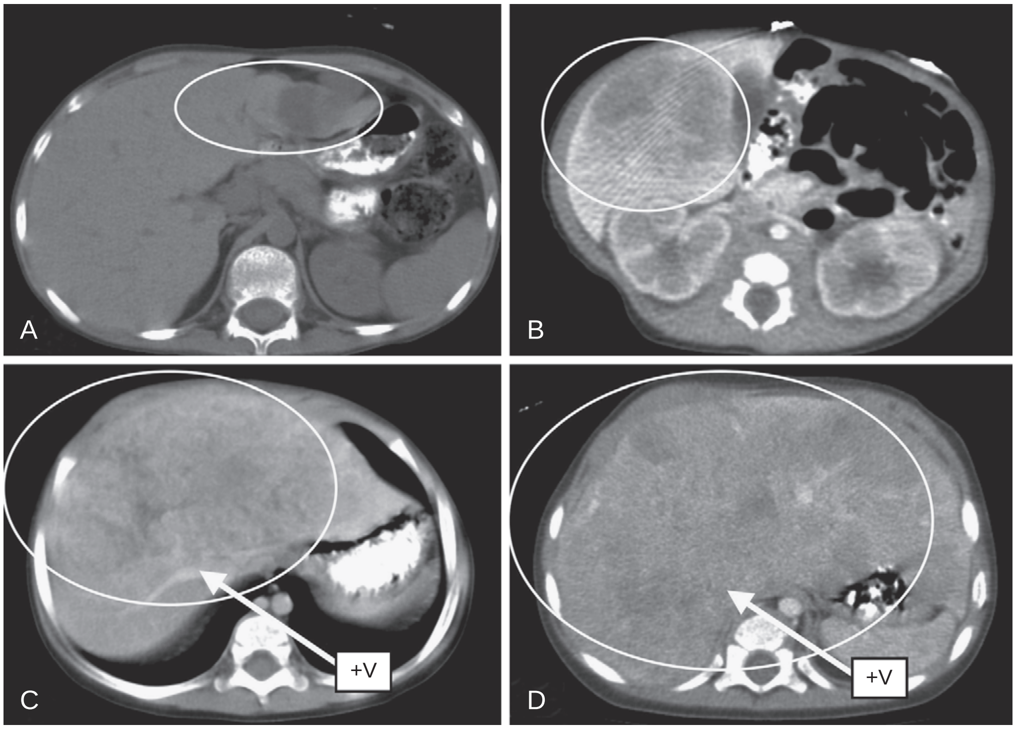

**FIGURE 33-5** Examples of PRETEXT for hepatoblastoma risk stratification. **A,** PRETEXT I, left lateral section. **B,** PRETEXT II, right anterior and right posterior sections. **C,** PRETEXT III, +V: left lateral section, left medial section, and right anterior section with invasion of all three hepatic veins (+V). **D,** PRETEXT IV, +V, +P: tumor involves all four sections and invades vena cava and portal bifurcation.

indicated by adding one or more of the following: V, vena cava or all three hepatic veins involved; P, main portal or *both* portal branches involved; C, involvement of the caudate lobe; E, extrahepatic contiguous growth (e.g., diaphragm or stomach), and M, distant metastases (mostly lungs, otherwise specify).[39]

### Treatment Strategy, Chemotherapy, and Surgery

In the treatment of hepatoblastoma, complete surgical resection remains the cornerstone of curative therapy. And yet, as has become increasingly clear in recent large multicenter trials, surgery alone cannot cure patients who present with advanced disease. More than half of the patients present with either an initial unresectable tumor or with distant metastases. In the early years when these children were treated with surgery alone, there was a 30% relapse rate in those patients whose tumor could be completely resected. Evidence that HB is a chemosensitive tumor began to accumulate in the early 1970s when responses were seen to combinations of cyclophosphamide, vincristine, 5-fluorouracil, and actinomycin-D,[94] but not until the introduction of cisplatin and doxorubicin–containing regimens in the 1980s was there a major impact of chemotherapy on survival.[6] Twenty years later, cisplatin remains the backbone of current chemotherapy regimen. In fact, in the most recent study of standard-risk HB by SIOPEL, SIOPEL 3, treatment results with cisplatin monotherapy were comparable to those achieved with cisplatin/doxorubicin combination chemotherapy (PLADO).[7] Chemotherapy may reduce tumor volume, making the tumor resectable, and may lead to the complete disappearance of lung metastases. The tumor response rate to the present cisplatin-containing chemotherapy regimens varies from 70% to 90%, according to the different series.[7,31,95–100] Neoadjuvant (preoperative) chemotherapy not only makes the tumor "smaller" and consequently more likely to be completely resected, but also more solid, less prone to bleeding, and better demarcated from the remaining healthy liver parenchyma.[101,102] Also, when chemotherapy is given as soon as possible after diagnosis, occult (micro)metastases in the lung have no delay in treatment. No matter how small the primary tumor, SIOPEL recommends preoperative chemotherapy in ALL patients as shown in Figure 33-6. This approach is hypothesized to increase the number of patients for whom complete surgical resection will be feasible, to reduce the surgical morbidity of resection, and to provide more time for making definitive surgical plans, including liver transplantation when indicated.[103,104] Because of the large number of countries participating in the SIOPEL studies, standardization of both sophisticated surgical approaches and supportive care measures has been difficult; therefore the use of preoperative chemotherapy in every case has permitted patients from countries with limited resources to participate in these studies.

In contrast to the SIOPEL approach, the North American "legacy groups" Children's Cancer Group (CCG) and Pediatric Oncology Group (POG) (now COG) and the German Study Group (GPOH) have historically recommended primary surgery, *whenever prudently possible*, as the initial treatment. The decision about which tumors are "resectable," and which ones are not, has been subjectively made by the treating surgeon; hence, the approach has been criticized for being highly variable. Because traditional Evans staging relies on the surgical resection decision at diagnosis (see Table 33-5), and because this is a surgeon-initiated subjective decision, the stage has often depended more on the surgeon than on the tumor. Figure 33-6 shows the North American strategy in COG study AHEP0731, which recommends tumor resection

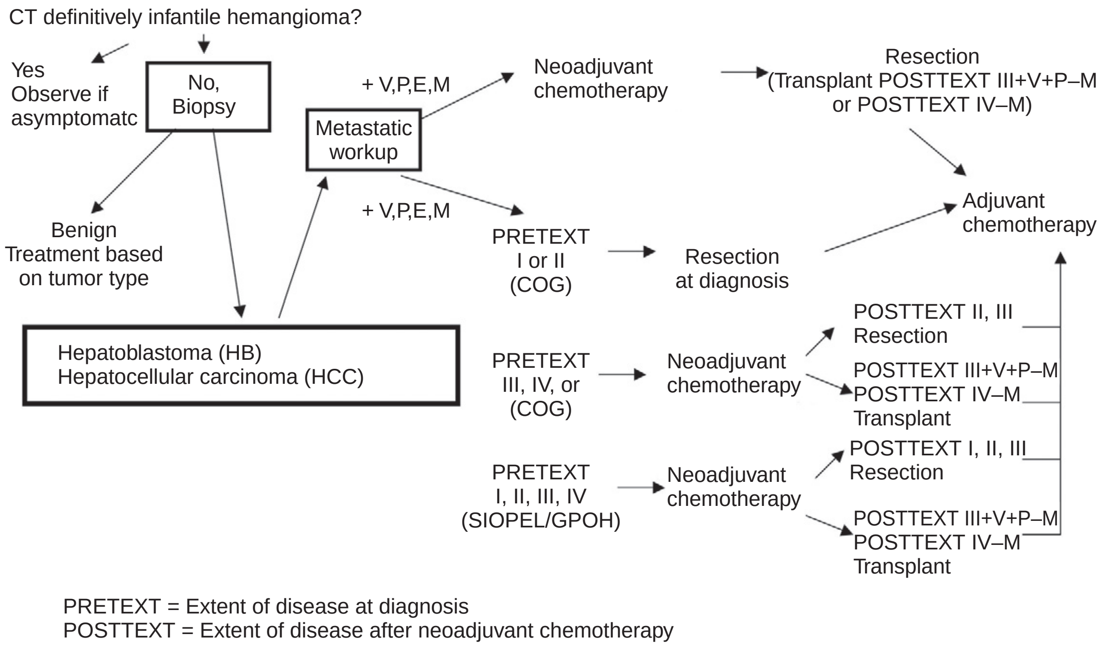

**FIGURE 33-6** Pediatric malignant liver tumor: simplified treatment algorithm. COG, Children's Oncology Group; CT, computed tomography; E, extrahepatic contiguous growth; GPOH, German Pediatric Oncology Hematology (study); M, metastasis; P, main portal or *both* portal branches involved; SIOPEL, International Society of Pediatric Oncology International Society of Pediatric Oncology (epithelial) liver tumor study group; V, vena cava or all three hepatic veins involved.

at diagnosis dictated by PRETEXT-defined surgical guidelines (PRETEXT I and II). Tumors can be resected by straightforward segmentectomy or lobectomy, and are resected at diagnosis. Following these guidelines, approximately one third of HB patients can successfully achieve a gross total resection of tumor at diagnosis, and among them it is possible to identify some that require minimal or no chemotherapy.[89,105] Although it has been debated, postsurgical complications do *not* appear to be more frequent with this approach in the modern era.[30,96,106,107] The potential to reduce cumulative chemotherapy exposure with upfront resection in PRETEXT I and II tumors is important given the ability of HB to develop resistance to standard chemotherapy.[32,82,84] Recent data on magnitude of AFP response actually suggest that the majority of chemotherapy tumor kill probably occurs in the first two cycles.[104]

The strategy in the German trials HB 89 and HB 94 was similar to that used in North America, that is, resection at diagnosis, when feasible, at the discretion of the operating surgeon. In a review of these studies, 30% of children with primary tumor resection had macroscopic or microscopic residual tumor.[31] Despite the larger number of advanced HB in the neoadjuvant chemotherapy group, an incomplete tumor resection was performed in only 18%. Based upon this statistically significant difference, GPOH adopted neoadjuvant chemotherapy for all patients in their latest trial, HB 99, and recommends against any surgical consideration of atypical, nonanatomic, or wedge resection.[18,98]

Surgical guidelines in the current COG trial, AHEP-0731 *do not* leave the decision about surgical resection at diagnosis up to the subjective discretion of the individual surgeon; objective resection guidelines are part of the protocol. PRETEXT is used to define which tumors should be resected at diagnosis (see Fig. 33-6). Resection at diagnosis is recommended for stage I/II only when segmentectomy or a facile, nonextended lobectomy will predictably yield a complete resection, that is, PRETEXT I or II tumors with at least 1 cm of clear margin anticipated upon review of diagnostic radiographic imaging. A POSTTEXT IIId tumor is a central tumor that may be best resected by mesohepatectomy in the hands of an experienced liver surgeon (Fig. 33-7). Transplantation is preferred in any tumor that invades the major vascular inflow (POSTTEXT +P) or outflow (POSTTEXT +V). If the PRETEXT (and POSTTEXT) suggests the need for major vascular reconstruction, which is sometimes called extreme resection (a resection performed in a patient who would otherwise meet criteria for liver transplantation) or liver transplantation, a referral for transplantation evaluation is advisable. Accuracy of PRETEXT is moderate (because of difficulty in differentiating tumor vessel compression from vessel ingrowth) with a slight tendency to overstage.[28] Nevertheless, good interobserver agreement has been reported, and comparing PRETEXT with POST-TEXT allows for an objective analysis of tumor response to chemotherapy.[39] The predictive value for survival using PRETEXT is excellent, and combining PRETEXT with traditional COG staging yields additional predictive value.[28,30]

*Postoperative* (adjuvant) chemotherapy is currently recommended by *all* study groups, for *all* patients with one small exception. Stage I pure fetal histology (PFH) in INT-0098 and COG P9645 received reduced or no chemotherapy[89,96,97] and has a 5-year event-free survival (EFS) and overall survival (OS) of 100% and 100%, respectively. Thus no chemotherapy is recommended for pure fetal histology patients resected at diagnosis in COG AHEP-0731. Cisplatin remains the backbone of the chemotherapy regimen, but the drug combinations differ somewhat between study groups. COG currently uses cisplatin/5-FU/vincristine (C5V) for low-risk tumors, C5V + doxorubicin for intermediate risk, and will investigate new agents (irinotecan) with upfront window

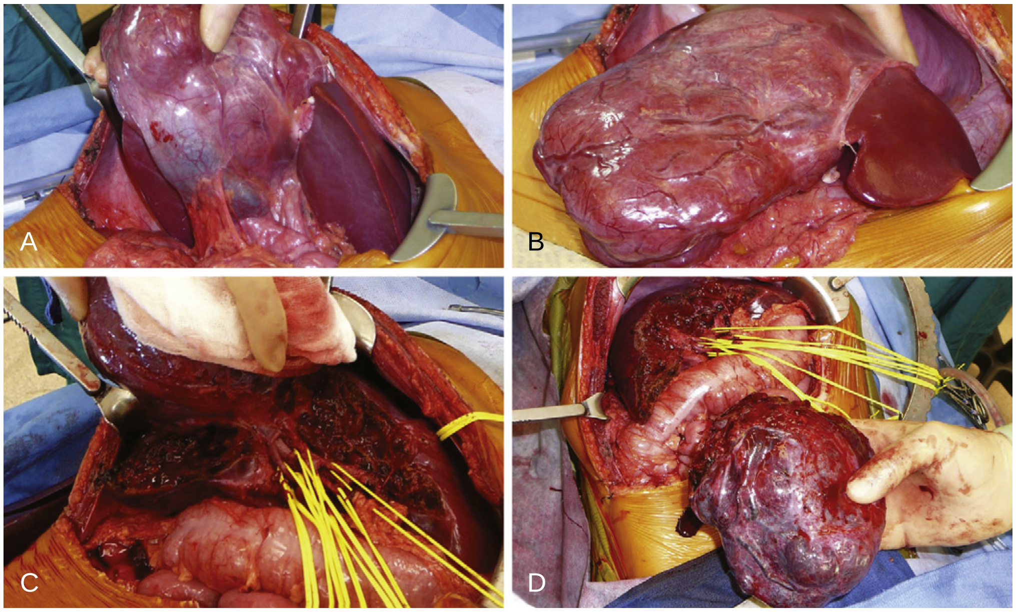

**FIGURE 33-7** Central PRETEXT IIId hepatoblastoma: resection with mesohepatectomy versus complete hepatectomy and transplantation, depends upon extent of macroscopic vessel involvement. **A,** Central hepatoblastoma involving left medial and right anterior sections (PRETEXT IIId). **B,** Resection with right or left trisegmentectomy would leave very little residual normal liver. **C,** Much of the normal liver can be saved by mesohepatectomy if the portal vessels are *not* encased and a good margin can be obtained. If tumor encases or invades the portal vessels, complete hepatectomy and transplantation is recommended. **D,** Frozen section shows negative margins.

therapy in high-risk tumors.[42] SIOPEL 3 compared cisplatin monotherapy with PLADO for standard risk[95] and used SUPERPLADO for high risk.[7] The current SIOPEL 4 high-risk study uses an intensified platinum regimen.[99] The recent GPOH trial HB-94 used IPA (ifosfamide/cisplatin/doxorubicin),[31] and the ongoing GPOH trial HB99 uses IPA for standard risk and carboplatin-VP-16 for high risk.[98] The recent Japanese trial JPLT-2 has used CITA (cisplatin/THP-Adriamycin [doxorubicin]) for standard risk and ITEC (ifosfamide/carboplatin/doxorubicin/etoposide) + HACE (hepatic artery chemoembolization) for high-risk patients.[108] Irinotecan, with or without doxorubicin, has been used in both North America and Europe for patients with relapse.[109,110]

In terms of overall survival rates, the results of the different study groups are generally comparable, projecting 3-year overall survival rates, regardless of the first therapeutic modality used, of 62% to 70% (Table 33-6).[7,31,95–100] The improved results in the high-risk group achieved in SIOPEL 3 highlight some important lessons learned over the past 2 decades. (1) With standard treatment, about 25% of patients who present with metastatic disease are ultimately cured, and alternative chemotherapy and surgical resection of pulmonary metastatic disease should be considered in patients who do not show an excellent early response to chemotherapy. (2) The presence of a positive microscopic margin may not portend a poor prognosis in patients who have had an excellent response to chemotherapy. (3) Liver transplantation or extreme resection (i.e., mesohepatectomy and major venous resection and reconstruction) should be considered in every child with unresectable HB (about 15% of cases).[9,10,102,111–113]

The current COG trial, AHEP-0731, is a risk-stratified study that seeks to diminish toxicity in low-risk patients, increase survival in intermediate-risk patients, and identify new agents(s) in high-risk patients.[107] Very-low-risk patients with pure fetal histology (PFH) hepatoblastoma resected at diagnosis receive no chemotherapy. Low-risk patients who have non-PFH histology resected at diagnosis receive two adjuvant cycles of cisplatin, 5-flouorouracil, and vincristine (C5V), a reduction from the standard four cycles of chemotherapy used in previous COG trials. For intermediate-risk patients with stage I SCU, stage II SCU, or any stage III hepatoblastoma the chemotherapy regimen will add doxorubicin to the C5V therapy (C5VD). High-risk patients with metastatic tumor or initial AFP less than 100 ng/mL will be treated with an upfront window of a novel agent (irinotecan) preceding the backbone therapy with C5VD.

### Liver Transplantation for Hepatoblastoma

In 1968, Starzl reported the first long-term survivor of liver transplantation, a child with hepatoma. From that time until the cluster of papers published by Al-Qabandi, Reyes, Pimpalwar, Molmenti, and Srivastin from 1999 to 2002,[114–118] most descriptions of the use of transplantation in hepatoblastoma were anecdotal case reports. Largely because of early negative experience with liver transplantation in the treatment of adult hepatocellular carcinoma, liver transplantation for the treatment of hepatic malignancy developed a reputation as a dreaded, last resort, heroic, and even potentially ethically inappropriate intervention. The biology of pediatric hepatoblastoma has proven to be very different from that of adult hepatocellular carcinoma, with cisplatin-based chemotherapy proven to be of significant value in a number of randomized trials. This availability of effective chemotherapy led credence to the bold statement by Reyes in his landmark paper in 2000 [115] that "in these children with unresectable tumors, the historical barrier of "unresectability" can be redefined with the concept of 'total liver resection' and salvage orthotopic liver transplantation (OLT)." Thus beginning about 2000, liver transplantation began to be offered to more and

more children as part of a planned treatment algorithm. With increased experience defining the optimal timing of transplantation, the outcomes with liver transplantation for hepatoblastoma have blossomed.

***Transplantation Outcomes for Hepatoblastoma*** In the past decade, more than a score of reports have appeared in the literature championing the potential role of liver transplantation in the treatment of unresectable pediatric hepatoblastoma (Table 33-7).[113–130] Transplantation, although potentially lifesaving, carries attendant consequences, including perioperative morbidity and mortality and the subsequent need for lifetime immunosuppression. The experience from Birmingham, United Kingdom illustrates contemporary experience, with 5-year disease-free survival of 100% when primary transplantation was performed in patients with a good response to chemotherapy, 60% after primary transplantation in patients with a poor response to chemotherapy, only 50% in patients with transplantation as a second option or "rescue transplantation," and 0% in patients not undergoing surgery.[116] In SIOPEL 1, overall survival at 10 years was 85% with a primary transplantation but only 40% for the children who underwent a rescue transplantation.[120] In a collaborative report of the world experience of liver transplantation for hepatoblastoma,[120] the overall survival rate at 6 years was 82% for 106 patients who received a primary transplantation, but only 30% for 41 patients who underwent a rescue transplantation.

***Indications and Contraindications for Transplantation in Hepatoblastoma*** The following criteria are currently used by COG and SIOPEL to select potential candidates for transplantation: (1) multifocal PRETEXT IV, multifocal tumor in all four liver sections at diagnosis; (2) unifocal PRETEXT IV, with neoadjuvant chemotherapy often these tumors will "downstage" to a POST-TEXT III and become amenable to conventional resection by trisegmentectomy; (3) POSTTEXT III+V, proximity of the tumor to the vena cava or all three major hepatic veins makes adequate tumor clearance without impaired venous outflow doubtful; (4) POSTTEXT III+P, proximity of the tumor to the portal venous bifurcation or both major branches of the portal vein makes adequate tumor clearance without impaired portal venous inflow doubtful; (5) Intrahepatic relapse or residual tumor after previous attempt at resection, known as rescue transplantation. Although these guidelines are very useful, some uncertainty and controversy remains regarding the management of multifocal tumors, patients with venous involvement who might be candidates for extreme resection, patients who present with pulmonary metastasis, and patients who are referred with relapse or residual tumor and require rescue transplantation.

***Transplantation for Multifocal Hepatoblastoma*** Both COG and SIOPEL currently recommend that all patients with multifocal PRETEXT IV tumors should undergo liver transplantation, even if one of the liver sections is apparently clear of tumor nodules after preoperative chemotherapy (Fig. 33-8). Microscopic foci of viable tumor are seen in explant livers despite the apparent radiographic disappearance of tumor nodules from these areas after preoperative chemotherapy.[131] In addition, multiple series have shown excellent results from primary transplantation and poor

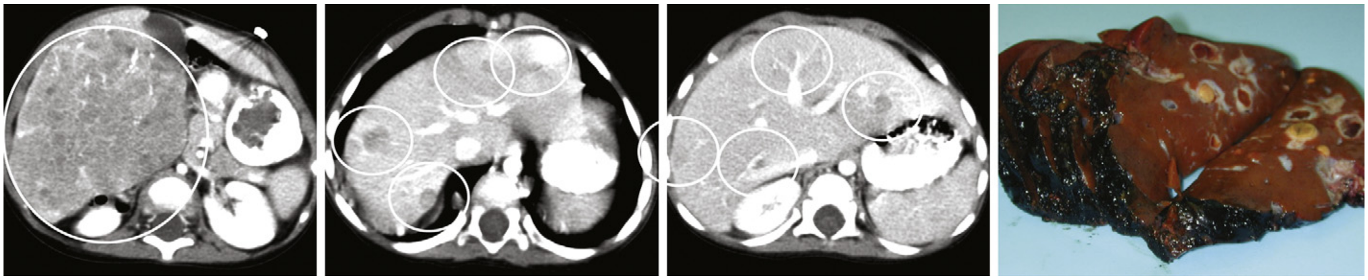

**FIGURE 33-8** PRETEXT IV multifocal hepatoblastoma. In the presence of extensive multifocal tumors, microscopic satellites should be assumed, and no distance of surgical margin can ensure complete surgical excision. Extensive multifocal tumors are best treated by complete hepatectomy and liver transplantation.

results from rescue transplantation.[116,120,124,126,129] In a recent series from Padova, predictors of failed conservative therapy included multifocality.[132]

***Major Venous Involvement: Transplantation versus Extreme Resection*** Aggressive resections, less than total hepatectomy, may be successful in select patients with tumor encroachment on the vena cava or main portal vein. Complex extensive resection, with vascular reconstruction if necessary, depends upon surgical expertise and a careful evaluation of the degree of vascular involvement and realistic ability to achieve complete, *and safe*, resection.[133,134] Poorly planned or executed operations risk excessive bleeding, inflow or outflow vascular obstruction, biliary leakage or stricture, cholangitis, and/or hepatic failure. Although most agree that extreme resection of tumors without liver transplantation will avoid the need for long-term immunosuppression,[102,113,132,133,135–137] outcomes with these techniques have not been rigorously reported. Current recommendations for referral of high-risk patients with hepatoblastoma to centers that have the ability to do an extreme resection, with liver transplantation as an immediately available safety net, should result in an improved ability to compare the outcomes of these two approaches.*

***Transplantation for Hepatoblastoma with Pulmonary Metastasis at Diagnosis*** An absolute contraindication to liver transplantation is persistent pulmonary metastases non-responsive to neoadjuvant chemotherapy and not amenable to surgical resection. Stable or progressive disease in the face of neoadjuvant chemotherapy is a relative contraindication to transplantation.[10,133] Lung metastases that disappear completely with chemotherapy, or with a combination of chemotherapy and surgical resection, do *not* pose a contraindication, yet the risk of post-transplantation pulmonary relapse is substantial, and therefore the use of liver transplantation for children with metastatic disease remains controversial.

* References 9,10,112,131,137,138

**TABLE 33-8**

**Liver Transplantation in Children with Hepatoblastoma and Pulmonary Metastasis at Diagnosis, Review of Literature (Meyers and Otte,[9] 2010)**

| *Pulmonary Metastasis at Diagnosis* | *No. of Patients* | *Post-transplantation Pulmonary Relapse* | *Alive without Evidence of Tumor* | *Died of Other Causes* |
|---|---|---|---|---|
| Lung lesions disappeared with chemotherapy | 24 | 9 (38%) | 14 (58%) | 1 (4%) |
| Pretransplantation pulmonary metastasectomy | 8 | 3 (38%) | 5 (62%) | |
| TOTAL | 32 | 12 (37%) | 19 (60%) | 1 (3%) |

Patients listed in table have been separately reported in the following series during the past 10 years: Perilongo, 2004[95]; Casanova, 2009[99]; Schnater, 2002[101]; Al-Qabandi et al, 1999[114]; Reyes et al, 2000[115]; Avila et al, 2006[124]; Cassas-Medley, 2007[126]; Superina et al, 1996[139]; Nathan 2009[140]; Otte, 2009.[141]

Table 33-8 shows the accumulated cases in the literature and presented at national and international meetings during the past 10 years.* Overall survival appears to be about 60% with no large difference in outcome when there is lung metastasis with complete radiographic resolution on chemotherapy versus pulmonary metastasectomy. Some centers do AFP imaging pretransplantation, PET-CT pretransplantation, median sternotomy with manual palpation of both lungs pretransplantation, and lobectomy rather than metastasectomy if the lung has more than four nodules in the same lobe.[142]

***Rescue Transplantation for Local Relapse Hepatoblastoma*** Multiple series have shown superior outcome after primary transplantation (about 80% overall survival) when compared with rescue transplantation (about 30% to 40% overall survival).[116,120,124,126,129] The basis for this is undoubtedly multifactorial, but two important reasons are (1) the likelihood of chemotherapy resistance in relapsed tumors and (2) the debilitated state of the patients when transplanted in the face of end-stage disease.

***Type of Allograft and Immunosuppression*** There is a trend to improved survival of children receiving a live-donor liver transplantation (LDLT).[120,121,128] When a living donor is available, pretransplantation chemotherapy can be scheduled optimally, with a rapid decision towards transplantation.[121] Whether living donor grafts might require less immunosuppression as suggested by Gras,[143] or whether alternative immunosuppression using rapamycin (sirolimus), a drug with both antineoplastic and immunosuppressive properties, will have any impact in children with hepatoblastoma remains to be seen. Many worry that the toxicity of chemotherapy might be potentiated by immunosuppression, but this has *not* been the experience at high-volume centers. With such a small number of patients in each of the individual series reported to date, it is not possible to make a clear recommendation at this time.

***Pediatric Liver Unresectable Tumor Observatory (PLUTO)*** SIOPEL, together with support from COG, GPOH, and the Study of Pediatric Liver Transplantation (SPLIT), has established a worldwide electronic registry for liver transplantation for childhood liver tumors (hepatoblastoma, hepatocellular carcinoma, and diffuse infantile hemangioma).[9,10,141,144] The link to obtain a password to register patients on this database can be accessed through the PLUTO Registry website: http://pluto.cineca.org/access.

## New Agents and Treatment Modalities

***Hepatic Arterial Chemoembolization (HACE), Transarterial Chemoembolization (TACE)*** HACE and TACE are different acronyms for the same interventional radiologic procedure, also sometimes referred to as transcatheter arterial chemoembolization. This technique continues to be quite popular in China where recent experience in infants and children showed a mean tumor shrinkage of 59%, mean decrease in AFP of 60%, mean tumor necrosis in the surgical specimens of 87%.[145] Widespread use has been somewhat limited by toxicity, which includes fever, pain, nausea, vomiting, transient coagulopathy, and, most worrisome, pulmonary oil (Lipiodol) embolism.[145–147] Pulmonary oil embolism is infrequent, and although fatalities have been reported, the clinical course is usually self-limited oxygen desaturation for 24 to 48 hours and pulmonary infiltrate for about a week.[148] Chemotherapeutic cocktails have included various combinations of cisplatin, doxorubicin, doxorubicin-eluting beads, vincristine, pirarubicin, mitomycin, and Lipiodol, followed by gelatin foam particles or stainless steel coils, and radioactive microspheres.[131,145–148] There are scattered case reports of cure without the need for surgical resection,[149] although it is most often used not as a definitive treatment, but rather as palliation for large unresectable tumors in the presence of uncontrolled metastatic disease.[145]

***Ototoxicity*** Both SIOPEL and COG have put considerable effort into investigations trying to decrease the significant ototoxicity induced by the use of cisplatin-based chemotherapy in young patients, especially infants. The risk of cisplatin causing bilateral moderate to severe high-frequency hearing loss is significantly increased in children younger than 5 years of age.[150] The COG 9645 trial failed to reduce ototoxicity with the agent amifostine.[151] The recently opened SIOPEL 6 study will investigate sodium thiosulfate[152] as an agent to decrease the cisplatin-induced ototoxicity. The current COG trial, AHEP0731, attempts to reduce ototoxicity by limiting the extended use of cisplatin in the low-risk patients.

***Hepatoblastoma Risk Stratification and International Collaboration*** Current data suggest that pure fetal histology and PRETEXT I and II tumors have a favorable prognosis.[28,30,89] Risk factors that seem to portend a worse outcome include metastatic disease at diagnosis (COG Stage IV, PRETEXT +M), PRETEXT IV, AFP < 100 at diagnosis, small cell undifferentiated histology and possibly macrotrabecular and/or extensive multifocal histology.[18,30,90,153] In 2007, SIOPEL, GPOH, and COG decided to embark on a mutual project that

was called the *C*hildhood *H*epatic Tumors *I*nternational *C*ollaboration (CHIC). The complete databases of these groups are in the process of being united to address prognostic questions requiring increased statistical power. To identify these common data points for prognostication and risk stratification, data regarding prognostic factors (i.e., histology AFP, stage, multifocality, biological markers) can thus be studied in much larger patient groups in which the clinical outcome is known. These developments are the starting point of a new trans-Atlantic converging cooperation on a large intercontinental scale that will be of eventual benefit for children with liver tumors.

***New Agents, Tumor Relapse*** The prognosis for a patient with recurrent or progressive hepatoblastoma depends on many factors, including the site of recurrence, prior treatment, and individual patient considerations. It was recently shown that in patients who initially received only cisplatin/5-FU/vincristine cure may be possible with a multidrug relapse regimen including doxorubicin.[109] Surgical resection of pulmonary relapse is possible and has been reported to produce long-term cure, but does not carry as good a prognosis as resection of pulmonary metastatic lesions present at diagnosis that simply fail to completely resolve on chemotherapy.[154–156] If possible, isolated metastases should be resected completely in patients whose primary tumor is controlled.[138,142,157] Success with autologous peripheral blood stem cell transplantation with a double conditioning regimen has been reported in a child with pulmonary relapse after liver transplantation.[158] Irinotecan has been used in chemotherapy relapse regimens with some success.[159] In recurrent refractory disease, phase I and II clinical trials may be appropriate and should be considered. Multidrug chemotherapy resistance is a key factor for the poor outcome of relapsed HB. Novel gene-directed treatment approaches, such as adenovirus-mediated cytosine deaminase/5-fluorocystine suicide gene therapy, may offer hope for treatment of these chemotherapy-resistant tumors in the future.[82,83] Information on current COG trials can be found at www.childrensoncologygroup.org.

## HEPATOCELLULAR CARCINOMA

### Epidemiology, Biology, and Genetics

In Western countries, hepatocellular carcinoma occurs approximately half as often as hepatoblastoma (HB) or in 23% of all primary pediatric liver tumor cases, most often in school-age children and adolescents. Although described previously, it was not until 1967 that childhood HCC was identified by Ishak and Glunz[3] as an entity to be distinguished from HB. In 1974, Exelby and colleagues[5] analyzed the clinical course of childhood HCC and found an overall dismal outcome.

HCC occurs predominantly in the setting of underlying liver disease and cirrhosis. Compared with adults, in children cirrhosis is less commonly part of the antecedent process, while congenital or acquired disorders of the liver, such as metabolic disease, are common.[17] Table 33-9 shows the conditions that are associated with HCC in children.[43,66,160–175] Patients with tyrosinemia seem to be a particularly high risk and should be vigilantly screened with serial AFP and imaging.[174] In East Asia and Africa, HCC is more common than HB because of the widespread prevalence of hepatitis B and C.[43] In Taiwan, where HCC is most often seen in carriers of the hepatitis B virus, vaccination programs targeted against hepatitis have led to a significant decrease in the incidence of HCC.[42] In contrast to hepatitis B, the cirrhosis and the subsequent development of HCC in the hepatitis C population usually takes several decades to develop.[176] The genetic syndromes associated with HCC are shown in Table 33-3.[54,55,62–68]

### Pathology

In the pediatric age group, more than two thirds of HCC occur in children older than 10 years of age, but only 0.5% to 1% of all HCC manifest before 20 years of age, and very few HCCs are diagnosed in children less than 5 years old. About 20% to 35% of children with HCC have underlying chronic liver disease. It is still disputed whether classical (adult-type) HCC in the pediatric age group is the same or a different disease with respect to HCC in adult patients. It is currently suggested that HCC forms a tumor family, consisting of adult-type HCC and its variants, fibrolamellar HCC, and a novel entity occurring in older children and young adolescents, transitional liver cell tumor (TLCT).[92]

HCC presents grossly as solitary or multiple (multifocal) lesions. Solitary tumors display four main growth patterns, that is, expanding (or pushing) mass lesions, pedunculated (or hanging) lesions, invading tumors with poor delineation, and multifocal tumors resembling metastatic disease. These growth patterns exert a considerable influence on the surgical resectability of the tumors. The color of the cut surfaces of HCCs depends, apart from bleeding and necrosis, on differentiation features of the tumor cells, for instance bile synthesis and accumulation.

The microscopic features of pediatric classical HCC are similar to or the same as those in adult patients. Many tumors exhibit a trabecular growth pattern with intervening sinusoid-like vascular channels and a reduced reticulin network. Regarding grading, Edmondson and Steiner developed a system comprising a scale of I to IV.[177]

***Fibrolamellar Hepatocellular Carcinoma (FL-HCC)*** This tumor usually arises in noncirrhotic livers of adolescents or young adult patients and is encountered more frequently in Western countries.[178] Overall, FL-HCC accounts for less than 10% of all HCCs. Recent data show that FL-HCC has biological features similar to that of adult-type HCC. FL-HCC shows vascular invasion in up to 35% of cases, frequently metastasizes into locoregional lymph nodes (about 50% of cases), and tends to show unusual spreading patterns, including intraperitoneal spread. FL-HCC is typically a solitary lesion that has a predilection for the left liver lobe (two thirds; unusual for hepatic primary tumors). It reveals well-defined margins and a central scar in 70%. The cut surface often shows a firm, tan to brown tissue with radiating septa, sometimes closely resembling focal nodular hyperplasia. The leading cell is a large and polygonal, hepatocyte-like cell with a granular cytoplasm of large vesicular nuclei. These cells form strands embedded in the typical fibrosclerotic stroma that may form a central stellate scar. A considerable proportion of the tumor cells contain large, ground glass–like inclusions, the so-called pale bodies, which are helpful in bioptic diagnosis. Periodic acid–Schiff (PAS)-positive globular inclusions in part contain alpha-1-antitrypsin and other glycoproteins. Typically, cells of FL-HCC show marked immunostaining for cytokeratin 7.[92]

***Transitional Liver Cell Tumor (TLCT)*** Transitional liver cell tumor is a recently identified liver neoplasm that occurs in older children and young adolescents. The term transitional had been proposed to denote a putative intermediate position of the tumor cells between hepatoblasts and more mature hepatocyte-like cells. TLCT are highly aggressive lesions that have a treatment response pattern clearly different from hepatoblastoma.[179] The usual presentation is that of a large or very large solitary hepatic tumor (mostly in the right liver lobe), commonly associated with very high serum AFP levels. Grossly, the tumors display an expanding growth pattern and sometimes exhibit a large central necrosis. Histologically, the tumor cells vary between HCC-type cells and cells found in hepatoblastoma, sometimes with formation of multinuclear giant cells. The lesions markedly express beta-catenin, typically in a mixed nuclear and cytoplasmic pattern.[180]

### PRETEXT and Staging

Children's Oncology Group staging for hepatocellular carcinoma does not use risk stratification and simply follows the traditional COG stage I, II, III, and IV shown in Table 33-5. Nevertheless, discussions with colleagues describing the extent of tumor involvement of the liver are based upon PRETEXT to aid in making key decisions about surgical resectability.

### Treatment Strategies

Hepatocellular carcinoma is relatively chemotherapy resistant and therefore carries a poor prognosis with a dismal rate of cure.[181,182] Complete surgical resection or hepatectomy and transplantation for tumor localized to the liver is often the only hope. Unfortunately, HCC is most often advanced at diagnosis, and cure is rarely possible in the setting of metastatic disease. Even with aggressive attempts at surgical resection, tumor relapse is common and tumor-free survival rates of not more than 25% to 30% can be achieved. These mostly depend on the extent of disease, and the main prognostic factor for childhood HCC is resectability. The first multicenter clinical trials on pediatric liver tumors were conducted in North America by the Children's Cancer Study Group (CCSG) and POG, some of which included HCC in addition to HB.[181] These studies confirmed the poor response of HCC to chemotherapy and radiation and the dismal rate of cure in the majority of patients.

The North American cooperative study (INT-0098) as well as SIOPEL 1[181,182] used pre-operative chemotherapy in an attempt to increase surgical resectability for children and adolescents with HCC, because this is the foundation for curative therapy of liver tumors. Of the 46 patients entered onto INT-0098, only 8 had completely resected tumors (stage I) at study entry, 25 had unresectable tumors (stage III), and 13 presented with metastatic disease (stage IV). Patients were randomized to receive cisplatin with either doxorubicin or 5-fluorouracil and vincristine. No differences were seen in response or survival rates between the two treatment regimens. Seven of the 8 stage I patients (88%) with complete tumor excision at time of diagnosis, followed by adjuvant cisplatin-based chemotherapy, survived. This is a significant improvement when compared with only 12 of 33 patients (36%) treated before the consistent use of adjuvant chemotherapy. This result suggests that adjuvant chemotherapy may be of benefit for patients with completely resected HCC. However, because one third of these initially resected patients have fared well without any additional chemotherapy, the question of the necessity for adjuvant chemotherapy will only be answered in a randomized trial. In contrast, outcome was uniformly poor for patients with advanced-stage disease. The 5-year event-free survival for stage III and IV patients was 23% and 10%, respectively (Table 33-10).

Hepatocellular carcinoma patients have been treated in three consecutive studies of the German Society for Pediatric Oncology and Hematology (see Table 33-10).[26] In the first study, HB89, neoadjuvant and adjuvant chemotherapy consisted of conventionally dosed ifosfamide, cisplatin, and doxorubicin (IPA), which did not show any substantial benefit.[26] Of the registered 12 patients, only 4 with resectable tumor survived. In the second study (HB94), patients with nonresectable HCC received conventionally dosed carboplatin and etoposide in addition to IPA, which seemed to produce at least short-term benefit.[26] Of the registered 25 patients, 9 had locally unresectable and 11 metastatic HCC. Three of the 9 and 1 of the 11 patients survived free of disease in addition to 4 of 5 patients with resectable tumor (total 8 of 25 = 32%).

Results of SIOPEL 1, 2, and 3 are shown in Table 33-10.[182,183] Only 2 of the 39 patients entered onto the SIOPEL-1 study underwent complete resection of the tumor at diagnosis, followed by chemotherapy, while the remaining 37 patients had preoperative chemotherapy with cisplatin and doxorubicin. Metastases were identified in 31% of the patients, and extrahepatic tumor extension, vascular invasion, or both in 39%. Although partial tumor response to chemotherapy was observed in 49% (18 of 37) of the patients, complete tumor resection was achieved in only 36% (14 of 39) of the patients. Outcomes of patients on this study were also unsatisfactory, with a 5-year event-free survival of 17%. All long-term survivors had complete surgical excision of their tumor. Twenty-one patients were enrolled on the subsequent

study SIOPEL 2. Data were available for 17 of these. One patient died 17 days after diagnosis from massive GI bleeding and never received treatment. Thirteen of the 16 treated patients received preoperative chemotherapy with cisplatin, carboplatin, and doxorubicin. Partial response to preoperative chemotherapy was observed in 6 of 13 cases (46%). Gross total tumor resection was achieved in 8 patients (47%), 3 at the time of diagnosis and 1 through liver transplantation. Nine tumors (53%) never became operable. One patient was lost to follow-up just before planned surgery. Four of the patients having resection of their tumors were alive at a median follow-up time of 53 months (range of 35 to 73 months). Twelve patients died because of progressive disease and one from surgical complications. The three-year overall survival for this study was 22%.

In comparing the results of these studies, the outcome for patients with HCC has shown no significant improvement, despite the progress in surgical techniques, chemotherapy delivery, and patient support. It seems obvious that a new treatment approach is needed to increase the rate of cure of childhood HCC.

In adults, fibrolamellar type of hepatocellular carcinoma has been traditionally associated with a higher resection rate and better survival when compared with the typical pathologic variant of HCC both in adolescents and young adults.[184,185] The higher resection rate for children and adolescents with the fibrolamellar variant of HCC was not supported by the studies reported by either Katzenstein[181] or Czauderna.[182] Patients with the fibrolamellar variant did not have a better outcome when compared with those with typical HCC, the 5-year event-free survival was 30% compared with 14%, respectively ($P = 0.18$), although the median survival was longer for patients with the fibrolamellar variant.

Given the poor response of HCC to chemotherapy and radiation, the mainstay of treatment is surgery. This means that, in contrast to hepatoblastoma, a primary radical tumor resection has to be attempted whenever possible using all available techniques in order to achieve this goal.[26] Therefore in school-age children and adolescents with a primary liver tumor the surgeon has to be prepared to perform highly sophisticated liver surgery after confirmation of the diagnosis by pathologic investigation of intraoperative frozen sections. Patients with the clinical constellation for advanced HCC should always be treated in consultation with a specialized center with experience in childhood liver surgery.

## Liver Transplantation for Hepatocellular Carcinoma in Children

***Outcomes, Indications, and Contraindications*** Published outcomes for liver transplantation in children with HCC are shown in Table 33-11.* The following guiding principles have been formulated by centers with particular expertise in pediatric liver transplantation. They are in a greater state of controversy and evolution than are the guidelines for HB. In most centers, the criteria for transplantation of multifocal and unifocal HCC are the same as for HB and do *not* follow adult limitations on size and number of nodules. Unlike HB, however, any history of pulmonary metastatic disease or extrahepatic disease is considered an absolute contraindication. Major vascular involvement, of the portal vein for example, is a relative contraindication depending upon the degree and severity of involvement.[142] It is important that consultation with a transplantation center with special expertise in pediatric liver surgery be considered early in the treatment to prevent delays and unwanted extended courses of chemotherapy while awaiting resection and transplantation.

***Response to Chemotherapy*** HCC tumor progression while on chemotherapy is a relative contraindication to transplantation, because occult extrahepatic micrometastatic disease is increasingly likely in this situation.

***Milan Criteria*** The Milan criteria, introduced by Mazzaferro in 1996, restrict transplantation in adults with HCC as follows: (1) single tumor diameter less than 5 cm; (2) not more than

three foci of tumor, each one not exceeding 3 cm; (3) no angioinvasion; (4) no extrahepatic involvement. Since the introduction of these criteria, long-term recurrence-free survival after liver transplantation in adults with HCC improved from 30% to 75%.[195–198] The problem with the Milan criteria in children is that 50% to 70% of children present with large de novo tumors and a large tumor burden in otherwise healthy livers, *and the Milan criteria were developed in adults with small tumors and underlying cirrhotic liver disease.* In children, the number of nodules, as stipulated by the Milan criteria, is usually not considered a contraindication to transplantation as long as the disease is confined to the liver. Furthermore, de novo pediatric HCC often shows features on a continuum with pediatric HB, and these "transitional liver tumors" may have a more favorable biology.[92–200] In view of the lack of improvement in results of conventional treatment of pediatric HCC during the past 2 decades, most clinicians treating pediatric HCC do NOT recommend adherence to Milan criteria in children who present with large de novo tumors, no cirrhosis, and no evidence of extrahepatic disease.[201]

***Metastatic Disease*** Metastatic disease is considered an *absolute* contraindication to liver transplantation in HCC, and a very careful and thorough evaluation to exclude metastatic microdeposits is essential.

***Post-transplantation Chemotherapy*** Guidelines for post-transplantation immunosuppression in HCC are the same as with transplantation for HB with one possible difference. Many centers would consider post-transplantation adjuvant antiangiogenic therapy with sorafenib in HCC. Experience in the transplantation population of patients is limited, but in any patient considered to be at high risk for tumor relapse, options for possible antiangiogenic therapy should be discussed. Similarly, many centers have begun to experiment with rapamycin (sirolimus) as a post-transplantation immunosuppressant because of its antineoplastic, antiangiogenic properties.[203–205]

## New Agents and Treatment Modalities

***Antiangiogenesis, Sorafenib*** New treatment modalities including metronomic chemotherapy,[206] and adjuvant antiangiogenic therapy[207] are the target of investigation based upon some early promising results. Most promising has been the recent adult experience with sorafenib, an antiangiogenic tyrosine kinase inhibitor, where a survival advantage has clearly been shown in prospective trials of sorafenib in the treatment of HCC in adults with unresectable tumors.[202] Interestingly, this seems to be also the case in some preliminary investigation in childhood HCC.[208]

***Chemoembolization and Therasphere*s** Hepatic arterial chemoembolization (HACE) and transarterial chemoembolization (TACE) refers to the intra-arterial administration of chemotherapeutic and vascular occlusive agents (generally gelatin or Lipiodol) along with cytotoxic drugs. The drugs most frequently used for chemoembolization are doxorubicin, mitomycin, and cisplatin. Intra-arterial injection of cytotoxic agents results in higher local concentration of drugs with reduced systemic side effects, while the intra-arterial embolization causes ischemic necrosis of the tumor. This therapeutic strategy has been used in a small number of children and adolescents with recurrent HCC while awaiting the availability of a liver donor, or as adjuvant therapy in an attempt to facilitate tumor resection.[145,209] There are no large trials in children; however, in a study of adult HCC patients without liver failure or cirrhosis, although TACE successfully reduced tumor growth, it frequently caused acute liver failure and did not

improve survival.[210] A related approach that combines radiation therapy with angiographic embolization has been the intra-arterial injection of yttrium-90 radioactive microspheres, called Therasphers.[211]

***Portal Venous Embolization*** Portal venous embolization has been used in adults with liver disease to induce hypertrophy of the remaining liver remnant[212] and reported experimentally in children.[213] The portal venous branch on the side of the tumor is cannulated percutaneously, and polyvinyl alcohol and coils are inserted to induce portal vein occlusion under fluoroscopic control. This has a dual effect of alcohol thrombosis of the embolized tumor and compensatory hypertrophy of the unharmed opposite liver lobe, increasing the potential hepatic functional reserve in patients with cirrhosis and underlying liver dysfunction in preparation for hepatic resection.

***Percutaneous Ablative Therapies*** Ablative percutaneous methods of local control may be considered, especially in recurrent tumors. They include percutaneous radiofrequency ablation (RFA), percutaneous ethanol injection (PEI), and cryotherapy. Cryotherapy refers to cold injury produced by cryoprobe delivery of liquid nitrogen, and although once popular in adults, it has now fallen out of favor because of superior results achieved with RFA and PEI. In most cases, these treatment approaches are palliative and are suitable for smaller tumors only, generally below 3 cm to 4 cm maximum diameter. RFA provides slightly better tumor kill than PEI (90% vs. 80% complete tumor necrosis) with fewer sessions (mean of 1.2 vs. 4.8).[199] It is also associated with fewer side effects; thus in many centers, RFA is now preferred versus PEI; however, RFA is contraindicated in lesions located adjacent to the major biliary ducts or to bowel loops. Complications of these ablative techniques occur in about 8% to 9% of cases, mainly in the form of pain, fever, bleeding, tumor seeding, and gastrointestinal perforation.[214] Percutaneous ablation has not been well studied in children.

## Hepatic Sarcomas

Primary hepatic sarcomas are rare. Outcome depends primarily on tumor histology, sensitivity to chemotherapy and/or radiotherapy, and the ability to achieve complete tumor resection.[215]

### Biliary Rhabdomyosarcoma

The classic presentation of biliary rhabdomyosarcoma is in young children (average age 3½ years) with jaundice and abdominal pain, and it is often associated with distension, vomiting, and fever.[13] Histology is exclusively embryonal or botryoid, both histologic subtypes of rhabdomyosarcoma that are known to have a favorable prognosis. Because the tumor most often involves the central biliary tree and porta hepatis, the ability to achieve gross total resection is rare. Fortunately, the tumor is often sensitive to both chemotherapy and radiation, and long-term survival is seen in 60% to 70% of patients. Surgical intervention has two goals: to establish an accurate diagnosis and to determine the local-regional extent of disease. Although chemotherapy is generally effective at relief of the associated biliary obstruction, patients remain at risk for biliary sepsis until the obstruction abates.

### Rhabdoid Tumor

Although pediatric rhabdoid tumors are most common in the kidney and brain, they do occur at other sites, including the mediastinum and liver. When primary to the liver, rhabdoid tumor is difficult to distinguish from the small cell undifferentiated (SCU) variant of hepatoblastoma. Given the aggressive biological behavior and poor prognosis seen with the SCU variant of HB, it has been suggested that some tumors previously classified as HB-SCU may actually have been hepatic rhabdoid tumors. The differentiation of an HB-SCU from a rhabdoid tumor is challenging and is important in terms of research, but possibly clinically irrelevant at present because both are biologically aggressive with poor response to chemotherapy. Malignant rhabdoid tumor of the liver is a rare and aggressive tumor of toddlers and school-age children that may present with spontaneous rupture.[216,217] These rare tumors are often chemoresistant and fatal,[216] although a recent case report documents the potential for cure with multimodal therapy, including ifosfamide, vincristine, and actinomycin D.[217] As with all locally aggressive liver tumors that respond poorly to chemotherapy, the most important treatment goal is complete surgical excision.

### Undifferentiated Sarcomas

Undifferentiated (embryonal) sarcoma of the liver is a rare childhood hepatic tumor that has historically been considered an aggressive neoplasm with an unfavorable prognosis. These tumors may arise in a solitary liver cyst.[218] Survival has improved in recent multimodal approaches, designed for patients with soft tissue sarcomas at other sites, including conservative surgery at diagnosis, multiagent chemotherapy, and second-look operation in cases of residual disease. Using these techniques several small series have reported survival in up to 70% of children.[219–221]

### Angiosarcoma

Although rare, personal experience and multiple case reports in the literature support the potential for malignant transformation of an infantile hemangioma to angiosarcoma.[222,223] Histologic verification of malignancy may be difficult, and this rare entity must be suspected if the biological behavior of an infantile hemangioma shows unusual progression or recurrence after a period of relative quiescence. Relatively chemoresistant, prognosis is generally poor.

### Aggressive Hemangiomatous Tumors

***Locally Aggressive Infantile Hepatic Hemangioma*** Infantile hemangioma is the most common benign tumor of the liver in infancy[19] with striking variability of the three subtypes of infantile hemangioma: focal, multinodular, and diffuse. Many focal lesions are often discovered incidentally and are localized and small enough to be of little clinical significance. Symptoms seen with larger lesions may include abdominal distention, hepatomegaly, congestive heart failure, vomiting, anemia, thrombocytopenia and consumptive coagulopathy, jaundice secondary to biliary obstruction, and associated cutaneous or visceral hemangiomas.[11] Contrast-enhanced CT scan shows an area of diminished density, and after bolus injection of intravenous contrast, there is contrast enhancement from the periphery toward the center of the lesion. Further, after a short delay, there is complete isodense filling

of the lesion and liver. Magnetic resonance angiography (MRA) has been used in complex cases to identify atypical radiographic features that may portend a poor prognosis.[224] Unfavorable radiographic features include central varix with arteriovenous shunt, central necrosis or thrombosis, and diffuse hemangiomatous involvement of the liver with abdominal vascular compression.[224] Arterial angiography may be used in infants with refractory symptoms in whom either hepatic artery ligation or embolization is considered.

If a definitive diagnosis of simple infantile hepatic hemangioma can be made radiographically, management can be noninvasive because spontaneous regression occurs in most cases, especially focal tumors. The terminology is confusing, however, with different authors often using the terms hepatic hemangioma, infantile hepatic hemangioma, hepatic hemangioendothelioma, or kaposiform hemangioendothelioma interchangeably.[225] True kaposiform hemangioendothelioma with Kasabach-Merritt (as opposed to the high-output heart failure from intrahepatic shunts seen in diffuse infantile hemangioma), rarely, if ever, presents as a primary hepatic tumor.[226] Hemangioendotheliomas are occasionally primary to the retroperitoneum, where they can invade the liver and obstruct the porta hepatis, causing portal hypertension. These tumors are discussed in more detail in Chapter 125.

Sometimes a large rapidly growing infantile hepatic hemangioma can be life threatening with intractable high-output cardiac failure from intralesional arteriovenous shunting, intraperitoneal hemorrhage, respiratory distress as a result of pulmonary congestion, and massive hepatomegaly compressing abdominal vasculature and producing abdominal compartment syndrome (Fig. 33-9). Historically, the initial medical intervention for symptomatic tumors has been corticosteroids. Many other medical treatment options exist, although no single treatment has been shown to be universally effective. Congestive heart failure is treated with supportive care, digitalis, and diuretics. Anemia and coagulopathy are treated with corrective blood product replacement therapy. Both success and complete failure have been reported variously with many other treatments, including epsilon-aminocaproic acid, tranexamic acid, low-molecular-weight heparin, vincristine, cyclophosphamide, interferon-2-alpha, AGM-1470, and newer generation antiangiogenic drugs.[227–231] Recent studies have shown that the large tumors may produce antibodies to thyroid-stimulating hormone (TSH), and screening to rule out secondary hypothyroidism is recommended.[232,233] Most recently, propranolol has been shown to inhibit the growth of infantile hemangioma.[234] Although rare, malignant transformation to angiosarcoma has been reported, and close follow-up is recommended.[223,224,235,236]

In infants who fail medical management, symptomatic solitary tumors may be treated by excision, hepatic arterial ligation, or selective angiographic embolization.[237] Treatment algorithms may stratify treatment based upon whether or not the tumor is solitary, multifocal, or diffuse.[238,239] About 65% of tumors are solitary or unifocal with a survival of 86% and death usually not caused by the tumor but by a comorbidity.[19] Thirty-five percent of tumors are multifocal or diffuse, with a survival somewhere between 60% to 100%, with death usually secondary to cardiorespiratory compromise caused by tumors refractory to medical and interventional management.[19,237,238]

## Metastatic and Other Liver Tumors

***Metastatic Liver Tumors*** Unlike the large body of literature concerning liver resection for metastatic colorectal tumors in adults, there is little published data that addresses the treatment of metastatic tumors in the liver following from abdominal solid tumors in childhood. A recent series from a large metropolitan children's cancer center reported only 15 such patients during a 17-year period, including neuroblastoma (7), Wilms' tumor (3), osteogenic sarcoma (2), gastric epithelial (1), and desmoplastic small round cell tumor (2).[240] Eleven of the 15 patients died of progressive disease; 4 had a local recurrence. These results lead the authors to conclude that the overall prognosis in these patients remains poor, and the decision to perform hepatic metastasectomy should be made with caution. The treatment approach should not, however, be uniformly nihilistic, because not all liver lesions in children with abdominal solid tumors turn out to be metastatic disease. Both nodular regenerative hyperplasia and focal nodular hyperplasia have been reported to mimic hepatic metastasis in children[241]; definitive diagnosis requires biopsy and/or resection.

Occasionally, a pancreatoblastoma may present with extensive hepatic metastasis (Fig. 33-10). Despite the alarming radiographic appearance at diagnosis, this tumor was, in fact,

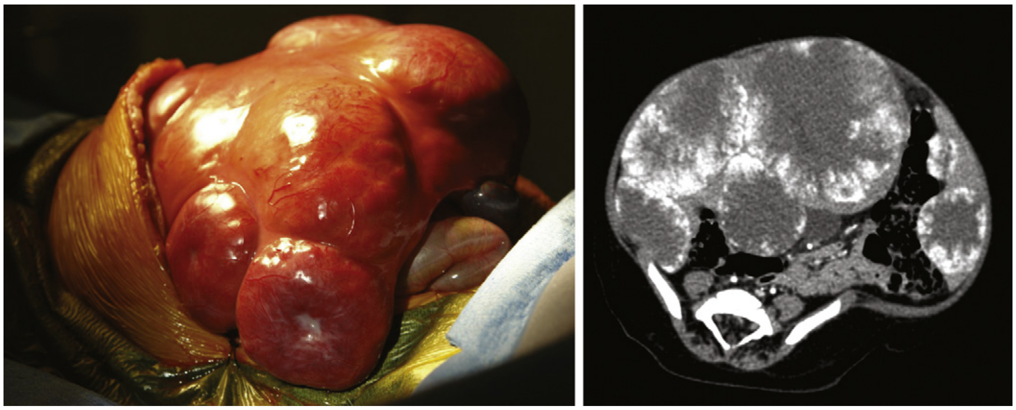

FIGURE 33-9 Symptomatic multifocal/diffuse infantile hepatic hemangioma. These tumors are benign but occasionally will be refractory to aggressive attempts at medical and percutaneous management. This tumor showed progressive growth despite chemotherapy and percutaneous embolization of largest nodules. The baby developed abdominal compartment syndrome and vena cava obstruction. Treated with temporizing abdominal decompressive laparotomy and, definitively, with hepatectomy and live-donor liver transplantation.

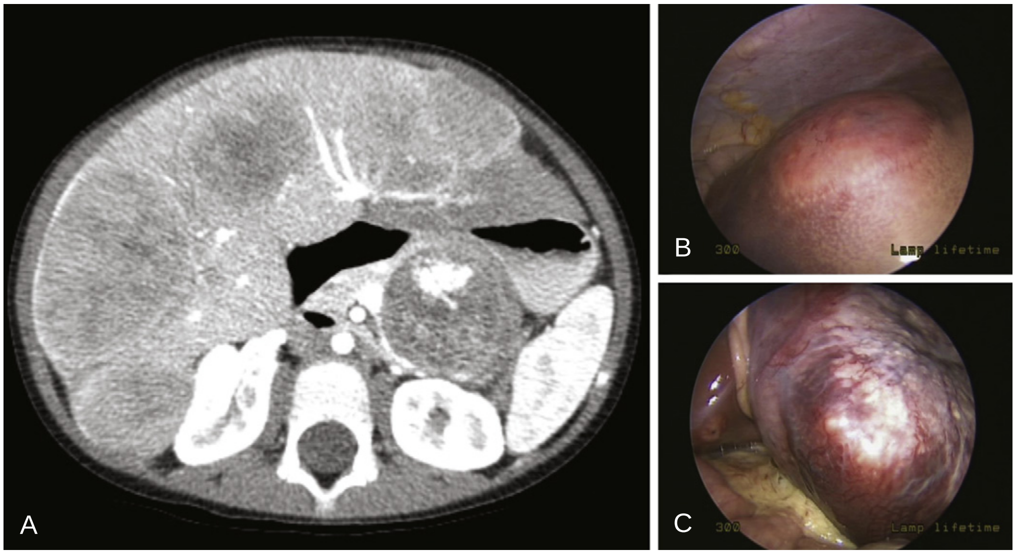

**FIGURE 33-10** Metastatic pancreatoblastoma. **A,** Infant with extensive metastatic tumor in the liver at diagnosis. **B** and **C,** Appearance at laparoscopic biopsy. Primary tumor is a pancreatoblastoma involving the body of the pancreas. Although the tumor metastases were extensive at diagnosis, they prove to be exquisitely chemosensitive with cisplatin/doxorubicin chemotherapy.

exquisitely chemosensitive, and the child did well after neoadjuvant chemotherapy, subtotal pancreatectomy, hepatectomy, and live-donor liver transplantation. Pancreatoblastomas are treated with multiagent chemotherapy analogous to hepatoblastoma and have a fair prognosis if chemosensitive.

### Liver Tumors as Secondary Malignancies

We recently saw a case of multiple lesions of focal nodular hyperplasia in the liver of a 10-year-old boy 9 years after treatment for stage IV neuroblastoma with double autologous stem cell transplantations. Given the history, we initially suspected metastatic neuroblastoma, but diagnostic laparoscopy and laparoscopic biopsy of multiple lesions showed focal nodular hyperplasia (FNH). Another case report of FNH in a child with a history of stage IV neuroblastoma showed foci of small cell undifferentiated hepatoblastoma in the resection specimen; so, very close follow-up is necessary if treatment of the FNH is nonoperative.[242] Liver tumors have been recognized as potential late effects and/or secondary malignancies in children who have previously undergone chemotherapy and radiation as toddlers.

### Hemophagocytic Lymphohistiocytosis

Hemophagocytic lymphohistiocytosis (HLH) may occasionally present as an abnormal liver mass in a newborn with coagulopathy. Predisposing factors include familial, herpes simplex virus, and severe combined immunodeficiency.[243] Diagnostic criteria according to HLH-2004 include fever, splenomegaly, bicytopenia, hypotriglyceridemia, hypofibrinogenemia, hemophagocytosis, low natural killer (NK) cell activity, hyperferritinemia, and high interleukin-2 (IL-2) receptor levels.[244] Treatment is with combination chemoimmunotherapy, including etoposide, dexamethasone, cyclosporine A, and anticipated mortality of about 40% is increased if the diagnosis or appropriate therapy is delayed.

### Langerhans' Cell Histiocytosis

Morphologic changes and clinical findings in Langerhans' cell histiocytosis (LCH) of the liver may resemble primary sclerosing cholangitis or a chronic nonsuppurative destructive cholangitis.[245] Therefore LCH is an important differential diagnosis of chronic destructive cholangitis with cholestatic liver disease, especially in children and young adults. Other involved organs include bone, pituitary, thyroid, and lungs.[246] The diagnosis can be verified by S-100 and CD-1a (antigen) immunohistochemistry. There have been rare reports of pediatric liver transplantation in toddlers with multisystem LCH, children who developed end-stage liver disease despite intensive chemotherapy.[247,248]

### Megakaryoblastic Leukemia

Rarely, congenital acute megakaryoblastic leukemia (AMKL) may present isolated to the liver, with ascites caused by massive infiltration of hepatic sinusoids by leukemic cells.[249] The bone marrow by microscopy and flow cytometry and the peripheral blood smear may not initially show the presence of blasts. Because the marrow fibrosis may not manifest until after the massive hepatic infiltration, it may initially be difficult to diagnose as leukemia. In most children with liver involvement the spleen, lymph nodes, and marrow will also be involved at diagnosis. But even in these cases, the diagnosis may be difficult both clinically and pathologically, and the hepatic and lymph node involvement is not uncommonly misinterpreted as solid tumor.[250]

CHAPTER 34

# Pediatric Gastrointestinal Tumors

Joseph T. Murphy and Robert P. Foglia

Primary gastrointestinal (GI) tumors are uncommon in infants and children, and GI malignancies account for less than 2% of all cases of pediatric cancer.[1] The presentation and histopathology of pediatric GI tumors differ significantly from those seen in adults. Although rare, GI malignancy should be considered in any child with signs and symptoms of intestinal obstruction, intractable pain, alteration in bowel habits, or GI bleeding that are not attributable to other more common and established diagnosis. Symptoms often persist for several weeks and may progress to intestinal obstruction requiring emergency surgery.[1,2] Children with unexplained gastrointestinal symptoms require a detailed diagnostic evaluation.[3]

## Esophageal Smooth Muscle Tumors

Esophageal leiomyomas and leiomyosarcomas are rare in children, with fewer than two dozen patients accounting for all documented pediatric esophageal smooth muscle tumors. Although esophageal smooth muscle tumors are often solitary in adults, in children they are frequently multifocal, with a third involving the entire esophagus and 70% extending into the proximal stomach. Children typically present with esophageal obstruction and dysphagia, food regurgitation, and chest pain. Barium swallow findings mimic achalasia, and a biopsy is required for definitive diagnosis. Leiomyomas in children are occasionally associated with familial syndromes, such as familial leiomyoma and Alport syndrome. Extensive surgical resection is necessary in the majority of cases.[4,5]

## Esophageal and Gastric Adenocarcinoma

Esophageal and gastric cancer in children is extremely rare. Between 1988 and 1996 the Surveillance, Epidemiology, and End Results (SEER) database documented esophageal malignancy in only three patients between 10 and 19 years of age, and none younger than 10 years.[6,7]

The development of Barrett esophagus secondary to chronic gastroesophageal reflux disease (GERD) is a primary risk factor for the development of esophageal adenocarcinoma. Children with severe neurologic deficits, such as cerebral palsy, and those with congenital defects involving the esophagus, such as esophageal atresia and tracheoesophageal fistula, are at increased risk for development of Barrett esophagus.[8] The incidence of Barrett esophagus has been estimated to be 0.02% among children with severe GERD and associated risk factors. Nevertheless, adenocarcinoma of the esophagus has been documented in adolescents with long-standing GERD, and surveillance with upper endoscopy and multiple longitudinal biopsies is appropriate for those children who have the mucosal changes of Barrett esophagus.[9,10]

Barrett changes can also be seen in the retained cervical esophagus following esophageal replacement surgery. Postoperative care of these patients requires control of gastric pH and long-term surveillance endoscopy with biopsy of the retained upper esophageal segment. Esophageal replacement surgery for a patient with esophageal atresia can be performed with retention of the distal esophageal segment. This remnant can develop severe chronic esophagitis and Barrett changes requiring resection. Because Barrett esophagus is a premalignant condition, the distal segment of the esophagus should be removed at the time of esophageal replacement surgery.[11] Esophageal carcinomas may also occur in children after caustic esophageal injuries. Endoscopic evaluation with biopsies should be considered for patients with chemical injuries to monitor for the development of premalignant changes.[12]

Between 1975 and 2007, the SEER database reported a gastric cancer incidence of 9.25 per 100,000 individuals, with an age-adjusted incidence of 0.1% for patients younger than 24 years.[6,13] Despite the rarity of this entity, there are case reports of adenocarcinoma of the stomach in children as young as 2.5 years. The tumors can arise from any anatomic location in the stomach, with nonspecific symptoms including epigastric pain, weight loss, vomiting, anemia, and symptoms associated with esophageal achalasia. Surgical resection is the primary therapeutic modality; however, curative resection is rare and mortality rates are high for children with this tumor.[14–16]

# Gastrointestinal Stromal Tumors

## EPIDEMIOLOGY

Gastrointestinal stromal tumors (GISTs) are rare mesenchymal tumors whose classification is hindered by anecdotal reports, failure to distinguish between primary and secondary GISTs, and the mixing of benign and malignant tumors in the reports.[17] In addition, GISTs arising from various anatomic sites have been reported together, making prediction of their clinical behavior difficult.[18] The most common site is the stomach (50% to 70%), followed by the small intestine (20% to 30%), colon or rectum (10%), and esophagus (5%).[19]

## CLINICAL PRESENTATION

Patients with GIST tumors present with nonspecific symptoms, often generalized abdominal pain, dyspepsia, and occult GI bleeding. Iron-deficiency anemia should prompt an investigation to exclude a GI tract malignancy as the cause.[1] Less commonly, patients present with a palpable abdominal mass or intestinal obstruction.[20] Standard imaging studies may assist in the diagnosis (plain radiographs and computed tomography [CT]). Endoscopy can identify a tumor mass in the stomach, duodenum, or colon.[21]

## PATHOLOGY

GISTs are classified as mesenchymal tumors of the GI tract thought to originate from the intestinal cell of Cajal, an intestinal pacemaker cell.[22] Historically, smooth muscle tumors, such as leiomyomas and leiomyosarcomas, and neural tumors, such as nerve sheath tumors, have been categorized as GISTs. GISTs are now defined as cellular spindle cell, epithelioid, or occasional pleomorphic mesenchymal tumors that express the KIT (CD117, stem cell factor receptor) protein, as detected by immunohistochemistry. Additional cell type markers, such as CD34, smooth muscle actin, desmin, and S-100 protein, are also used to establish a diagnosis of GIST. These histologic and immunohistochemical features now distinguish GISTs from leiomyomas, leiomyosarcomas, neural tumors, and other tumors of smooth muscle origin.[23] Prognosis relies on traditional pathologic staging criteria, such as size, extent of tumor invasion into mucosa or surrounding organs, mitotic index, and nuclear pleomorphism. However, no single feature is consistently reliable in predicting outcome.[24]

Determining prognosis of pediatric patients with GIST tumors can be controversial. The usual criteria for assessing risk of malignancy (i.e., tumor size, mitotic activity, anatomic location) are not reliable in pediatric GIST. Children frequently present with multiple gastric nodules, making identification of a dominant mass difficult. Secondly, there exists a wide variation in proliferation index between patients and even among multiple tumors within the same patient. Furthermore, some pediatric patients develop GIST metastasis despite being classified as low risk by adult criteria, and others with low proliferation indices develop recurrent disease in perigastric nodal basins, the peritoneum, or liver.[25] Pediatric GIST is distinguished as a separate clinical, pathologic, and molecular subset with a predisposition for females, multifocal gastric tumors, and wild-type *KIT/PDGRA* genotype. This is in contrast to older-age, adult GIST and even GIST in young adults. All these factors must be considered when distinguishing benign from malignant pediatric gastric stromal tumors.[18,26]

## ASSOCIATED CONDITIONS

The Carney triad consists of a gastric leiomyosarcoma, functioning extraadrenal paraganglioma, and pulmonary chondroma. The gastric stromal tumors are usually located along the lesser curve or antrum and produce few symptoms; however, continued growth leading to mucosal ulceration, GI bleeding, and serosal involvement is common. Despite the possible development of additional gastric tumors in the remaining stomach, if feasible, partial gastrectomy is recommended as the initial operation, to avoid the complications of more extensive gastric resection, particularly in teenaged patients. Because the multifocal nature of the tumor can lead to local recurrence, regular follow-up is mandatory to assess for new gastric tumors. Adjuvant therapy has been unsuccessful in treating metastatic disease. Evaluation for adrenal tumors in patients with gastric stromal sarcomas and pulmonary chondromas should be considered, and a family history should be obtained from patients with the Carney triad. Recently, an autosomal dominant inheritance of paragangliomas and gastric GIST, called the Carney-Stratakis syndrome, has been identified, representing a separate condition affecting both males and females. Succinate dehydrogenase subunit gene mutations, typically associated with familial paragangliomas, have been implicated in the pathogenesis of Carney-Stratakis syndrome.[27–30]

An uncommon, histologically distinct subset of GIST, called a GI autonomic nerve tumor (GANT), has been described in children. Pediatric GANTs have a female prevalence and symptoms that may include anemia, abdominal pain, fullness, emesis, and a palpable abdominal mass. Although adult GANTs are found predominantly in the small intestine, pediatric GANT lesions are primarily gastric tumors. The majority of pediatric patients have localized disease at the time of diagnosis. Younger age, localized disease, gastric location, and small tumor size at diagnosis are associated with favorable prognosis. Immunocytochemical and ultrastructural evaluation is required to differentiate these tumors from GIST. Established pathologic criteria for malignancy are not well defined for the pediatric GANT because of the low incidence of these tumors. Surgical resection of the tumor is the treatment of choice, because there appears to be no definite role for chemotherapy or radiation.[10]

## TREATMENT

Complete surgical excision of GISTs, along with the pseudocapsule, is the treatment of choice. Achieving negative pathologic margins is frequently possible, because GISTs tend to hang from and do not diffusely infiltrate the structure from which they arise. Consequently, wedge resection of the stomach or segmental resection of the intestine provides adequate therapy; wide resection is not necessary.[17] In addition, because the status of microscopic margins does not appear to be important for survival, vital structures should not be sacrificed if gross tumor clearance has been attained. GIST rarely metastasizes to lymph nodes; so, lymphadenectomy is seldom warranted.[19]

The high rate of local and distant recurrence underscores the need for adjuvant therapy. GIST has traditionally been resistant to radiotherapy; however, imatinib mesylate, a selective KIT, PDGF-RA, PDGR-RB, and BCR-ABL tyrosine kinase inhibitor, has been successful as a first-line agent in treating advanced and metastatic GIST in adult patients. Imatinib blocks the constitutive activity of KIT receptor in GIST cells.[21] Recently, a mutation in the c-*KIT* gene on exon-11 associated with increased risk of recurrence and higher mortality was identified.[19] The efficacy of imatinib is related to GIST genotype, with *KIT* exon-11–mutated GISTs being more sensitive to imatinib than wild-type (WT) tumors. While imatinib mesylate has been effective adjuvant therapy for adult GISTs, pediatric GIST lesions are frequently less responsive. The lack of efficacy may result from pediatric GISTs being predominantly WT genotype and lacking the *KIT* mutations more commonly detected in adult GIST tumors.[31,32] Second-generation kinase inhibitors (i.e., sunitinib, nilotinib, sorafenib, and dasatinib) have demonstrated in vivo and in vitro efficacy in treatment of malignancy with *KIT* mutations.[33–36] Although investigations of adjuvant and neoadjuvant tyrosine kinase inhibitors are ongoing, surgical excision remains the initial option for pediatric GISTs. Adjuvant chemotherapy with imatinib and other agents may be used in cases of incomplete resection, tumor spillage, or other high-risk factors. For recurrent or metastatic GIST, a trial of a kinase inhibitor, followed by surgical resection, may be effective. Neoadjuvant tyrosine kinase inhibitor chemotherapy may similarly reduce unresectable GIST lesions making surgical resection possible. These therapies may decrease the incidence of postoperative GIST recurrence and spread, and thereby extend survival.[34,35]

### SURVIVAL

The long-term survival following surgical resection of pediatric GIST is difficult to determine, because most reports contain small numbers of children or include adults. Moreover, given recent changes in the recognition and pathologic identification of these tumors, many older series contain tumors that are actually not GISTs. Factors associated with long-term survival following surgical resection include small tumor size, low mitotic index, genotype, and gastric primary location.[20] Pediatric GISTs present with a higher incidence of metastasis than comparable adult gastric tumors. However, the biology of pediatric lesions appears more indolent than adult disease with significant long-term survival, despite the presence of metastatic disease and with or without effective adjuvant chemotherapy.[25]

## Intestinal Tumors

### MYOFIBROMATOSIS

Infantile myofibromatosis is a mesenchymal tumor that can arise in the skin, muscle, bone, subcutaneous tissue, or viscera. It is the most common fibrous tumor of infancy. Myofibromatosis presents with either solitary or generalized lesions, with or without visceral involvement. Most lesions spontaneously regress; however, extensive intestinal myofibromatosis is associated with significant morbidity and mortality.[37,38] Various chemotherapeutic interventions have demonstrated limited efficacy, significant treatment toxicity, and long-term morbidity. However, the combination of low-dose chemotherapy and long-term total parental nutrition for life-threatening infantile myofibromatosis can provide symptomatic relief and inhibit disease progression.[39,40]

### LYMPHOMA

Lymphoma is the most common small bowel malignancy in children, with high-grade non-Hodgkin lymphoma comprising 74% of these tumors. Burkitt lymphoma constitutes the most common histologic subtype. The majority of patients (50% to 93%) present with lymphoma localized to the distal small bowel, although tumor may occur anywhere from the stomach to the rectum.[41]

Patients may present with chronic GI distress, occult blood per rectum, hematochezia, and/or an abdominal mass. An acute worsening of symptoms may result in emergency surgery for treatment of ileocolic intussusception, with lymphoma creating the lead point (46%), acute appendicitis (22%), perforation (11%), or obstruction (8%). Higher mortality is associated with advanced disease stage, intestinal perforation, high-grade histology, and T-cell lymphomas.[42]

Surgical management depends on disease presentation, as well as extent of disease at presentation. Bulky disease is usually not completely resectable. Extensive resection of bulky retroperitoneal or mesenteric disease does not enhance survival; nevertheless, complete surgical resection (including bowel resection), if possible, significantly enhances the prognosis of patients with intestinal lymphoma, especially when included in a multimodality treatment approach. Tumor downstaging by complete resection allows for decreased duration and intensity of post-operative chemotherapy. When operating for a complication of intraperitoneal disease, the extent of the procedure should be limited to resolution of the complication and resection of sufficient tissue to ensure an accurate diagnosis. If limited disease is encountered, complete resection and an evaluation of mesenteric, perihepatic, and periaortic nodes should be undertaken to assess for regional metastatic spread. Two-year cumulative survival for intestinal B-cell lymphoma is 94% and 28% for intestinal T-cell lymphoma. The overall 5- and 10-year survival rates for all intestinal lymphoma patients treated with multimodality therapy (surgery, radiation, chemotherapy) are 52% and 44%, respectively. The corresponding disease-free survival rates are 43% and 38%, respectively.[43–48]

## Carcinoid Tumors

### EPIDEMIOLOGY

Carcinoid tumors originate from neuroendocrine cells within the GI tract. These neoplasms derive from GI epithelial and subepithelial endocrine progenitor cells that function as part of the amine precursor uptake and decarboxylation (APUD) system.[49] Carcinoids can also be found in the lungs, mediastinum, thymus, liver, pancreas, bronchus, ovaries, prostate, testes, and kidneys.[50] Pediatric carcinoid tumors typically occur in the GI tract—stomach, small intestine, appendix (most common), and rectum. Carcinoid tumors of the appendix occur with an estimated incidence of 1 case per million children per year, with a slight female predominance.[51–53]

### DIAGNOSIS

Carcinoid tumors are classified according to the location of origin in the primitive gut (foregut, midgut, and hindgut). Foregut tumors include carcinoids of the lung, bronchus, stomach, proximal duodenum, and pancreas. Midgut tumors arise from the distal duodenum, jejunum, ileum, and right colon, including the appendix. These account for 60% to 80% of all carcinoids in adults and children.[54–56] Hindgut tumors arise in the transverse and distal colon and rectum. Tumors can also arise from a Meckel diverticulum, enteric duplications, and the mesentery. Appendiceal carcinoids are the most common, with more than 70% of these tumors developing at the appendiceal tip. Pediatric carcinoid tumors are often discovered incidentally during an operation for presumed appendicitis or another unrelated diagnosis. Although clinical signs of acute appendicitis or gynecologic pathology may prompt exploration, true inflammatory changes of acute appendicitis are not often induced by the carcinoid, possibly because of the distal location of the tumor and absence of proximal luminal obstruction.[51,53,55]

The most serious complication of carcinoid tumors is a carcinoid crisis, which is most often associated with foregut tumors, larger tumors, and high serum/urine 5-hydroxyindoleacetic acid (5-HIAA) levels. Although pediatric carcinoids vary in size, carcinoid syndrome (flushing, diarrhea, abdominal pain, tachycardia, hypertension, hypotension, altered mental status, and coma) has not been typically associated with tumors confined to the appendix.[53,54] In contrast, pediatric patients with extra-appendiceal carcinoid tumors, such as in the lung or liver, are often symptomatic. Biologically active amines (serotonin, catecholamines, histamine) and metabolites (5-HIAA) are characteristically elevated in the plasma and urine of patients with symptomatic carcinoid tumors.[57] Patients with extra-appendiceal carcinoids frequently present with disseminated disease at the time of diagnosis and have a higher incidence of recurrent tumor following the initial diagnosis and resection.[58]

### TREATMENT

Tumor size at presentation dictates surgical decision making for carcinoid tumors of the appendix. For appendiceal carcinoid tumors less than 2 cm in diameter, surgical resection of the appendix and mesoappendix is considered curative. Long-term follow-up demonstrates minimal disease recurrence and a rare likelihood of metastatic disease.[51,52,58,59] Carcinoid tumors greater than 2 cm, those with cecal involvement, lymphatic invasion, lymph node involvement, mesoappendix infiltration, positive resection margins, goblet cell malignancy, or cellular pleomorphism with a high mitotic index require a more extensive resection (i.e., a right hemicolectomy with associated resection of the mesocolon).[55,60,61]

### SURVIVAL

Complete resection of localized appendiceal carcinoid tumors can result in cure, with greater than a 90% survival rate. Diminished disease-free and overall survival is associated with carcinoids larger than 2 cm, older age, positive lymph nodes, extra-appendiceal spread, distant metastatic disease, and tumors with atypical histologic features.[62]

## Colorectal Adenocarcinoma

Adenocarcinoma of the colon and rectum is the most common cancer of the GI tract, with approximately 142,570 new cases and 51,370 deaths in the United Sates in the past year. The lifetime risk of developing colorectal cancer in the general population is 1 in 19.[6] However, colorectal cancer in children is rare, with an estimated incidence of 0.3 to 1.5 cases per million.[63,64] Although reported as early as 9 months of age, the median age at diagnosis for pediatric cases is 15 to 19 years. Pediatric colorectal cancer accounts for 2% of malignancies in adolescents.[65–67]

Colorectal cancer differs greatly between adults and children. These differences include the presenting signs and symptoms, primary site of the tumor, pathologic findings, stage, and prognosis. Carcinoma of the colon is associated with several predisposing factors, including ionizing radiation (e.g., CT scan, therapeutic radiation treatments), polyposis syndromes, urinary diversion with previous ureterosigmoidostomy, and chronic parasitic infection. Various environmental factors, including herbicide exposure, may also be associated with tumor formation.[68]

## Polypoid Disease of the Gastrointestinal Tract

Polyps are common, occurring in 1% of all children, and are the most frequent source of rectal bleeding in the young child (2 to 5 years old). Most polyps are benign lesions and are either hamartomas or result from lymphoid hyperplasia. Some hamartomas, however, have the potential for dysplastic, adenomatous or neoplastic transformation because of germline mutations and somatic inactivation of *STK11, SMAD4, BMPR1A,* and *PTEN* genes.[68–71]

Isolated juvenile polyps (i.e., retention polyps, inflammatory polyps, cystic polyps) are considered hamartomas. They constitute 80% of polyps in children with 40% to 60% found in the rectosigmoid colon. If multiple (typically two to five polyps) they may be found in the proximal colon as well. They are one of the most common sources of GI bleeding in young children, but are rarely seen in adolescence. Colonoscopy of the entire colon is diagnostic and therapeutic if endoscopic removal is warranted.

Lymphoid polyps (lymphoid nodular hyperplasia) account for 15% of pediatric polyps and are submucosal lymphoid aggregates, specifically localized to distal small bowel, colon, and rectum (Peyer patches). Bleeding results from mucosal erosion and can usually be managed expectantly. Uncontrolled bleeding or irreducible intussusception requires surgical intervention.

*Juvenile polyposis coli syndrome* is transmitted in an autosomal dominant fashion. Affected individuals are at increased risk for colorectal malignancy with cumulative risk for cancer of nearly 50% to 70% by age 60 years.[63,64,72] A diagnosis of juvenile polyposis coli requires at least 5 polyps throughout the GI tract, or 1 polyp and a family history of juvenile polyposis. Most patients typically have 50 to 100 polyps including gastric and small bowel polyps. Higher numbers of polyps are associated with more severe symptoms, including chronic bleeding, anemia, hypoproteinemia, and failure to thrive.

These patients and their families require long-term endoscopic surveillance (semiannual panendoscopy) with subsequent total abdominal colectomy if mucosal dysplasia, persistent bleeding, or rapid increase in polyp number is detected. Depending on individual circumstance, there also appears to be a role for prophylactic total colectomy and rectal mucosectomy with an endorectal pull-through procedure.

*Diffuse juvenile polyposis of infancy* is a nearly universally fatal disease typically diagnosed within the first few months of life. Patients present with diarrhea, lower GI bleeding, intussusception, prolapse, obstruction, protein-wasting enteropathy, macrocephaly, and hypotonia. Despite involvement of the entire GI tract, bowel rest and total parenteral nutrition (TPN) permit selective surgical resection. However, survival beyond 2 years of age is rare.

*Diffuse juvenile polyposis* presents with hematochezia, abdominal pain, and prolapse from hamartomatous polyps in the colon and rectum in infancy to 5 years of age. Although hamartomas typically do not have premalignant potential, chronic polyp inflammation is thought to result in reactive hyperplasia that then progresses to dysplasia or adenomatous changes.

Several genetic disorders carry significant risk for the subsequent development of colon carcinoma and are characterized as polyposis syndromes. They include Gardner syndrome (adenomatous polyposis and soft tissue and bone tumors), Turcot syndrome (familial adenomatous polyps and central nervous system tumors), and familial polyposis coli. Both Gardner syndrome and familial polyposis are autosomal dominant disorders and are associated with adenomatous polyps in the colon and the small intestine. Because the entire surface of the colon can be carpeted with thousands of polyps, the ability to carry out effective surveillance and identify suspicious lesions is low. Recommendations for and the timing of colon resection are based on the likelihood of the development of malignancy. There is little question that colectomy is the appropriate treatment for patients with familial polyposis coli (familial adenomatous polyposis), Gardner syndrome, and Turcot syndrome.

*Peutz-Jeghers syndrome* is defined by polyposis of the intestinal tract and melanotic skin lesions. It is inherited as an autosomal dominant trait. Germline mutations in *LKB1, STK11,* and *ENG* genes may have a causative role in the pathogenesis of this syndrome.[73,74] Despite equal sex distribution, symptoms appear earlier in males. Brown and black melanotic spots occur in the rectum, around the mouth, lips, buccal mucosa, feet, nasal mucosa, and conjunctivae, typically presenting at puberty. Adolescents characteristically complain of frequent defecation, rectal bleeding, abdominal pain, vomiting, and may present with anemia or recurrent episodes of intussusception. Polyps are found in the small intestine (55%), stomach and duodenum (30%), and the colorectal bowel (15%). The risk of death because of cancer for those with Peutz-Jeghers syndrome is 50% by 60 years of age. There is a 13-fold increased risk of death because of GI cancer and a 9-fold increased risk for all other malignancies. Rapid growth, severe dysplasia, villous changes, or larger polyps (greater than 15 mm) may indicate GI malignancy and necessitate aggressive surgical intervention. However, repeated, extensive intestinal resections may result in short-bowel syndrome resulting from the multifocal and recurrent nature of these polyps.

*Gardner syndrome* patients present with adenomatous, rather than hamartoma polyposis, and extraintestinal lesions, including bone tumors (80%), sebaceous/inclusion cysts (35%), and desmoid tumors (18%). Bone lesions include cysts of the mandible, fibromas, and osteomas of the skull and face. These patients also may develop hypertrophy of the retinal pigmented epithelium. The syndrome is inherited in an autosomal dominant pattern. Various mutations of the adenomatous polyposis coli (*APC*) gene are associated with Gardner syndrome (*APC* polymorphism in exons 13 and 15), implicating this as a phenotypic variant of familial adenomatous polyposis (FAP). The intestinal polyps that characterize this syndrome have a 100% likelihood of undergoing malignant transformation.[75,76] Desmoids are fibroblastic tumors of the abdominal wall and mesentery that present as dysplasia or a malignant fibrosarcoma. They often become apparent after diagnosis of GI disease and carry a high mortality. Small desmoid tumors, if amenable to excision, have a 10% local recurrence. However, many desmoid lesions are unresectable at presentation. Slow-growing tumors can be treated with sulindac, tamoxifen, vinblastine, and methotrexate, while symptomatic, aggressive tumors require doxorubicin and dacarbazine or high-dose tamoxifen and radiation therapy.

*Turcot syndrome,* also considered a variant of FAP, is characterized by polyposis and brain tumors (e.g. gliomas, ependymomas). Carcinoma of the colon is prevalent in young adults. Chronic bloody diarrhea, hypoproteinemia, weight loss, anemia, malnutrition, bowel obstruction, and intussusception are common presenting symptoms. Medulloblastoma development is associated with *APC*-related mutations, while microsatellite gene instability (typical of hereditary nonpolyposis colon cancer) is associated with glioblastoma multiforme diagnosis.[77] *Cronkhite-Canada syndrome* is typified by multiple hamartomatous polyps in the stomach and colon. It is a variant of juvenile polyposis and is associated with early-onset skin hyperpigmentation, alopecia, and nail changes. Chronic diarrhea results in malabsorption, hypovitaminosis, hypoproteinemia, and fluid and electrolyte imbalance.

*Osler-Weber-Rendu syndrome* is characterized by childhood (less than 10 years of age) GI bleeding from cutaneous and hepatic telangiectases and vascular malformations in 50% of affected individuals. Telangiectases are found on the lips, oral and nasopharyngeal membranes, tongue, and perilingual areas. Lesions may also involve the brain, lungs, and liver. Within the GI tract, they occur commonly in the stomach and small bowel, causing significant recurrent GI bleeds throughout childhood. It is inherited in an autosomal dominant manner, and 80% of patients have a family history of the disease. With a high incidence of colon carcinoma or multiple juvenile colonic polyps, all Osler-Weber-Rendu patients with new-onset anemia or GI bleeding require lower GI tract evaluation.[78,79]

## Hereditary Associations

Although the majority of childhood colorectal carcinomas are not associated with hereditary factors, approximately 25% of childhood cases have some associated predisposing condition, that is, at least two first-degree relatives with colon cancer, genetic/polyposis syndromes (1%), inflammatory bowel disease (1%), and hereditary nonpolyposis syndromes (5%

to 6%). The progression toward tumor development may occur secondary to tumor suppressor gene mutation, loss of heterozygosity, or a mutational event.[80] Phenotypically normal colonic epithelium may develop hyperplasia as a result, then progress to adenoma formation, dysplasia, and finally, invasive carcinoma. Mutations associated with development of colon cancer may result from exposure to environmental influences or be the result of accumulated DNA transcription errors. Typical of these genetic changes are *APC* inactivation, *K-ras* activation, and *TP53* gene mutations.

*Familial adenomatous polyposis (FAP)* is inherited as an autosomal dominant trait that accounts for less than 1% of all colorectal cancer. A diagnosis of FAP requires greater than 5 colonic polyps, polyps throughout the GI tract, or polyps associated with a family history of juvenile polyposis. Extensive colonic polyposis (i.e., greater than 100 adenomatous polyps) is common, with some patients having thousands of polyps. Symptomatic patients often present with frequent bloody stools, anemia, and abdominal pain. Long-standing symptoms may signify the presence of a malignant lesion. Patients identified through family history should be assessed in early adolescence prior to the development of symptoms. All patients require early colonoscopic screening to determine the extent of polyposis and the possibility of malignancy. Colorectal carcinoma occurs by age 20 years in 7% of patients and by age 25 years in 15% of patients. Untreated FAP characteristically progresses to colorectal cancer by age 39 years. In contrast, gastric polyps seen with FAP are usually benign hamartomas. FAP patients are also at risk to develop desmoid tumors, congenital hypertrophy of retinal pigment epithelium, duodenal and periampullary adenocarcinomas, thyroid malignancy, and hepatoblastoma.[81,82]

The *APC* gene, a tumor suppressor gene on the long arm of chromosome 5, is known to contain a mutation in 80% to 90% of FAP patients. If a defective *APC* allele is inherited from one parent, a mutation acquired during childhood in the other *APC* gene results in the loss of function of the tumor suppressor gene product.[83] Inactivation of the *APC* alleles results in activation of subsequent signaling pathways leading to uncontrolled cell growth. Malignant progression from adenoma to dysplasia, then to malignancy, may occur. Site-specific *APC* gene mutations correlate with various FAP phenotypes and the development of associated tumors. Classic FAP is associated with central gene mutations, while a less aggressive, attenuated FAP presentation correlates with peripheral *APC* gene mutations. The development of malignancy is also associated with accumulation of other oncogene/tumor suppressor gene mutations, such as *K-ras* activation and *TP53* mutation, in otherwise quiescent adenomas.

Sulindac, a nonsteroidal anti-inflammatory drug (NSAID), and celecoxib, a cyclooxygenase-2 (COX-2) inhibitor, have been used to reduce polyp numbers by induction of epithelial cell apoptosis. Despite the unique mechanism of action of these agents, they have not completely eliminated the risk of colorectal cancer in FAP patients.[84,85] FAP patients with few polyps are still at risk of early colorectal cancer. Resection is indicated even if extensive polyposis does not develop. Surgical options include total proctocolectomy with permanent ileostomy, total abdominal colectomy with ileorectal anastomosis, coloproctectomy with perseveration of the anal sphincter, coloproctectomy with ileoanal pull-through, and total colectomy with rectal mucosectomy and endorectal (J-pouch) pull-through. Each of these procedures has their proponents. Total colectomy with a rectal mucosectomy and endorectal pull-through has gained popularity in recent years. This procedure removes all "at-risk" colonic mucosa and laparoscopic techniques have been demonstrated to be practical, effective, and safe. Endorectal pull-through procedures typically incorporate a distal J-pouch ileal reservoir. Although straight ileal pull-through procedures initially have higher stool frequency, differences in stool frequency between straight pull-through and J-pouch patients have been reported by some authors to be negligible by 24 months. A number of patients treated with a J-pouch may require later treatment for intermittent pouchitis.[86,87] Total proctocolectomy with permanent ileostomy carries significant risk of postoperative urinary bladder atony, impotence, and retrograde ejaculation because of disruption of nervi erigentes during the pelvic dissection. More commonly used for adult colorectal pathology, this technique has limited utility for treatment of pediatric patients because of the psychological and physiologic impact of a permanent stoma.[88] Procedures involving the preservation of the distal rectum can result in the development of colorectal cancer. Forty-four percent of patients undergoing an ileorectal anastomosis require subsequent treatment for rectal polyps that develop in the remaining mucosa. The risk of rectal cancer in these patients is 10% at age 50 years and 29% by age 60 years. Polyps remaining or developing in preserved colorectal segment significantly increases the risk for subsequent cancer. Those with retained rectal mucosa at risk require annual flexible endoscopic surveillance of the pelvic pouch.[89–91] The significant long-term risk of rectal cancer in these patients makes this procedure unacceptable for treatment of FAP in the adolescent population.

*Hereditary nonpolyposis colon cancer (HNPCC)* has an autosomal dominant inheritance, is the most common hereditary colon cancer syndrome, and accounts for 2% to 3% of all colorectal cancers. It is characterized by early onset, multiple family members affected, and is 5 times more prevalent than familial polyposis–related colon cancer.[92] In contrast to familial adenomatous polyposis, HNPCC malignancy may develop in the absence of adenomatosis of the colon and rectum. Unlike sporadic colorectal tumors, HNPCC colorectal cancer usually develops in a proximal colon lesion and occurs at a younger age (approximately 45 years).

Disease may be limited to the colon in the Lynch syndrome I, where malignancies occur in the cecum and ascending colon more often than in other colorectal sites (70%). These tumors are characterized by poorly differentiated and mucin-producing lesions (i.e., signet cell). Lynch syndrome II is further defined by the development of synchronous and metachronous extracolonic cancers, such as carcinomas of the endometrium, uterus, ovary, stomach, small bowel, pancreas, hepatobiliary tract, brain, genitourinary system, and upper uroepithelial tract. They usually manifest in the second decade of life. HNPCC patients are categorized by the Amsterdam criteria: colorectal cancer in at least three relatives spanning two generations. One of these individuals is a first-degree relative of the other two and one of these individuals must have a diagnosis prior to age 50 years. Patients with the Lynch syndromes have a 50% to 70% lifetime risk of developing cancer and a threefold increased incidence of colorectal cancer compared with the general population.[93–96]

Hereditary nonpolyposis colon cancers, unlike FAP, do not have inherited defects in the *APC* gene. HNPCC tumors are characterized by mutations in genetic loci (*MSH2, MLH1, PMS1, PMS2,* and *GTBP*) resulting in defective DNA nucleotide mismatch recognition and repair. Greater than 90% of these mutations are in *MSH2* and *MLH1* genes on chromosome arms 2p and 3p, respectively. These genes are inherited in a dominant manner with 90% penetrance. Although benign adenomas appear with the same incidence in HNPCC patients as in the general population, DNA-repair–deficient HNPCC adenomas are more likely to grow and progress to invasive cancer than in the general population. As a result, a benign tumor may progress to cancer in as few as 3 to 5 years.[97]

Patients suspected of carrying *MSH2* and *MLH1* mutations may be tested for DNA mismatch-repair gene mutations. A total abdominal colectomy, rather than hemicolectomy or a segmental resection, is recommended, because the risk of recurrent colorectal cancer is 45% spanning 10 years. Patients who have undergone subtotal colectomy must undergo lifelong endoscopic evaluation of their remaining rectal segment. Subtotal colectomy with a rectal mucosectomy and endorectal pull-through has not been studied in this population. Patients who are poorly compliant with colonoscopic surveillance may be candidates for prophylactic colectomy. Asymptomatic HNPCC gene carriers may reduce their risk of invasive cancer through prophylactic colectomy or surveillance colonoscopy and polypectomy, starting with biannual colonoscopy at age 25 to 30 years and annually after age 40 years. All Lynch syndrome patients must undergo lifelong screening for extracolonic malignancies as well.[98,99]

## Other Associations

There is a strong association between long-term inflammatory bowel disease and the development of colon carcinoma. After the first 10 years with ulcerative colitis, the likelihood of cancer development increases from 1% to 2% per year.[100] Those with ulcerative colitis–associated carcinoma typically present with malignancy at a young age, have multifocal lesions, and have had a history of colitis involving the entire colon rather than isolated, left-sided disease. Crohn disease is an inflammatory bowel disease in which the risk for colon cancer is significantly greater (more than 20 times) than that in the general population.[101] Crohn-associated colon cancer may develop in an area of colon that appears grossly normal, making the diagnosis of malignancy more difficult than with ulcerative colitis. Routine surveillance contrast enema and colonoscopy are recommended for all patients with either ulcerative colitis or Crohn disease. Biopsies should be performed on suspicious areas as well as on random areas of the colon during the colonoscopy.[102]

Ureterosigmoidostomy performed for urinary diversion predisposes to the subsequent development of malignancy in the colonic segment used as a diversion conduit. Five percent of patients with ureterosigmoidostomy develop colon cancer, often at the site of ureteral implant. Chronic inflammation, possibly resulting from exposure to intermittently infected urine, has been shown to predispose to the development of colon cancer. Close follow-up and annual sigmoidoscopy is warranted for all patients following this type of urinary diversion, which is now infrequently used.

In the United States, approximately 600,000 abdominal and head CT studies are performed annually on children under 15 years of age. The risk of later malignancy related to diagnostic pediatric CT scan is directly proportional to the age of the child at the time of the study. It is estimated 500 of these individuals may ultimately die from a malignancy attributable to the CT irradiation received as a child. Secondary colorectal malignancies may also result from therapeutic radiation, especially if the abdomen was included in the field of primary irradiation. Radiation colitis and adenomatous polyps can develop years after radiation exposure and colonic adenocarcinoma decades later. Immunohistochemical studies suggest a radiation-induced *TP53* mutation may lead to the eventual development of colorectal cancer in these individuals.[67,103–105]

## Diagnosis

In children with colorectal tumors, presenting symptoms are nonspecific and include abdominal pain, nausea, and vomiting, and changes in bowel habits with the development of constipation, particularly with left-sided lesions. Physical findings include abdominal distention, tenderness, and a palpable mass. Many will have guaiac-positive stools. Lower GI (rectal) bleeding may be present in a third of patients and, as with adults, is more prevalent in those with cancer of the left colon and rectum. Significant weight loss affects 20% to 30% of patients.

The median length of time from onset of symptoms to presentation is often months; at least one report cited almost a year between the onset of symptoms and the diagnosis.[106] Diagnosis can be delayed if symptoms are repeatedly attributed to common pediatric conditions such as chronic gastroenteritis.[107] Delay in diagnosis may also be related to adolescents' tendency to minimize or hide embarrassing symptoms and the low index of suspicion of pediatricians for this rare entity. Rectal bleeding, commonly a sign of benign pathology, such as polyps or hemorrhoids, should also raise the suspicion of a colorectal malignancy. Delay in diagnosis contributes to the advanced stage of disease in many children. Most colonic lesions in adults are rectosigmoid in location and are identified by sigmoidoscopy. In contrast, childhood colorectal cancer is relatively evenly distributed throughout the colon, with one third of the tumors located in the right colon.[63,107] Colonoscopy, therefore, is required to obtain a biopsy for diagnosis.

## Sporadic Colorectal Carcinoma

Sporadic colon cancer in the young is an aggressive disease whose morphology and natural history differ from those of familial adenomatous polyposis, hereditary nonpolyposis colorectal cancer, and adult colon cancer. The location, stage, and histologic type of pediatric colorectal tumors differ markedly than the same disease in adults. Primary colorectal tumors in children occur frequently in the right and transverse colon, as opposed to the predominant rectosigmoid distribution found in adults. Approximately 40% of adults with colon cancer have involvement of regional lymph nodes or have distant metastases (Dukes stage C or D lesions) at diagnosis. In children, more than 80% of tumors are Dukes stage C or

D at diagnosis.[63,64,106,107] In addition, more than half of the colorectal tumors in children are mucinous adenocarcinomas. The mucinous subtype has an aggressive course and is known to metastasize early. Both advanced stage of disease at presentation and the preponderance of mucinous subtype contributes to a poorer prognosis in children.[66] Accumulation of DNA base-pair mistakes resulting from defective mismatch repair processes (microsatellite instability) is an early step in the process leading to malignant transformation. Patients with colorectal cancer and high microsatellite instability are more likely to have multiple synchronous or metachronous colorectal cancers and are diagnosed at a younger age than those without microsatellite instability.[71,108] Microsatellite instability is not, however, associated with a family history of colorectal cancer or of phenotypic features.[81]

The utility of carcinoembryonic antigen (CEA) has been well established in adults with colon cancer; however, there is little evidence of similar utility in pediatric patients. CEA levels correlate with a change in tumor burden in only 60% of children with colorectal tumors. A number of children with Dukes stage C or D lesions have been shown to have normal antigen levels at the time of diagnosis.[107] In addition, CEA levels do not correlate well with long-term response to treatment in children and therefore should not be used as a definitive marker of recurrence.[64]

## Treatment

The primary treatment for colon cancer in children is surgical resection consisting of a wide excision of the involved colon, the mesentery, and the lymphatic drainage area. Unfortunately, resection for cure is possible in only 40% to 70% of pediatric patients because of advanced stage at diagnosis; these percentages are much lower than for adults. The ovaries and the omentum are common sites of metastasis. If resection for cure is performed, omentectomy, and in female patients, oophorectomy, is appropriate in patients identified with associated ovarian disease.[109]

No rigorously tested or widely accepted therapeutic protocols are available specifically for children with colorectal carcinoma. The use of adjuvant chemotherapy consisting of irinotecan, oxaliplatin, and leucovorin has been described in conjunction with 5-fluorouracil. The use of adjuvant chemotherapy, combined with second-look surgery in select cases, may improve survival.[3,68,107,110] As in adult rectal cancer, preoperative radiation therapy may convert unresectable rectal carcinoma to resectable tumors in selected patients. Although anecdotal case reports indicate these therapies can be beneficial, no data documents the utility of either chemotherapy or radiation therapy for cure or palliation; hence, prognosis and survival are most directly related to successful complete resection. The overall rate and duration of disease-free survival among children with colon carcinoma are low, with less than 30% of patients surviving 5 years. In patients who have resection for cure, predictors of survival include node involvement and histologic grade.

## Summary

The biology of pediatric colorectal carcinoma is different from colorectal malignancy in adults. The presentation, histologic type, stage, and prognosis differ sharply. Most cases of childhood colorectal cancer arise from previous adenomas. Children with syndrome-associated adenomas are at increased risk for colorectal carcinoma. This suggests that genetics play a greater role than previously thought, and fewer cases are truly sporadic. Understanding the molecular basis of colon carcinoma in children should facilitate the identification of patients at high risk and result in prophylactic intervention or earlier diagnosis and reduce mortality.

CHAPTER 35

# Diagnosis and Treatment of Rhabdomyosarcoma

Kevin P. Mollen and David A. Rodeberg

Historically, the mainstay of therapy for rhabdomyosarcoma (RMS) has been aggressive surgical resection, often including a significant amount of normal tissue along with the tumor.[1] As a result, operations were often disfiguring and outcomes disappointing, with survival rates from 7% to 70% depending on tumor location. It was not until chemotherapy was added to the RMS treatment algorithm in 1961 that outcomes began to improve. The addition of radiotherapy in 1965 to select patients further improved outcomes and decreased the need for aggressive radical operations. Recognition of the crucial contribution of multimodal therapy to the treatment of RMS led to the establishment of the Intergroup Rhabdomyosarcoma Study Group (IRSG) in 1972. The goal of the IRSG was to oversee the development of treatment protocols for RMS. Now called the Soft Tissue Sarcoma Committee of the Children's Oncology Group, this collaborative group has completed a number of cooperative group trials evaluating new drug combinations, chemotherapy dosing, imaging evaluation of tumors, radiotherapy, and surgical strategies for local tumor control and tumor biology.[2] During this time period, the overall 5-year survival rate of RMS has increased from 25% to 70% (Fig. 35-1).[3,4]

## Rhabdomyosarcoma Patient Demographics

Rhabdomyosarcoma is the most common type of soft tissue sarcoma diagnosed during the first 2 decades of life, accounting for 4.5% of all cases of childhood cancer.[5] It is the third most common extracranial solid tumor of childhood after Wilms' tumor and neuroblastoma. Age at presentation follows a bimodal distribution, with peak incidences between 2 and 6 years and again between 10 and 18 years of age.[6] This distribution reflects the incidences of the two major histologic subtypes of RMS. The incidence of embryonal RMS is highest at birth and extends through childhood before declining, while alveolar RMS peaks during childhood and adolescence.[7] Approximately 65% of all RMS cases occur in children younger than 6 years of age. Slightly more males (58.4%) are affected than females (41.6%), and whites have a higher incidence than African Americans (rate ratio 1.2).

## Rhabdomyosarcoma Tumor Biology

Rhabdomyosarcoma is a malignant tumor of mesenchymal origin.[5] RMS also falls under the greater category of small, blue, round-cell tumors of childhood that includes neuroblastoma, lymphoma, and primitive neuroectodermal tumors (PNET). The two major histologic subtypes of RMS are embryonal and alveolar. Embryonal RMS (ERMS) is the most common type of RMS, affecting two thirds of all patients with disease. ERMS can be further broken down into spindle-cell and botryoid subtypes. ERMS is typically composed of spindle-shaped cells with a rich stroma. In addition to occurring in younger patients, ERMS has a favorable survival rate of 60%. Tumors occur more frequently in the head and neck region as compared with the extremities. Spindle-cell histology is common in paratesticular lesions, whereas botryoid lesions are generally polypoid masses filling the lumen of hollow viscus, such as the vagina, bladder, and extrahepatic bile ducts. Alveolar RMS (ARMS) occurs in older children, and tumors are most commonly located on the trunk or extremities. These lesions are composed of small, round, densely packed cells arranged around spaces resembling pulmonary alveoli. However, this histologic classification of RMS may, in the near future, be supplanted by gene array analysis.[8] Prognosis is worse in ARMS than ERMS, with a 5-year survival rate of 54%. For all histologic types of RMS, outcome is heavily dependent on age at diagnosis, the primary anatomic site, extent of disease (tumor size, invasion, nodal status, metastatic disease), and the completeness of surgical excision. The Soft Tissue Sarcoma Committee is investigating the outcomes of patients by disease characteristics and tumor biology to refine risk-adapted therapy for the treatment of RMS.[2]

The exact nature of the pathogenesis of RMS is unclear; however, many hypotheses exist. It is largely thought that RMS arises as a consequence of regulatory disruption of skeletal muscle progenitor cell growth and differentiation.[9] Pathogenic roles have been suggested for the *MET* proto-oncogene, which is involved in migration of myogenic

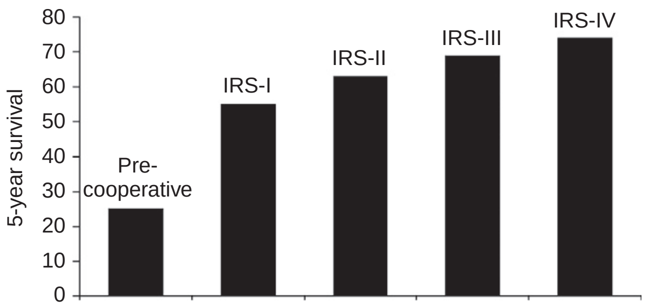

**FIGURE 35-1** Improvement in survival for RMS during the past 40 years.

precursor cells, and the *TP53* proto-oncogene, which is responsible for tumor suppression.[10,11] At the chromosomal level, ERMS is characterized by a loss of heterozygosity at the 11p15 locus, with a loss of maternal information and duplication of paternal genetic information. Within this locus lies the insulin growth factor II (IGF-II) gene.[12–14] Both ERMS and ARMS overproduce IGF-II, which has been shown to stimulate RMS tumor growth, suggesting that IGF-II plays a role in unregulated growth of these tumors.[15] Although the significance is unclear, ARMS is frequently tetraploid, whereas ERMS lesions are generally diploid. Translocations of the *FKHR* transcription factor gene from chromosome 13 with either the *PAX3* (chromosome 2) or *PAX7* (chromosome 1) transcription factor genes occur frequently in ARMS.[16–18] In these *PAX/FKHR* fusions, the DNA binding domain of *PAX* is combined with the regulatory domain of *FKHR*. This results in increased PAX activity leading to the de-differentiation and proliferation of myogenic cells. Understanding the role of these fusion proteins in tumor development may provide insight into treatment strategies and potential biomarkers for the diagnosis of RMS.[8] For example, it has been demonstrated that approximately 25% of ARMS tumors are translocation negative. By gene array analysis, these fusion negative ARMS tumors more closely resemble ERMS overall and have a similar prognosis to ERMS. It has therefore been proposed that tumors should be divided into *PAX/FKHR* fusion–positive and –negative tumors rather than the more ambiguous alveolar and embryonal histologies.

Although most cases of RMS occur sporadically, the disease is associated with familial syndromes, including Li-Fraumeni and neurofibromatosis I. Li-Fraumeni is an autosomal dominant disorder and is usually associated with a germline mutation of *TP53*. Patients with this syndrome present with RMS at an early age and have a family history of other carcinomas, especially premenopausal breast carcinoma.[19–22] Neurofibromatosis is an autosomal dominant genetic disorder characterized by optic gliomas, café-au-lait spots, and neurofibromas.[23] The association of RMS with Li-Fraumeni and neurofibromatosis appears to involve malignant transformation through the inactivation of the *TP53* tumor suppressor gene and hyperactivation of the *RAS* oncogene.[24,25] Nevoid basal cell carcinoma (Gorlin syndrome) is an autosomal dominant disorder caused by mutations in the *PTCH* tumor suppressor gene mapping to chromosome 9q22.3.[26] Animals with mutations in the *PTCH* gene have elevated levels of the tumor growth–promoting IGF-II and develop spontaneous RMS.[27,28] The association of mutations in the *PTCH* gene in human disease with spontaneous development of RMS is supported by the finding that up to 30% of sporadic cases of ERMS demonstrate molecular abnormalities at the 9q22.3 locus.[29,30] Autopsy findings suggest that one third of children with RMS also have congenital anomalies, suggesting that prenatal events may also contribute to tumor development.[31] Although no specific carcinogens have been identified, benzenediazonium sulfate has been shown to induce RMS in mice.[32] Maternal marijuana or cocaine use in pregnancy may be an environmental factor that contributes to the development of RMS.[33,34]

## Presentation of Rhabdomyosarcoma

Rhabdomyosarcoma typically presents as an asymptomatic mass found by the patient or the parents of younger children.[5] Specific symptoms vary based on the site of occurrence and extent of disease. These symptoms are generally related to mass effect or complications of the tumor. The most common sites of primary disease are the head and neck region, the genitourinary tract, and the extremities.

## Preoperative Workup

Patients with suspected RMS require a complete workup prior to surgical intervention.[5] Standard laboratory work, including complete blood counts (CBC), electrolytes, and renal function tests, liver function tests (LFTs), and urinalysis (UA) should be performed. In addition, imaging studies of the primary tumor should be performed with computer tomography (CT) or magnetic resonance imaging (MRI). CT is advantageous for the evaluation of bone erosion and abdominal adenopathy, whereas MRI provides better definition of the tumor and surrounding structures. MRI is preferable for limb, pelvic, and paraspinal lesions. Metastatic workup includes a bone marrow aspirate and bone scan, CT of the brain, lungs, and liver, and lumbar puncture for cerebrospinal fluid collection. Tumor imaging defines the proximity of tumors to vital structures and determines size. Both factors are important when determining if the tumor can be primarily resected or if neoadjuvant therapy is required to decrease tumor size and thereby decrease the morbidity of resection. It has been demonstrated that the size of the primary mass, as determined by pretreatment imaging, carries prognostic significance. Recent evidence would suggest that tumor volume and patient weight may be superior predictors of failure-free survival than tumor diameter and patient age in patients with intermediate-risk RMS.[35,36] Evaluation of regional and distant lymph nodes by clinical and radiographic means should be performed, because this is an important component of pretreatment staging.

Metabolic imaging using $^{18}$F-fluorodeoxyglucose positron emission tomography (FDG PET) has become widely used in the adult population to determine the extent of disease in the setting of many cancers; however, there is limited experience in the pediatric population. Recent studies have suggested that FDG PET would be both a sensitive and specific tool in the clinical determination of the extent of disease in childhood sarcomas.[37–40] Further, when combined with CT, it may be more accurate than conventional imaging modalities in staging patients or re-staging patients at the time of recurrence.[41,42]

It is unclear what role FDG PET will have in the clinical evaluation of RMS, although there are several settings in which this imaging modality may improve our pretreatment staging and thus alter treatment for patients. FDG PET may enhance the evaluation of regional adenopathy versus traditional modalities. Similarly, FDG PET may offer improved detection of occult metastases, helping to differentiate them from normal structures. Finally, this modality may offer a guide to the diagnosis and treatment of recurrent disease. The diagnosis of a recurrence in a previously operated field is often difficult to obtain with conventional imaging methods. FDG PET/CT may offer an enhanced diagnostic tool and, more important, may offer tumor viability information which will guide further surgical therapy. One of the goals of ongoing trials will be to investigate the role of FDG PET in RMS.

## Pretreatment Clinical Staging

Staging of RMS is determined by the site of the primary tumor, primary tumor size, degree of tumor invasion, nodal status, and the presence or absence of metastases, and it is based solely on the preoperative workup of imaging and physical examination. This is expressed in a tumor-node-metastasis (TNM) classification system modified for the site of tumor origin (Fig. 35-2). Adequate pretreatment clinical staging requires a thorough physical examination and preoperative imaging. Several investigators have validated the modified TNM staging system as a reliable predictor of patient outcome.[43]

## Surgical Principles

### BIOPSY

Open biopsy of a mass suspected to be RMS should be performed to confirm the diagnosis. Care should be taken to obtain adequate specimens for pathologic, biological, and treatment protocol studies. For small lesions in areas that will be treated with chemotherapy and radiation or for metastatic disease, core needle biopsy may be appropriate for diagnosis.[44,45] Although less invasive than open biopsy, core needle biopsy obtains a smaller tissue sample, which increases sampling error and the number of inconclusive findings. This smaller volume of tissue may prevent the performance of adequate molecular biology studies. Image guidance with ultrasonography may increase the accuracy of sampling while helping to avoid inadvertent puncture of surrounding structures.[46] Clinical and radiographic positive lymph nodes should be confirmed pathologically. Open biopsy is recommended; however, fine-needle aspiration or core needle biopsy of lymph nodes may be performed at the discretion of the surgeon's judgment and pathologist's recommendations.[44,47] Sentinel

| Stage | Sites | T | Size | N |
|---|---|---|---|---|
| 1 | Orbit<br>Head and neck (excluding parameningeal)<br>GU nonbladder/ nonprostate | $T_1$ or $T_2$ | a or b | $N_0$ or $N_1$ or $N_x$ |
| 2 | Bladder/prostate, extremity, cranial parameningeal, other (includes trunk, retroperitoneum, etc.) | $T_1$ or $T_2$ | a | $N_0$ or $N_X$ |
| 3 | Bladder/prostate, extremity, cranial parameningeal, other (includes trunk, retroperitoneum, etc.) | $T_1$ or $T_2$ | a<br>b | $N_1$<br>$N_0$ or $N_1$ or $N_x$ |
| 4 | All | $T_1$ or $T_2$ | a or b | $N_0$ or $N_1$ |

| | | |
|---|---|---|
| Definitions: | Tumor T(site)$_1$– | Confirmed to anatomic site of origin<br>(a) <5 cm in diameter (b) >5 cm in diameter |
| | T(site)$_2$ | Extension and/or fixative to surrounding tissue<br>(a) <5 cm in diameter (b) >5 cm in diameter |
| | Regional nodes– | |
| | $N_0$ | Regional nodes not clinically involved |
| | $N_1$ | Regional nodes clinically involved by neoplasm |
| | $N_x$ | Clinical status of regional nodes unknown (especially sites that preclude lymph node evaluation) |
| | Metastasis– | |
| | $M_0$ | No distant metastasis |
| | $M_1$ | Metastasis present |

FIGURE 35-2 TNM Pretreatment Staging Classification. Staging before treatment requires thorough clinical, laboratory, and imaging examinations. Biopsy is required to establish histologic diagnosis. Pretreatment tumor size is determined by external measurement or MRI or CT, depending on anatomic location. For less accessible primary sites, CT also will be used for lymph node assessment. Metastatic sites will require some form of imaging confirmation (but not histologic confirmation, except for bone marrow examination). CT, computed tomography; GU, genitourinary; MRI, magnetic resonance imaging.

node biopsy may offer a safe and less invasive means of lymph node evaluation for extremity and truncal lesions, although its role in RMS is yet to be determined but will soon become the focus of a clinical trial.[48–51]

## RESECTION OF THE MASS

Surgical biopsy of a primary lesion is often performed prior to a definitive surgical resection. If this is the case, pretreatment reexcision (PRE) is advisable. PRE is a wide reexcision of the previous operative site with adequate margins of normal tissue prior to the initiation of adjuvant therapy. PRE is most commonly performed on extremity and trunk lesions but should be considered the treatment of choice whenever technically feasible.[52]

The primary goal of surgical intervention is wide and complete resection of the primary tumor with a surrounding rim of normal tissue. A circumferential margin of 0.5 cm is considered adequate; however, there is minimal data to support this recommendation. Such a margin may be unobtainable, however, especially with head and neck tumors. Because of these limitations, adequate margins of uninvolved tissue are required unless excision would compromise adjacent organs, result in loss of function or poor cosmesis, or is not technically feasible. All margins should be marked and oriented at the operative field to enable precise evaluation of margins. If a narrow margin occurs, several separate biopsies of "normal" tissue around the resection margin should be obtained. These specimens should be marked and submitted separately for pathologic review. Communication between the pathologist and surgeon is mandatory to ensure that all margins are accurately examined. The surgeon should not bisect or cut the excised tumor into specimens prior to sending it to the pathologist. Any microscopic or gross tumor should be marked with small titanium clips in the tumor bed to aid radiotherapy simulation and subsequent reexcision. Published outcomes analyses have shown that a clear margin and no residual disease (group I) is superior to residual microscopic margins (group II) or gross residual disease (group III).[2,3,52–54] Tumors that are removed piecemeal are considered group II even if all gross tumor is removed.

## LYMPH NODE SAMPLING/DISSECTION

Lymph node status is an important part of pretreatment staging and therefore directly impacts risk-based treatment strategies in RMS. Regional lymph node disease (N-1) has been identified in ARMS as an independent poor prognostic factor in stage 3 patients.[2] Data from IRS-IV would suggest that N-1 disease in patients with ARMS is associated with tumor characteristics that carry a poor prognosis, such as older age, more invasive tumors ($T_2$), large tumor size (>5 cm), and unfavorable primary sites.[55] In addition, N-1 disease was present in 23% of all RMS patients, predominantly in primary tumor sites, such as perineum, retroperitoneum, extremity, bladder/prostate, parameningeal, and paratesticular. N-1 disease alters both failure-free survival (FFS) and overall survival (OS) for ARMS but not ERMS.[55] For patients with N-1, ARMS outcomes were more similar to patients with single-site metastatic disease than those with only local disease. However, for ERMS other prognostic factors, such as patient age, tumor invasion (T stage), site of primary tumor, and the presence of metastasis at initial presentation, were more important prognostic factors than N-1 disease. In addition, it has previously been shown that in patients with otherwise localized disease, such as an extremity, N-1 disease may be associated with an inferior outcome.[56,57] Clinical and radiographic positive nodes should therefore be biopsied to confirm tumor involvement, thus ensuring correct assessment of disease risk and assignment of optimal therapy. Lymph node removal has no therapeutic benefit, therefore prophylactic lymph node resection plays no role in therapy.[57] Therefore clinical and/or radiographic negative nodes do not require pathologic evaluation except in extremity tumors and for children older than 10 years of age with paratesticular tumors.[58,59] In both of these sites, the high incidence of nodal disease and false-negative imaging necessitates pathologic evaluation of regional nodal basins.

The use of sentinel node mapping to determine regional node status has proven to be beneficial in adult breast cancer and melanoma. For childhood RMS, sentinel node mapping is not yet the standard of care but may prove to be effective.[48] Sentinel node mapping has proven its utility in determining nodal status in pediatric skin and soft tissue malignancies and will likely become the standard of care for identifying the regional nodes involved with tumor.[60]

If regional nodes are positive then distant nodes should be harvested for pathologic evaluation. Tumor identified in these nodes would be considered metastatic disease and would therefore alter therapy using the current risk-based protocols. For upper extremity lesions, the distant nodes would be the ipsilateral supraclavicular (scalene) nodes. In the lower extremity, the distant nodes would include the iliac and/or paraaortic nodes. For paratesticular RMS, the ipsilateral paraaortic lymph nodes above the renal vein are considered distant nodes.[60]

## CLINICAL GROUP

The extent of residual disease after resection is one of the most important prognostic factors in RMS. For this reason, a clinical grouping system was developed in 1972 to stratify patients into groups that would more accurately reflect their prognosis and treatment options. Currently, patients are assigned to a clinical group based on the completeness of tumor excision and the evidence of tumor metastasis to the lymph nodes or distant organs after pathologic examination of surgical specimens (Fig. 35-3). This system differs from TNM staging in that determination of each patient's clinical group is based on the extent of the surgical resection instead of tumor size and site.

| Group | Criteria |
|---|---|
| I | Localized disease, completely resected<br>A. Confined to organ or muscle of origin<br>B. Infiltrating outside organ or muscle of origin: regional nodes not involved |
| II | Compromised or regional resection including:<br>A. Grossly resected tumors with microscopic residual tumor<br>B. Regional disease, completely resected, with nodes involved and/or tumor extension into an adjacent organ<br>C. Regional disease, with involved nodes, grossly resected, but with evidence of microscopic residual tumor |
| III | Incomplete resection or biopsy with gross residual disease remaining |
| IV | Distant metastases present at outset |

FIGURE 35-3 Clinical grouping for RMS patients.

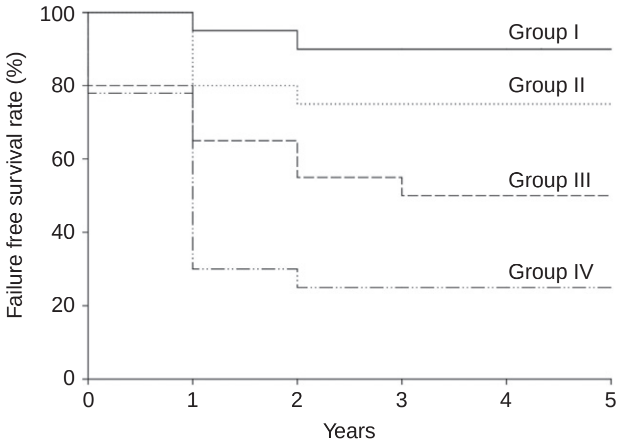

**FIGURE 35-4** Rhabdomyosarcoma survival based on completeness of surgical resection (clinical group).

Data from IRS-III and IRS-IV demonstrate that five-year failure-free survival rates vary according to clinical grouping and by histologic type (Fig. 35-4).[2] One criticism of clinical grouping is that variation of surgical techniques make comparisons of clinical grouping between different institutions problematic.[61] Nonetheless, this system offers a tremendous companion to preoperative staging in determining patient risk assessment and prognosis (Fig. 35-5).

### SECOND-LOOK OPERATIONS AND AGGRESSIVE RESECTION FOR RECURRENCE

After completing adjuvant therapy, patients with RMS are reimaged with CT or MRI. If residual tumor remains, or if the outcome of therapy remains in doubt, a second-look operation (SLO) may be considered. SLO can be performed to confirm clinical response, to evaluate pathologic response, and to remove residual tumor in order to improve local control.[62] As with the initial operation, the goal of SLO is complete resection of disease. Data from IRS-III suggested that SLO results in the reclassification of 75% of partial responders to complete responders after excision of residual tumors. These operations were most effective in extremity and truncal lesions.

In general, an aggressive surgical approach is used for recurrent RMS. Data would suggest that resection of recurrent RMS confers a 5-year survival of 37% compared with 8% survival in a group of patients without aggressive resection.[63] Given these results, SLO and aggressive resection for recurrence can be important tools for the treatment of RMS.

However, resection of residual masses after completion of adjuvant therapy may not be warranted. Associated morbidity of resection and the inability to achieve complete resection in some cases need to be considered. Further, it is not uncommon to find an absence of viable tumor tissue in resected samples.[63a] This brings into question the utility of aggressive re-resection and suggests that better means of detecting viable tumor is crucial. As discussed, PET/CT may provide the crucial information required to make these decisions.

## Chemotherapy

It was not until the 1960s that chemotherapy was recognized as an important adjunct to surgery in the treatment of RMS. Today, all patients with RMS receive some form of chemotherapy. Standard therapeutic regimens consist of a combination of vincristine, actinomycin-D, and cyclophosphamide (VAC). Although tremendous advances have been made in improving the outcomes of patients with isolated local and regional disease, little progress has been made in improving outcomes for advanced RMS tumors. The limiting factor has been an inability to improve significantly upon standard chemotherapeutic regimens. Dose intensification of vincristine and actinomycin-D is not possible because of their neurotoxic and hepatotoxic side effects. Studies evaluating dose intensification of cyclophosphamide found that although patients tolerate higher doses, outcomes of intermediate-risk tumors are not changed.[64] These findings have lead to the evaluation of new drug combinations and the development of risk-based treatment protocols.[65]

The combination of ifosfamide and etoposide was tested in a Phase II therapy window in IRS-IV. When combined with VAC, ifosfamide, and etoposide therapy resulted in a better 3-year survival rate, with less bone marrow toxicity when compared with the use of vincristine and melphalan with standard VAC regimens.[66] Other chemotherapeutic regimens being developed to treat advanced rhabdomyosarcoma have

| Risk group | Pretreatment stage* | Clinical group# | Site# | Histology |
|---|---|---|---|---|
| Low 1 | 1 or 2 | I or II | Favorable or unfavorable | EMB |
| | 1 | III | Orbit only | EMB |
| Low 2 | 1 | III | Favorable | EMB |
| | 3 | I or II | Unfavorable | EMB |
| Intermediate | 2 or 3 | III | Unfavorable | EMB |
| | 1–3 | I–III | Favorable or unfavorable | ALV |
| High | 4 | IV | Favorable or unfavorable | EMB |
| | 4 | IV | Favorable or unfavorable | ALV |

* Pretreatment stage dependent on site of disease
# Favorable sites: Orbit, genitourinary tract, biliary tract nonparameningeal head and neck

**FIGURE 35-5** Risk-based stratification of patients to guide degree of therapy and prognosis for RMS patients. ALV, alveolar; EMB, embryonal.

incorporated doxorubicin and the topoisomerase inhibitor irinotecan. Although used as a single agent, irinotecan is of little value, it may be a useful adjunct to current VAC regimens for the treatment of advanced RMS.[67–69] Another topoisomerase inhibitor, topotecan has shown some promise in patients with stage 4 disease when combined with cyclophosphamide.[70–72] However, alternating these drugs with standard VAC therapy has not shown any benefit in intermediate-risk patients.[73] Multiple drugs are currently being evaluated for the treatment of RMS in Phase I and II trials.

# Radiation Therapy

Radiotherapy is an important adjunct to therapy for many children diagnosed with RMS, offering improved local control and outcomes. Candidates for radiotherapy primarily include those with group II (microscopic residual disease) or group III (gross residual disease) disease. The impact of therapy is influenced by the location of the primary tumor and amount of local disease (tumor stage and clinical grouping) at the time radiotherapy is initiated.[74,75] Among patients with group II disease, low-dose radiation (40 Gy at 1.5 to 1.8 Gy/fraction) is associated with local tumor control rates of at least 90%.[76] For patients with group III disease, radiation doses are more commonly 50 Gy.[77] A randomized study within the IRS-IV protocol demonstrated that twice-daily irradiation at 110 cGY per dose, 6 to 8 hours apart (hyperfractionated schedule) for 5 days per week is feasible and safe. This schedule, however, is difficult to accomplish in small children who require twice-daily sedation for treatment. Unfortunately, the hyperfractionated schedule demonstrated no improvement in local control over conventional radiation therapy.[78]

Radiation therapy in very young children with RMS poses a unique therapeutic challenge. Concerns over the technical difficulties associated with external beam radiotherapy in young children and late side effects of therapy have led to the evaluation of strategies that reduce the total burden of therapy without sacrificing local control. Modern techniques, such as intensity modulated radiation therapy (IMRT) and proton beams, may improve outcome without compromising long-term function.[79,80] Ongoing studies continue to evaluate the dose of radiation necessary for local control of the tumor.

# Assessment of Response to Treatment

Although European RMS trials have incorporated the use of conventional radiologic modalities to evaluate the response to induction therapy and help tailor subsequent therapy, this has not been employed in the United States. IRS-IV data demonstrated no predictive value of radiographic response after 8 weeks of induction therapy.[81] Further, radiographic evidence of a complete response to therapy in group III RMS was not associated with a reduction in disease recurrence and death.[63a] Clearly, the significance of persistent radiographic masses in patients treated for RMS is unknown. Conventional imaging modalities offer no information about the biology of these masses and are unable to differentiate between active tumors and scar. It is possible that FDG PET may offer useful clinical information in patients treated or partially treated for RMS.

## SPECIFIC ANATOMIC SITES

Rhabdomyosarcomas are unique among solid tumors in that they may occur in many different areas of the body. Tumors in different parts of the body may behave differently than those in other areas. In addition, some areas of the body offer unique obstacles to surgical resection. As such, some specific anatomic sites of tumor occurrence will be discussed separately.

### Head and Neck (Superficial Nonparameningeal)

Approximately 35% of RMS arises in the head and neck region. Of these tumors, 75% occur in the orbits. Other sites include the buccal, oropharyngeal, laryngeal, or parotid areas.[3] The histologic variant of RMS correlates to some extent with the location of the orbital tumor. ERMS and differentiated types more commonly arise in the superior nasal quadrants, whereas ARMS generally originate within the inferior orbit.[83] For all head and neck RMS, biopsy is required for the confirmation of diagnosis. Resection may be limited by the inability to obtain an adequate margin, and therefore the success of resection is heavily dependent on location.[84–86] Lymph nodes are rarely involved in childhood head and neck RMS; however, clinically or radiographically positive nodes must be biopsied.[87] Outcomes correlate strongly with tumor location. Orbital RMS carries the best prognosis and is least likely to extend to the meninges. These tumors generally present earlier in the course of disease. Tumors arising in nonorbital parameningeal locations have a high likelihood of meningeal extension. If meningeal extension occurs after chemotherapy and radiation therapy, the outcome is often fatal.[88]

### Parameningeal Sites

Parameningeal RMS includes tumors arising in the middle ear/mastoid, nasal cavity, parapharyngeal space, paranasal sinuses, or the pterygopalatine/infratemporal fossa region. These tumors are considered high risk because of their propensity to cause cranial nerve palsy, bony erosion of the cranial base, and intracranial extension.[89] Wide local excision is recommended but is often not feasible because of the location of the tumors. Craniofacial resection for tumors of the nasal areas, paranasal sinuses, temporal fossa, and other deep sites are reserved for expert surgical teams. The recognition of poor outcomes associated with meningeal extension has lead to a propensity for early radiation therapy of primary tumors and adjuvant chemotherapy.[87] For patients with unresected tumors and/or lymph node-positive disease, the use of three-drug chemotherapy regimens (including an alkylating agent) plus local or regional radiation may be beneficial. The optimal dosing and timing of radiation are not yet determined.[84]

### Trunk

Accounting for only 4% to 7% of tumors, RMS of the trunk is associated with a poor prognosis. Symptoms for RMS of the trunk often occur late in the progression of disease, which leads to late diagnoses. Complete surgical resection is difficult, particularly when the pleura and peritoneum are involved. In

addition, resections are frequently morbid and associated with poor cosmetic outcomes. Resection may necessitate major chest wall or abdominal wall reconstruction with prosthetic materials or with flaps.[90,91] Indicators of poor prognosis include advanced stage at presentation, alveolar histology, recurrence disease, tumor size greater than 5 cm, lymph node involvement, and the inability to undergo gross total resection.[92,93]

### Abdominal Wall

Abdominal wall RMS generally presents as a painless, firm mass. Many abdominal wall primaries can be removed completely at presentation or following neoadjuvant chemotherapy. However, tumors arising from the interior abdominal wall may not be noticed until significant tumor progression has occurred, thus rendering resection much more challenging. Tumor excision should include full-thickness resection of the abdominal wall, including the skin and peritoneum with a margin of normal tissue. Reconstruction of the abdominal wall can be performed with mesh or myocutaneous muscle flaps in an attempt to preserve function and cosmesis after resection. Data would suggest that localized tumors of the abdominal wall can be resected with good outcomes and that younger children with abdominal wall RMS fare better than adolescents, possibly because of a higher proportion of unfavorable histology in the older group of children.[94] If the size or location prevents adequate excision, neoadjuvant chemotherapy should be initiated to reduce tumor size and facilitate subsequent resection.

### Chest Wall

The differential diagnosis for malignant chest wall masses includes Ewing sarcoma, primitive neuroectodermal tumors (PNET), and RMS. Diagnostic biopsies are performed in the long axis of the tumor, parallel to the ribs. Wide local excision of chest wall lesions with a 2-cm margin, including the previous biopsy site, involved chest wall muscles and involved ribs, as well as wedge excision of any involved underlying lung, is recommended. Thoracoscopy performed at the time of resection may be helpful in determining the extent of pleural involvement and tumor extension to the underlying lung. Chest wall reconstruction can be performed using a number of techniques employing prosthetic mesh, myocutaneous flaps, and titanium ribs. Chest wall lesions have a worse prognosis than other trunk lesions, with a 1.8-year survival rate of only 42%.[90] Although radiotherapy may be beneficial for local control of tumor, this option is associated with significant morbidity, including pulmonary fibrosis, decreased lung capacity, restrictive defects from altered development of the thoracic cavity, and scoliosis.[95] There is also no proven survival benefit.

### Biliary Tract

Classically, patients with biliary RMS present at a young age (average age 3.5 years) with jaundice and abdominal pain, often associated with abdominal distension, vomiting, and fever. Workup reveals a significant direct hyperbilirubinemia and a mild elevation of hepatic transaminases. Gross total resection of biliary tract RMS is rarely possible and is often unnecessary because of good outcomes with chemotherapy and radiation. Currently, open biopsy is the only definitive role of surgery in the treatment of biliary RMS, although this is controversial. The histology of these tumors is often the botryoid variant of embryonal RMS, which carries a good overall prognosis.[96] Biliary obstruction can be relieved by stenting, but external biliary drains should be avoided because of infectious complications. Overall, outcomes are good unless distant metastases are present at the time of diagnosis.[97,98]

### Paraspinal Sites

Paraspinal RMS is rare (3.3% of all RMS) and carries a poor prognosis. These tumors tend to spread along anatomic structures, such as neurovascular bundles and fascial sheaths, occasionally causing spinal cord compression. Complete excision of paraspinal lesions is often difficult to perform because of large tumor size at presentation and proximity to the vertebral column and spinal canal.[92,99] Recurrence rates for paraspinal RMS are high (55%) with the majority of these occurring at distant locations. The lung is the most common site of distant metastasis followed by the central nervous system.[99]

### Retroperitoneum/Pelvis

Like paraspinal tumors, retroperitoneal/pelvic lesions are often discovered at an advanced stage and thus generally carry a poor prognosis. These tumors can envelop vital structures, making complete surgical resection challenging. Neoadjuvant chemotherapy may play a role in tumors that cannot be safely resected at the time of diagnosis. With the exception of group IV metastatic disease, aggressive resection is recommended and has been shown to offer improvement in survival.[100] Group IV patients with embryonal histology and those who present at less than 10 years of age may also undergo surgical debulking.[101] It has been demonstrated that excising greater than half of the tumor before chemotherapy resulted in improved rates of failure-free survival when compared with patients who did not undergo debulking.[102] This is the *only* setting in which surgical debulking of RMS has shown any benefit.

### Perineal/Perianal Sites

Perineal tumors are rare and usually present at an advanced stage. Characteristics associated with improved survival include a primary tumor size less than 5 cm, less advanced clinical group and stage, negative lymph node status, and age less than 10 years of age. Interestingly, histology does not affect overall outcome for these tumors. Resection of these tumors can be challenging because of proximity to the urethra and anorectum. At resection, particular care should be taken to preserve continence. If anorectal obstruction exists, a temporary colostomy may be necessary. Patients presenting in clinical group I had 100% overall survival at 5 years compared with 25% for group IV patients.[103]

### Extremities

Rhabdomyosarcoma of the extremities accounts for 20% of all new diagnoses. The majority of these tumors have alveolar histology and thus a poor prognosis. The cure rate for children with extremity RMS has, however, improved steadily from 47% in IRS-I to 74% in IRS-III.[104,105] As with many types of RMS, complete gross resection at initial surgical intervention is the most important predictor of failure-free survival. The primary goal of local tumor control in extremity tumors is limb-sparing complete resection. Amputation is rarely necessary for tumor excision. Positive regional lymph nodes are

found in 20% to 40% of patients and are associated with decreased overall survival (46% survival rate for node-positive patients compared with 80% survival for node-negative patients). Seventeen percent of IRS-IV patients with clinically negative nodes were found to have microscopic nodal disease on biopsy. In light of this, surgical evaluation of lymph nodes is necessary to accurately stage children with extremity RMS, even in the absence of clinically positive nodes.[60] Currently, axillary sampling is recommended for upper extremity lesions, and femoral triangle sampling is recommended for lower-extremity lesions. Sentinel lymph node mapping may be a useful adjunct in the setting of extremity RMS. If regional nodes are involved, then x-ray therapy (XRT) fields are adjusted to incorporate regional lymph node basins. This approach is associated with decreasing rates of local and regional recurrence.[57] In-transit nodal involvement at the time of diagnosis, present in 4% of IRS-IV patients, has also been identified as a factor contributing to regional treatment failure. This may be evaluated by MRI, or possibly FDG PET, at the time of diagnosis. Radiation therapy (RT) should be used at regional lymph node sites in these patients.[106]

### Genitourinary Sites: Bladder/Prostate

Rhabdomyosarcoma of the bladder or prostate typically presents with urinary obstructive symptoms. These lesions are typically of embryonal histology (73%). The major goal of surgery is complete tumor resection with bladder salvage. This can be achieved in 50% to 60% of patients.[107,108] Partial cystectomy has resulted in similar survival rates and improved bladder function compared with more aggressive resections.[109,110] Bladder dome tumors frequently can be completely resected, whereas more distal bladder lesions frequently require ureteral reimplantation or bladder augmentation. Prostatic tumors require prostatectomy, often combined with an attempt at bladder salvage with or without ureteral reconstruction.[53] Continent urinary diversion may be necessary if tumors are unresectable or have a poor response to medical therapy. Lymph nodes are involved in up to 20% of cases. Therefore during biopsy or resection, iliac and para-aortic nodes should be sampled, as well as any other clinically involved nodes. An analysis of patients with bladder or prostate RMS in IRS-IV revealed that 70% of these tumors arose from the bladder with an overall 6-year survival of 82%.[111] Of these patients, 55 retained their bladder without relapse, but only 36 had normal bladder function. Urodynamic studies have been used to evaluate bladder function after treatment.[112]

### Genitourinary Sites: Vulva/Vagina/Uterus

Traditionally, females with primary tumors of the genital tract underwent aggressive resection followed by chemotherapy with or without radiation.[113–115] Newer treatment approaches rely more heavily on neoadjuvant chemotherapy to reduce tumor size and minimize the extent of resection in an attempt to preserve organ function. Primary tumors of the vagina are about 5 times more common than cervical tumors. The vast majority of these tumors are classic embryonal or are of the botryoid subtype. This may account for the more favorable prognosis that these tumors display.[116] These tumors respond well to chemotherapy, with impressive tumor regression that often precludes the need for radical operations such as pelvic exenteration. Vaginectomy and hysterectomy are performed only for persistent or recurrent disease. Primary uterine tumors require resection with preservation of the distal vagina and ovaries if they do not respond to chemotherapy. Oophorectomy is only indicated in the setting of direct tumor involvement. For those patients presenting with nonembryonal RMS of the female genital tract, more intensive chemotherapeutic regimens are recommended to reduce the risk of recurrence. Prognosis for this tumor site with only locoregional disease is excellent, with an estimated 5-year survival of 87%.[117]

### Paratesticular Sites

Paratesticular RMS generally presents as a painless scrotal mass. Histology is generally favorable, with most tumors showing the spindle-cell subvariant of embryonal histology. Survival rates are greater than 90% for patients presenting with group I or II disease.[118,119] Radical orchiectomy via an inguinal approach with resection of the spermatic cord to the level of the internal ring is the standard of care. Open biopsy should be avoided, because the flow of lymphatics in this region facilitates spread of the disease. If a transscrotal biopsy/resection has been performed, subsequent resection of the hemiscrotum is required. If unprotected spillage of tumor cells occurs during tumor resection, these patients are considered clinical group IIa regardless of the completeness of resection.[120] The incidence of nodal metastatic disease for paratesticular RMS is 26% to 43%.[121,122] Unfortunately, studies have demonstrated that CT is a poor means of evaluating lymph node positivity in the retroperitoneum.[123] In addition, patients older than 10 years of age or those with enlarged nodes have a much higher incidence of node positivity.[59] Those patients should therefore undergo an ipsilateral retroperitoneal nodal resection. Suprarenal nodes should be evaluated, because positive nodes in this area place a patient in group IV with disseminated metastatic disease.

## Metastatic Disease

Rhabdomyosarcoma metastasizes both through hematogenous and lymphatic routes. Children with metastatic RMS have very poor survival rates. For the IRS studies I through III, children with metastatic disease had a 5-year disease-free survival of 20%, 27%, and 32%, respectively, in each of the successive studies. Recently studies have employed the use of upfront "window studies" to address potential chemotherapeutic regimens that would improve the disease-free survival period when given to patients with newly diagnosed metastatic RMS. One such study evaluated the combination of ifosfamide and doxorubicin for the treatment of children with metastatic disease who are less than 10 years of age, have embryonal histology, and lack nodal, bone, or bone marrow involvement. This treatment strategy increased 5-year failure-free survival to 28% and 5-year overall survival to 34%.[68] Despite these improvements, more intensive research into chemotherapeutic regimens for group IV disease should be investigated to improve overall outcome.

## Prognosis

The prognosis of patients with RMS is dependent on many factors. Favorable prognostic factors include embryonal/botryoid histology, primary tumor sites in the orbit and

nonparameningeal head/neck region and genitourinary nonbladder/prostate regions, a lack of distant metastases at diagnosis, complete gross removal of tumor at the time of diagnosis, tumor size less than or equal to 5 cm, and age less than 10 years at the time of diagnosis.[77] Clinical grouping was identified as one of the most important predictors of failed treatment and tumor relapse.[2,77] These factors become important in the designation of treatment groups for risk-based therapy.

For group II patients, Smith and colleagues performed a retrospective review of patients enrolled in IRS-I through IRS-IV to determine the risk factors for relapse. Those patients in group II at highest risk for treatment failure had alveolar/undifferentiated histology, unfavorable primary sites, regional disease with residual tumor after gross resection and node involvement, or were treated with early therapeutic regimens (IRS-I or IRS-II). Current therapy for patients with group II tumors results in 85% survival long term, indicating that risk-based therapeutic strategies have assisted with failure-free survival.[124]

Patients with group III disease have incomplete resection or biopsy only prior to chemotherapy and irradiation. Wharam and colleagues determined that predictors of failure-free survival in group III include tumor size less than 5 cm, primary sites of orbit and bladder/prostate, and TNM staging equivalent to $T_1/N_0N_x$ tumors in stage I or stage II. Since radiotherapy is important for local control of group III disease, the incidence of local failure was stratified by radiotherapy dosing (<42.5 vs. 42.5 to 47.5 vs. > 47.5 Gy) and was not significantly different among these dose ranges.[125]

Approximately 15% of patients with RMS present with metastases (group IV) at the time of diagnosis.[104] Patients in group IV have poor outcomes despite aggressive multimodality treatments, with only 25% expected to be free of disease 3 years after diagnosis.[104,105] A review of prognostic factors and outcomes for children and adolescents with metastatic RMS in IRS-IV found that 3-year overall survival and failure-free survival was improved if there were two or fewer metastatic sites and the histology of the tumor was embryonal. Compared with patients without metastatic disease, group IV patients in the IRS-IV study were more likely to be older (median age 7 years vs. 5 years), had a higher incidence of alveolar histology (46% vs. 22%), had tumors that were more invasive ($T_2$: 91% vs. 49%) and larger (>5 cm: 82% vs. 51%), a higher incidence of lymph node involvement ($N_1$: 57% vs. 16%), and had a greater proportion of extremity and truncal/retroperitoneal primary sites (48% vs. 25%). This study concluded that not all children with metastatic RMS have uniformly poor prognoses, suggesting that therapy should be tailored according to these factors.[126]

Future clinical trials and a better understanding of the molecular biology driving RMS tumor behavior may assist with customized clinical therapies that will improve outcome and failure-free survival in patients diagnosed with RMS.

CHAPTER 36

# Other Soft Tissue Tumors

Andrea Hayes-Jordan

## Nonrhabdomyosarcoma Soft Tissue Sarcoma in Children: Background and Overview

Approximately 8% of childhood malignancies are soft tissue sarcomas. Half of these are nonrhabdomyosarcoma soft tissue sarcomas (NRSTSs). There are more than 50 histologic types, and genetic patterns are poorly understood. When surgical resection is feasible, ≈60% of patients are expected to achieve long-term survival with or without radiation therapy.[1] Patient outcome is largely based on age, the presence of metastasis at diagnosis, and size and depth of the lesion. Here we focus on the most common primary histologic types and differences in presentation and surgical treatment of childhood NRSTS and other common pediatric soft tissue tumors.

The treatment for children and adolescents with NRSTS has not previously been standardized, nor have there been any pediatric cooperative group trials as for rhabdomyosarcoma (RMS). Because there are many histologic subtypes of NRSTS, standardization of treatment is difficult. The first risk-based prospective trial of NRSTS in children and adolescents will complete enrollment soon, with results anticipated in 2013. In this trial, patients with NRSTS are treated as low, intermediate, or high risk based on criteria previously ascertained in a thorough review of 121 patients by Spunt.[2,3] In patients with surgically resected NRSTS, univariate analysis revealed clear risk factors. Positive surgical margins ($P = 0.004$), tumor size greater than or equal to 5 cm ($P < 0.001$), invasiveness ($P = 0.002$), high grade ($P = 0.028$), and intra-abdominal primary site ($P = 0.055$) had a negative impact on event-free survival (EFS). Multivariate analysis confirmed all of these risk factors, except for invasiveness. Local recurrence was predicted by intra-abdominal primary site ($P = 0.028$), positive surgical margins ($P = 0.003$), and the omission of radiation therapy ($P = 0.043$). As expected, the biology of the tumor, assessed by tumor size greater than 5 cm, invasiveness, and high grade, predicted distant recurrences. Children and adolescents with initially unresectable NRSTSs are a subgroup with pediatric NRSTSs that is particularly high risk. These are large tumors, greater than 5 cm, which involve critical neurovascular structures of the extremity, trunk, abdomen, or pelvis. In these patients, the 5-year estimated overall survival and EFS were 56% and 33%, respectively, and postrelapse survival was poor, 19% despite multimodality therapy.[4]

In addition to the tumor being unresectable, age is a prognostic indicator in pediatric NRSTS. Patients less than 1 year of age have an excellent prognosis, whereas the adolescents and young adults have the worse prognosis compared with younger patients or older adults.[2] A 34-year review of patients treated at St. Jude Children's Research Hospital (SJCRH) revealed the overall 5-year survival estimate for children less than 1 year of age was 92% compared with 36% in those 15 to 21 years of age. Patients between 1 and 15 years of age had an intermediate survival of approximately 60%. Survival after relapse was poor in all age groups less than 18 years, except those less than 1 year of age. The 5-year estimate of postrelapse survival in patients less than 1 year of age was 80% compared with the 15- to 25-years cohort in which survival was 21%. The type of chemotherapy used in these patients was variable; surgical excision was generally completed for lesions less than or equal to 5 cm, and for most patients, incisional biopsy was performed for lesions greater than 5 cm, followed by chemotherapy, reexcision, and radiation therapy or amputation.[5]

### INFANTILE FIBROSARCOMA

Patients in the study above who were less than 1 year of age had infantile fibrosarcoma (IF). This is a very rare form of NRSTS that occurs primarily during the first year of life, but can appear up to year 4. IF presents as a rapidly growing mass in the trunk or extremities. It can erode bone and usually reaches a large size.

Most cases of IF have a specific translocation t(12;15)(p13;q25)[6–8] leading to fusion of *ETV6 (TEL)*, a member of the ETS family of transcription factors, on chromosome 12p13, and *NTRK3 (TRKC)*, which encodes a tyrosine kinase receptor for neurotropin-3[9,10] on chromosome 15q25. Other cytogenetic abnormalities include trisomy 11; random gains of chromosomes 8, 11, 17, and 20[11]; deletion of the long arm of chromosome 17[12]; and a t(12;13) translocation.[13] The helix-loop-helix dimerization domain of *ETV6* fuses to the protein tyrosine kinase domain of *NTRK3*. The fusion protein results in ligand-independent chimeric protein tyrosine kinase activity with autophosphorylation. This leads to constitutive

activation of Ras-MAPK and P13K-AKT pathways through insulin receptor substrate-1, which is tyrosine-phosphorylated,[14–16] and through the activation of c-*Src*.[17] The fusion protein also associates with TGF-beta II receptor, which can be oncogenic by leading to inhibition of TGF-beta receptor signals that mediate tumor suppression.[18]

Identical genetic findings have been reported in the cellular variant of congenital mesoblastic nephroma, a microscopically similar tumor of the kidney,[19,20] and in secretory carcinoma of the breast[21] and acute myeloid leukemia,[22] implying oncogenesis by lineage-independent activation of kinase-related signaling pathways.

### SYNOVIAL SARCOMA

Synovial sarcoma (SS) and malignant peripheral nerve sheath tumor (MPNST) are the most common pediatric NRSTSs. SS is characterized by a very specific fusion gene 18[t(X;18) (p11.2;g11.2)]. Its etiology is unknown.[23] In evaluating the three largest reviews of pediatric SS, common principles are evident. For children 0 to 16 years old and tumors less than 5 cm in size, overall 5-year survival (OS) is 71% to 88%. In this group, the addition of chemotherapy did not improve survival. In patients 17 to 30 years old, the addition of chemotherapy does improve metastasis-free survival. In patients with SS tumors greater than 5 cm that are deep and invasive and without metastasis, OS is 50% to 75%, and chemotherapy responsiveness is 50% to 60%.[24] It is clear that for SS survival does not depend on surgical margins but depends on size (>5 cm) and local invasiveness. Brecht and colleagues found event-free survival was 92% and 56%, respectively, when SS tumors were less than or equal to 5 cm or greater than 5 cm.[24] Figure 36-1 shows the leg of a child with synovial sarcoma that was not responsive to chemotherapy and required resection down to the periosteum of the tibia. Radiotherapy does have a role in this disease and is recommended after marginal resection or before anticipated marginal resection, such as the one pictured.[23]

### MALIGNANT PERIPHERAL NERVE SHEATH TUMOR

Malignant peripheral nerve sheath tumor (MPNST), also called schwannoma or neurofibrosarcoma, usually arises in proximity to nerve sheaths. MPNST develops in a preexisting neurofibroma in approximately 40% of patients, particularly those with neurofibromatosis type 1 (NF-1).[25] In a review of 171 patients the 5-year OS and progression-free survival was 51% and 37%, respectively. Multivariate analysis revealed absence of NF-1 and tumor invasiveness to be poor prognostic variables. The overall response of the patients who received neoadjuvant chemotherapy was 45%. Some partial responses were seen in patients with initial unresectable disease, because of neurovascular involvement.[25] Neoadjuvant radiotherapy failed to maintain or achieve local control in 45% of patients (26 of 58). Neither chemotherapy nor radiotherapy produced any statistically significant difference in outcome. This article concluded by stating "…complete surgical resection is the mainstay of successful treatment."[25] In another much smaller series, the same patterns in outcome were seen.[26]

## Surgical Approach and Presentation of Nonrhabdomyosarcoma Soft Tissue Sarcoma

Unlike rhabdomyosarcomas, NRSTSs are relatively chemoinsensitive. In the above pediatric studies and in adult multi-institutional studies, the impact of chemotherapy on outcome is minimal. In large American Joint Commission on Cancer (AJCC) stage 3 tumors, overall survival was no different whether or not chemotherapy was added to surgery and also if neoadjuvant or adjuvant radiation therapy was added.[27] Complete surgical excision provides the best outcome. Patients usually present with a painless mass, sometimes identified after a recent episode of trauma. Pediatric patients who have an extremity or trunk mass that is greater than 5 cm, should have a magnetic resonance imaging (MRI) examination, followed by core needle or open biopsy. If NRSTS is identified and no mutilating limb-sparing surgical excision is feasible, resection should be completed. If margins are microscopically positive, postoperative radiotherapy should be given in high-grade tumors and tumors larger than 5 cm. Low-grade tumors that are less than 5 cm can be reexcised or just watched closely. If surgical excision is not feasible without amputation or severe morbidity, whether less than or greater than 5 cm, preoperative chemotherapy and radiotherapy should be administered. If surgical excision is feasible, but R1 resection is anticipated, the type of radiotherapy, whether

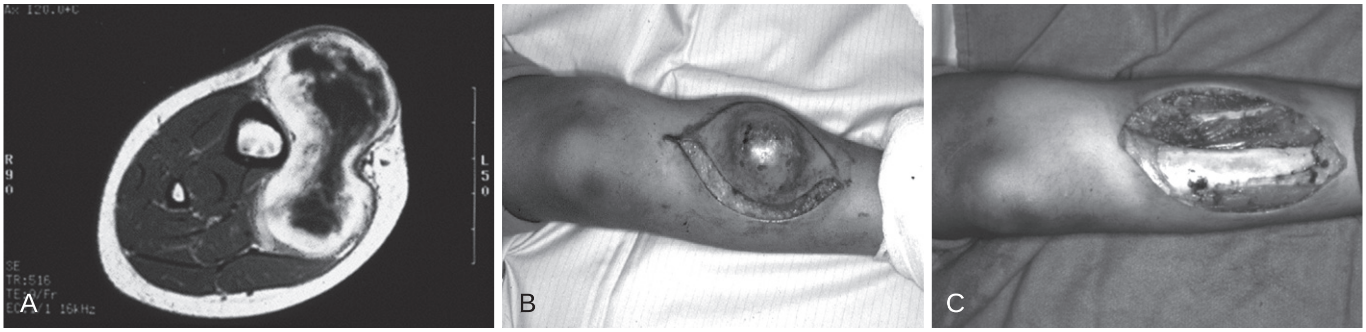

**FIGURE 36-1** **A-C**, Magnetic resonance (MR) image of a child with synovial sarcoma abutting the tibia. Neoadjuvant chemotherapy was not successful in reducing the size of the tumor. Marginal resection with postoperative radiation or brachytherapy is a preferred alternative to amputation.

preoperative or postoperative brachytherapy, proton beam therapy, or external beam therapy, should be discussed with the radiation oncologist, with the goal in pediatric extremity tumors to avoid the growth plate in younger patients who are still growing. In tumors less than 5 cm, complete surgical excision with negative microscopic margins is the goal. In the case of unexpected malignant pathology, primary reexcision is recommended. For all NRSTSs, negative microscopic margins should be achieved; however, there is no consistent reliable evidence to establish the appropriate width of the margins.

NRSTSs are graded histologically to help predict outcome. Grade 1 is any NRSTS with low malignant potential, such as infantile fibrosarcoma, with mitotic activity less than 5 mitoses per high-powered field (HPF). NRSTSs with tumor necrosis less than 15% and mitotic activity of 5 to 10 mitoses per HPF are graded 2, and specific histologic subtypes with known aggressive behavior and/or any sarcoma with tumor necrosis of more than 15% or mitotic activity of more than 10 mitoses per HPF are graded 3.[28]

Cytotoxic chemotherapy (Adriamycin, ifosfamide, vincristine, dactinomycin, etc.), will be effective, at best, in 45% to 50% of patients from the evidence we have to date.[4] (This does not include targeted therapy, because there are not yet sufficient data to analyze at this time.) Very close observation by imaging is warranted if neoadjuvant chemotherapy is chosen, because an increase in tumor size may preclude limb-sparing, nonmutilating surgery, and an abdominal or pelvic tumor may become unresectable.

Sentinel lymph node biopsy, although recommended for rhabdomyosarcoma to evaluate normal-appearing lymph nodes, is only recommended in histologic subtypes of NRSTS that have high risk of lymph node metastasis. These include epithelioid sarcoma and clear cell sarcoma, which have an approximate incidence of lymph node metastasis of up to 30%. Synovial sarcoma metastasizes to the lymph nodes about 15% of the time.

Computed tomography (CT) scan of the chest is a necessary part of the workup to exclude lung metastasis. Lung metastasis occurs in approximately 30% of patients with NRSTS. Because NRSTSs are relatively chemoinsensitive, surgical resection of lung metastasis is recommended. Thoracotomy is the recommended approach in order to palpate the lung for any tumors that may have been missed on imaging.

## Desmoplastic Small Round Cell Tumor

Desmoplastic small round cell tumor (DSRCT) is a malignant neoplasm in the soft tissue sarcoma family that arises from the peritoneal surface of the abdomen and pelvis. No more than 200 cases have been reported worldwide since the disease was first described in 1989 by Gerald and Rosai[29] and Ordonez.[30] The tumor is most prevalent in young white males.[29–30] Presenting symptoms include abdominal pain, constipation, and abdominal distension with ascites. Overall survival is approximately 30% to 55% despite chemotherapy, radiotherapy, and aggressive surgical resection.[31,32] Because most DSRCT patients present with multiple abdominal tumor implants (Fig. 36-2), microscopic tumor cells can be left behind, despite the complete resection of dozens to hundreds of tumors. The most widely accepted standard of care for DSRCTwas multimodality therapy with the P6 regimen: cyclophosphamide, doxorubicin, and vincristine, alternating with ifosfamide and etoposide for seven total courses,[31] followed by aggressive debulking surgery to remove all visible disease.[32] It is clear that without complete resection of all visible disease survival is poor.[32] Hyperthermic intraperitoneal chemotherapy (HIPEC) is a new therapeutic modality recently used in children; its results are promising, but studies are ongoing. Hyperthermia and chemotherapy have synergistic cytotoxicity that is of value in the treatment of microscopic disease in adult carcinomas. HIPEC has been applied successfully in adults with extensive peritoneal disease, commonly observed with mesothelioma, appendiceal, colon, and gastric carcinoma.[33–37] A recent publication shows that DSRCT can now be treated safely with aggressive cytoreductive surgery followed by (HIPEC) in children.[38] The study included 23 pediatric adolescent and young adult patients with DSRCT. HIPEC was compared with standard chemotherapy, radiation therapy, and surgical debulking. The patients were mostly males (96%). The age of the HIPEC patients ranged from 5 to 25 years of age. Complete resection (CR0) to less than 1.0-cm tumor size was achieved in all 8 patients who underwent HIPEC. Operative times ranged from 7 to 16 hours. Figure 36-3 shows the setup used in the operating room to deliver HIPEC. In the pediatric patients, the estimated 12-month disease-free survival (DFS) rate was 53% for the HIPEC group, compared with 14% for the non-HIPEC group. Median 3-year survival in this small group of patients was 29% with chemotherapy and radiotherapy alone, compared with 71% in the HIPEC with cytoreductive surgery group. The severe morbidities that occurred were partial bowel obstruction managed nonoperatively, prolonged ileus/gastroparesis, transient renal insufficiency, and one patient developed cardiomyopathy secondary to resection of more than 3 kg of tumor, causing release of tumor necrosis factor. HIPEC is an option in treating this rare tumor.[38]

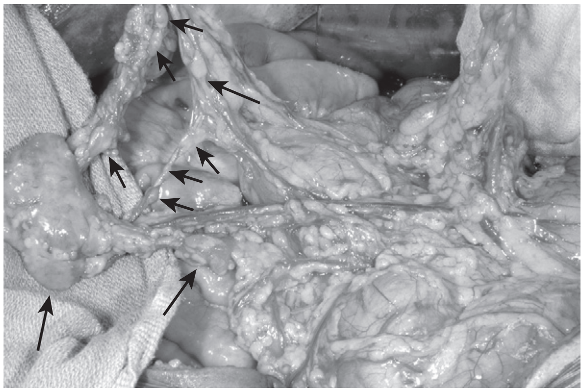

**FIGURE 36-2** Desmoplastic small round cell tumor in the omentum of a 5-year-old boy after six cycles of chemotherapy. Peritoneal disease has similar appearance. This child had 402 nodules removed at this operation.

## Desmoid Tumors

Desmoid tumors are very different than DSRCT. These are intermediate-grade sarcoma-type tumors that are locally very aggressive and can be fatal, but usually do not metastasize. Desmoid fibromatosis is a mesenchymal neoplasm. It is encountered

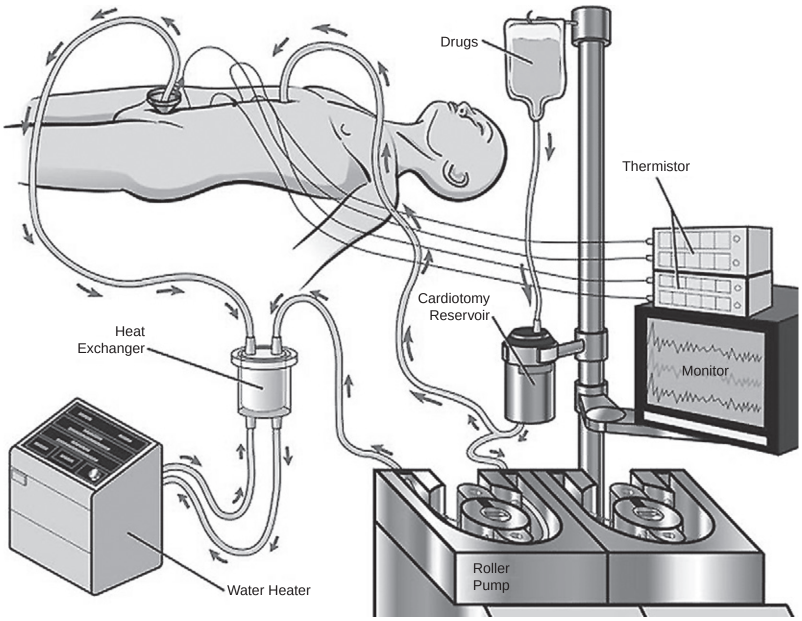

**FIGURE 36-3** Setup for hyperthermic intraperitoneal chemotherapy (HIPEC) therapy for children with "sarcomatosis" after cytoreductive surgery.

in two settings—within the context of familial adenomatous polyposis (FAP) and sporadically.[39] Here we focus on the sporadic group. Desmoid tumors can arise in any body site and are much more common in women. Surgery has been the therapeutic mainstay, but radiotherapy plays an important role in treatment as do systemic therapies, such as the tamoxifen and sulindac combination and nonsteriodal anti-inflammatory drugs (NSAIDs).[40–46] Desmoids have a very unique course in that they can recur locally and can be more aggressive or regress spontaneously. However, they have no capacity for metastasis.[39] Resecting recurrent tumors can be potentially mutilating. Some large retrospective studies[42,47,48] demonstrated that microscopically positive (or grossly positive) margins were predictive of increased frequency of local recurrence on retrospective multivariate analysis, although radiation improved outcome in one study. Other studies[40,49–51] have failed to demonstrate an effect of microscopic margin on recurrence. Some of these differences may result from the mixture of disease sites, pattern of application of adjuvant radiotherapy, and selection of patients treated by surgical approach. In the end, surgical therapy must be tailored to what is achievable in terms of margins with preservation of functional status for the individual patient.[39] Incomplete resection or positive microscopic margins in desmoid tumors should be treated with adjuvant radiotherapy. Figure 36-4 provides a helpful algorithm to follow.

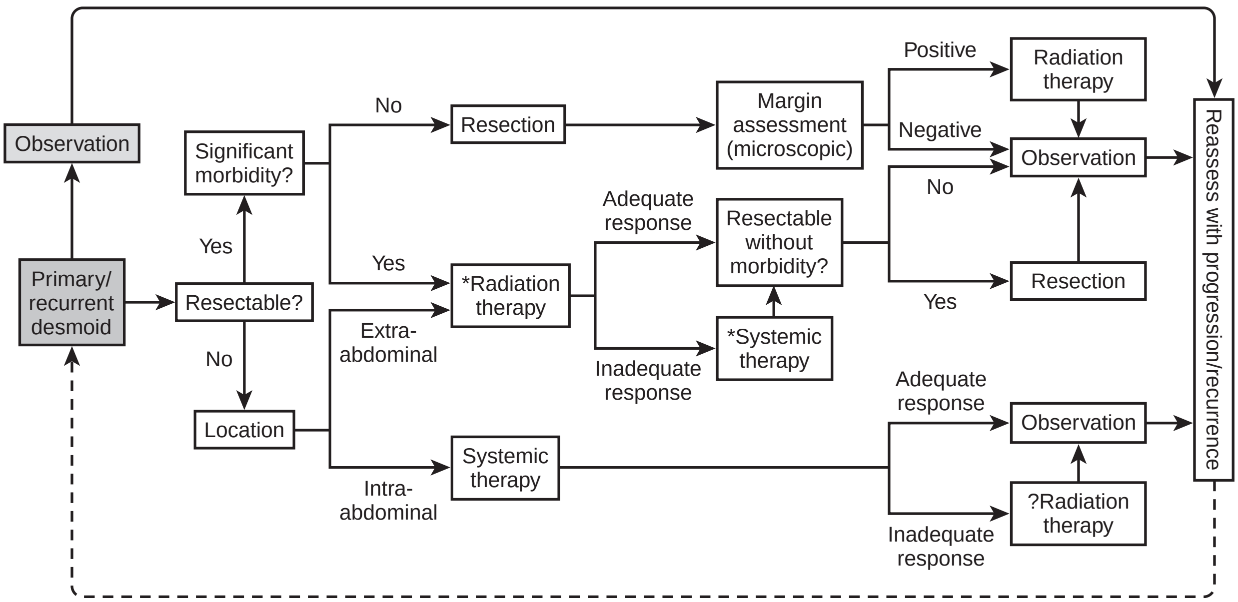

**FIGURE 36-4** General treatment protocol for desmoid tumors at the University of Texas M.D. Anderson Cancer Center. The route of initial observation for certain cases, to avoid overtreatment advocated by some, is depicted in *gray*. Given the propensity for progression on treatment and local recurrence, all treatment pathways ultimately end in observation. *Radiation therapy can be preceded, and even precluded, by systemic therapy in certain cases of initially unresectable extraabdominal desmoid tumors.

## Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is a relatively common soft tissue tumor. Its peak age is in young adulthood, but it is frequently present in children and at birth. DFSP occurs primarily on the trunk and extremities. It can present as a plaque on the skin or in a more diffuse multinodular pattern.[52,53] The latter is more common in children. Pigmented dermatofibrosarcoma, giant cell fibroblastoma, and fibrosarcoma can arise in DFSP.[54,55]

Dermatofibrosarcoma protuberans has a reciprocal translocation, t(17;22)(q22;q13.1), resulting in fusion of the genes *COL1A* (encoding the alpha 1 chain of collagen type 1, a heterotrimer) on 17q21-22 and *PDGFB1* (encoding the beta chain of platelet-derived growth factor, a homodimer) at 22q13.[55,56] The same fusion is also seen in supernumerary ring chromosomes derived from t(17;22),[57] which are found in adult cases of dermatofibrosarcoma. Fusion gene transcripts can be detected by reverse transcriptase–polymerase chain reaction (RT-PCR).[53,58] This is not usually required for diagnosis but might be useful in guiding therapy, especially for superficial fibrosarcomas.

Dermatofibrosarcoma protuberans has a high local recurrence rate, especially if incompletely excised, and can metastasize in 5% of cases, usually after multiple local recurrences. Therefore complete excision with negative margins is crucial, and 2- to 3-cm margins are recommended. However, in areas such as the head and neck, lesser margins are acceptable.

Platelet-derived growth factor receptor (PDGFR) is a receptor tyrosine kinase, which in dermatofibrosarcoma protuberans is constitutively activated by autocrine or paracrine mechanisms as a result of overproduction of its ligand platelet-derived growth factor-beta (PDGFB),[59] leading to cellular proliferation.[60] This has suggested the use of the tyrosine kinase inhibitors imatinib[61] and, more recently, sunitinib or sorafenib in locally advanced or metastatic disease,[62–63] but fibrosarcomatous variants without the translocation do not respond[64,65] so that genetic analysis is indicated before targeted therapy. In the only multicenter Phase 2 study published to date, imatinib was found to be effective preoperative therapy in 36% of patients ($n = 25$) by reducing tumor size by an average of 20%. Response was measured by physical exam, ultrasonography, and MRI. Decrease in average diameter by 1 cm on physical exam, 1 cm by ultrasonography, and 2 cm by MRI were observed, respectively. In 21 of 25 patients, the fusion gene *COL1A1-PDGFB* was detected. Therefore when DFSP is located in places where a decrease in size provides a significant advantage in wound closure, neoadjuvant imatinib is a viable option.

CHAPTER 37

# Teratomas and Other Germ Cell Tumors

Frederick J. Rescorla

Pediatric germ cell tumors are rare tumors that are unique due to their varied clinical presentation and locations. Approximately 20% of pediatric germ cell tumors are malignant, and they represent 1% to 3% of all malignant tumors in childhood and adolescence.[1,2] Three features distinguish these childhood tumors from many other malignancies as well as their counterparts: In children, the extragonadal tumor site is more common than the gonadal site, whereas in adults, only 10% are at extragonadal sites; yolk sac tumor is the predominant malignant histology, and a serum marker (alpha fetoprotein, AFP) exists to follow response to therapy and monitor for recurrent disease; and the introduction of modern chemotherapy with cisplatin and bleomycin significantly increased survival for affected children and has allowed neoadjuvant therapy with vital organ preservation in initially unresectable cases.

Abnormal or arrested migration of primordial germ cells results in deposition of cells in the sacrococcygeal region, retroperitoneum, mediastinum, and pineal gland of the brain, resulting in the potential of extragonadal germ cell tumors at these sites. Whereas in adults 90% of germ cell tumors are at gonadal locations, in childhood, the extragonadal site is more common until puberty, at which time the gonadal sites are more common. The totipotential nature of these cells results in a wide variety of histologic patterns, and in addition, one quarter of pediatric tumors have more than one histologic component.[2] The management of these tumors is dependent upon complete surgical resection at diagnosis or after neoadjuvant therapy, accurate and thorough histologic examination, and selective use of chemotherapy. Prior to the late 1970s, the survival of advanced-stage tumors was dismal; however, Einhorn's introduction of cisplatin, vinblastine, and bleomycin for disseminated testicular cancer in 1977 changed the treatment of all germ cell tumors with dramatic results.[3] Subsequent studies validated the use of chemotherapy in a neoadjuvant fashion, thus allowing vital organ preservation in advanced cases with frequent massive tumor shrinkage. The role of the surgeon in determining resectability and performing a proper staging operation is vital.

Current therapy within the Children's Oncology Group (COG) is risk based: with surgery alone for stage 1 testes and ovary tumors and all immature teratomas, with anticipated survival of 95% to 100%; surgery and chemotherapy for all remaining gonadal tumors (except stage IV ovary) and low-stage (I-II) extragonadal, with anticipated survival of 90% to 100%; and surgery and intensive chemotherapy for high-risk (stage III-IV) extragonadal and stage IV ovary, with survival between 75% and 90%, depending on site and stage.

## Embryology and Classification

Primordial germ cells arise near the allantois of the embryonic yolk sac endoderm and are evident at the fourth fetal week. They migrate along the midline dorsal mesentery to the genital ridge, arriving by the end of the sixth fetal week. The migration of the germ cells appears to be mediated by the c-KIT receptor and stem cell factor; the latter is expressed in increasing levels from the yolk sac to the genital ridge.[4,5] Arrested migration is presumed to account for the extragonadal locations in the normal path of the germ cells (retroperitoneum), whereas aberrant migration results in cells at other extragonadal sites (pineal, sacrococcygeal).

### CLASSIFICATION

Teilum[6] proposed the germ cell origin of gonadal tumors, and the pathway of differentiation is listed in Figure 37-1. Seminoma (or dysgerminoma) is a primitive germ cell tumor that lacks the ability for further differentiation. It is unusual in childhood and occurs most frequently in the mediastinum, pineal gland, and at the gonadal sites during the adolescent years. Embryonal carcinoma is composed of cells capable of further differentiation into embryonic or extraembryonic tumors. Teratomas are the most common germ cell tumor and are composed of elements from one or more of the embryonic germ layers and contain tissue foreign to the anatomic site of origin.[7,8]

Mature and immature teratomas are considered benign lesions. It is, however, imperative to have a thorough and accurate pathologic review, because 25% of germ cell tumors in childhood are mixed tumors with more than one histologic

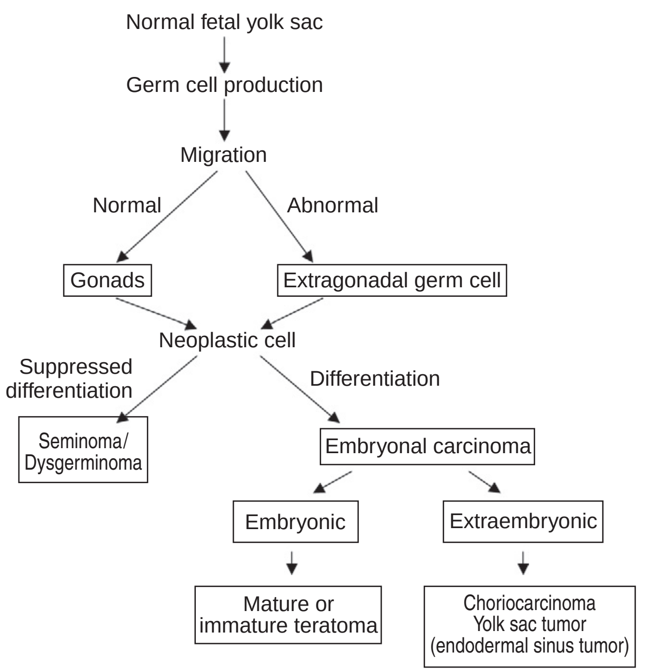

**FIGURE 37-1** Classification system for development of germ cell tumors.

component.[2] Certain sites are more likely to have mixed tumor histology, with ovary (46%) and mediastinal (61%) the most common.[9,10] Mature teratomas contain well-differentiated tissue, whereas immature teratomas contain neuroectoderm and are graded between 1 and 3 based on the number of low-power fields of primitive neuroepithelium.[11] There has been debate about the treatment of immature teratomas. Many adult reports of ovarian tumors have considered grade 3 lesions malignant, and these patients have been treated with chemotherapy. A review of childhood immature teratomas demonstrated an association between high-grade immaturity and the presence of microscopic foci of endodermal sinus tumor,[12] with malignant foci observed in 83% of grade 3 immature teratomas as the only risk factor for recurrence.[13]

Yolk sac tumors (endodermal sinus) and choriocarcinoma are well-differentiated, highly malignant tumors. Yolk sac is the more common histology in childhood and occurs primarily in the sacrococcygeal region, ovary, and prepubertal testes.

# Genetics and Risk Factors

Germ cell tumors demonstrate a bimodal age distribution with peaks at 2 and 20 years of age. Pediatric germ cell tumors differ in several aspects from their adult counterparts. Pediatric yolk sac tumors are more likely to have DNA ploidy, whereas adolescent and adult germ cell tumors are usually aneuploid.[14] In children younger than 4 years of age, the primary malignant germ cell tumor is yolk sac, and these are diploid or tetraploid; the teratomas are diploid with normal karyotypes and are benign.[15–17] Childhood yolk sac tumors have also demonstrated deletion of chromosomes 1p and 6q in 50% of specimens.[18] In addition, a smaller percentage demonstrates amplification of c-*MYC*. The isochromosome i (12p), which is identified in most pubertal or postpubertal testes tumors, is not observed in prepubertal tumors. Gains of 12p have been noted in malignant ovarian germ cell tumors but not in ovarian immature teratomas.[19]

The presence of intersex disorders is a known risk factor for gonadoblastoma, an in-situ germ cell tumor with the ability to differentiate into dysgerminoma, immature teratoma, yolk sac tumor, or choriocarcinoma.[20] One risk group includes testosterone deficiency, androgen insensitivity syndromes, and 5-alpha-reductase deficiency, which are androgen-deficient males. The presence of any portion of a Y chromosome is considered a risk factor in these children.[21] Risk of malignancy in androgen insensitivity is 3.6% at age 20 and 22% at age 30[22]; in view of this, gonadectomy usually in adolescence, is recommended. Gonadal dysgenesis is associated with a risk of malignancy of 10% at age 20 and 19% at age 30.

Undescended testes have an increased risk of malignancy, with the rate highest for intraabdominal testes. Approximately 0.4% of all males have undescended testes, however, it is observed in 3.5 to 12% of the testicular cancer population.[23] One study noted that although intraabdominal testes only account for 14% of undescended testes, they account for nearly 50% of tumors in the undescended testes group. The effect of orchiopexy on the risk of testes cancer is not known, and 20% of the tumors in patients with undescended testis occur in the descended testis.[24] Seminomas occur in a higher percentage of undescended testes (60%) compared with the descended testes tumors (30% to 40%),[25] and one study observed that orchiopexy decreases the incidence of seminoma.[26] The early identification of these children is important, because a recent report noted a 2-year-old boy with a large yolk sac tumor in an intraabdominal testis with lymph node involvement.[27] Surgery and chemotherapy yielded a successful outcome.

# Risk-Based Therapy

The survival of patients with advanced-stage germ cell tumors was poor prior to the introduction of modern chemotherapy, with most survivors having had low-stage surgically excised tumors. Surgery and chemotherapy consisting of vincristine, actinomycin, cyclophosphamide, and doxorubicin was the primary therapy in the 1960s and 1970s.[28] In 1975, Samuels and colleagues[29] introduced bleomycin with vinblastine for advanced-stage testicular tumors, and in 1977, Einhorn and Donohue[3] reported success with cisplatin, vinblastine, and bleomycin in disseminated testicular cancer. This therapy dramatically transformed the treatment of germ cell tumors. Even after the introduction of cisplatin-based regimens, the early results in children were poor. A report from the Children's Cancer Group (CCG) of children treated between 1978 and 1984, using cisplatin and bleomycin alternating with other agents (cyclophosphamide, dactinomycin, and doxorubicin), reported 4-year survival and event-free survival (EFS) of 54% and 49%, respectively, with ovarian tumors higher at 67% and 63%, respectively, and extragonadal tumors at 48% and 42%, respectively.[30] The lower survival in the early study may have been due to the inclusion of less effective chemotherapy that lengthened the intervals between the courses of the more effective cisplatin and bleomycin.

The subsequent CCG/Pediatric Oncology Group (POG) intergroup studies conducted between 1990 and 1996 used only cisplatin, etoposide, and bleomycin (PEB). The overall 6-year survival was 95.7% for stage I and II ovarian and

testes and 88.9% for stage III-IV gonadal and stage I-IV extragonadal.[31–33] The higher-risk group (stage III-IV gonadal and stage I-IV extragonadal) were stratified to either standard or high-dose cisplatin, and the overall survival was not different between the groups, but the toxicity was higher with the high-dose cisplatin, and it has therefore not been incorporated in the current study.

Based on these past studies, the current COG protocol for malignant germ cell tumors is risk based (Fig. 37-2). The overall goal is to maintain the excellent survival from the past intergroup study while decreasing the toxicity of the chemotherapy. Mature teratoma is considered to be a benign lesion, and these tumors are not entered on the current protocol. Immature teratomas at all sites are treated with surgery and observation. The 3-year survival for immature teratomas on the last study was 93% among 73 patients with immature teratoma, and four of the five recurrences were salvaged with platinum-based chemotherapy.[13,34] Stage I ovarian and testes tumors are treated with surgery and observation, although this portion of the protocol is currently suspended (see Ovary section). Stage II-III ovary and stage II-IV testes currently receive three cycles of PEB administered during 3 days compared with four cycles during 5 days on the prior study, thus resulting in significantly less total chemotherapy. Higher-risk tumors (stage IV ovary and stage III-IV extragonadal), are currently not a part of a protocol but would received PEB.

# Testes

## CLINICAL PRESENTATION AND INITIAL EVALUATION

Testicular germ cell tumors in children are one of the rarer germ cell tumor types, with an incidence of 0.5 to 2.0 per 100,000.[35] The bimodal age distribution of testes tumors, with a small peak in the first 3 years of life and a much larger peak in young adults, suggests a difference in the tumors of these age groups. The malignant germ cell tumors in the younger group are predominantly yolk sac tumors, whereas most adolescent and adult testes tumors are seminomas and mixed tumors. Several other factors provide evidence of differences between pediatric and adult testes tumors. Intratubular germ cell neoplasia (ITGCN), which is a carcinoma in situ, is commonly identified in adults with malignant germ cell tumors but does not occur in association with prepubertal yolk sac tumor. Adult testes tumors usually have a chromosomal gain of the short arm of chromosome 12p (isochromosome 12p), whereas this is not seen in prepubertal yolk sac tumors.

Testicular tumors are rare in boys prior to puberty, and during this time non–germ cell Sertoli tumors and paratesticular rhabdomyosarcomas are more common, whereas germ cell tumors predominate in pubertal and adult males. Paratesticular neuroblastoma has also been reported arising from an embryonic adrenal rest along the spermatic cord.[36,37] Although it is difficult to determine the incidence of malignancy in prepubertal testes tumors, several reports would suggest that it is less common than in adults. In one large series,[38] 74% of all tumors were benign, with teratoma accounting for 48% and yolk sac tumors only 5%. This has affected the initial surgical evaluation of these children in order to avoid unnecessary radical orchiectomy.

FIGURE 37-2 Low- and intermediate-risk–based scheme for pediatric germ cell tumors. Children's Oncology Group AGCT 0132, opened November 2003.

Most testicular tumors present as a painless scrotal mass. In the intergroup CCG/POG study (1990 to 1996)[31] of malignant testes tumors, 76% of the stage 1 boys presented with a testicular mass and 17% with generalized scrotal swelling. The preoperative diagnosis was tumor in 79%, hydrocele in 11%, hernia in 3%, and acute scrotum or torsion in 3%.

Preoperative workup includes a thorough physical examination, looking for signs of androgenization as well as metastatic disease. Metastatic disease is relatively uncommon in prepubertal testes cancer, but if present, is usually in the retroperitoneum or chest. Testicular ultrasonography is useful to identify extratesticular lesions and may be useful to identify or raise the suspicion of a teratoma. Benign testes tumors tend to be well circumscribed with sharp borders and decreased blood flow on Doppler studies.[39] Preoperative AFP levels should be obtained, and this level was elevated in 98% of the children with malignant tumors in the most recent study.[31] If the preoperative diagnosis is a testicular malignancy (elevated AFP), it is reasonable to obtain an abdominal computed tomography (CT) scan, because the presence of enlarged nodes after an inguinal exploration can be due to either a reactive or malignant process.

## OPERATIVE MANAGEMENT

The standard approach consists of an inguinal incision, with initial control of the vessels at the level of the internal inguinal ring with subsequent mobilization of the testes. A preoperative elevation of AFP indicates the presence of yolk sac tumor and thus precludes consideration of testes-sparing surgery, and a radical orchiectomy is performed with ligation of the cord at the internal ring. If the AFP is normal, there is a much greater chance that the mass represents a benign lesion, and in these instances, the field can be draped off and the tunica opened. Enucleation is often possible, leaving a large amount of residual normal testes.[40] If frozen section analysis reveals a benign lesion, the tunica is closed, and if malignant, an orchiectomy is completed. Unfortunately, this is not always possible, and in a recent review from the U.K. Children's Cancer Group, 48 of 53 boys with mature or immature teratoma had radical orchiectomy.[41] There were no recurrences in the five treated with enucleation. Bilateral testes-sparing surgery

| Stage | Extent of disease |
|---|---|
| I | Limited to testis (testes), completely resected by high inguinal orchiectomy; no clinical, radiographic or histologic evidence of disease beyond the testes. |
| II | Transscrotal biopsy; microscopic disease in scrotum or high in spermatic cord (<5 cm from proximal end). Tumor markers fail to normalize or decrease with an appropriate half-life. |
| III | Retroperitoneal lymph node involvement, but no visceral or extraabdominal involvement. Lymph nodes > 4 cm by CT; or > 2 cm and < 4 cm with biopsy proof. |
| IV | Distant metastases, including liver. |

**FIGURE 37-3** Current Children's Oncology Group staging system for childhood testes cancer.

has been reported for testes teratoma.[42] A more recent report noted no atrophy or recurrence with enucleation in a large group of benign testes tumors.[43]

## POSTSURGICAL TREATMENT

Testicular teratomas are benign lesions and are treated with enucleation, if possible, and then postoperative observation. Testicular immature teratomas are also benign germ cell tumors, and surgery alone (enucleation if possible) is definitive treatment. Higher-grade immature teratomas are, however, associated with yolk sac tumors. In a (CCG/POG) review, grade 1 and 2 immature teratomas were not associated with yolk sac tumors, whereas 2 of 3 grade 3 lesions were associated with yolk sac tumors.[13]

Yolk sac tumor is the primary malignant prepubertal testes cancer. The current staging is noted in Fig. 37-3. The role of surgery alone for stage I testes tumors was reported in the 1980s[44] and confirmed in an initial small series.[45] The U.K. Children's Cancer Study Group[46] and the Testicular Tumor Registry of the Section of Urology of the American Academy of Pediatrics,[47] in larger series (73 and 181 children, respectively), confirmed the safety of surgery alone for stage I malignant testes tumors.

The intergroup trial of testes cancer (CCG/POG; 1990–1996)[31] confirmed the excellent outcome with stage 1 testes tumors treated with surgery alone (Table 37-1). This study of 63 boys (median age 16 months) reported AFP elevation in 98%. In patients with the preoperative diagnosis of tumor, the surgical guidelines were followed in 84% of boys but were followed in only 27% with a nontumor diagnosis. Although overall adherence to surgical guidelines did not affect outcome, scrotal violation was associated with a 75% recurrence rate compared with 15.5% in those without scrotal violation. All recurrences were successfully treated with surgery and chemotherapy.

Stage 2 boys on the CCG/POG study included only 17 patients, and 11 were stage II because of a transcrotal procedure.[32] Survival was excellent (see Table 37-1) with surgery and chemotherapy. Higher-stage 3 and 4 boys received surgery and were then randomized to standard or high-dose cisplatin, both with etoposide and bleomycin.[33] Sixteen were recurrences from stage 1 disease (median age 3.1 years), and the rest were newly diagnosed and much older (median age 16 years). Despite the advanced disease, outcome was

excellent (see Table 37-1). The toxicity with high-dose cisplatin was significant without added benefit, and it has therefore been eliminated from current protocols.

The current protocol of the Children's Oncology Group is designed to reduce the total dose and days of chemotherapy (Fig. 37-2). As noted in the staging, if the retroperitoneal nodes are greater than 4 cm in size, it is assumed to be due to tumor, whereas nodes between 2 and 4 cm require biopsy to confirm status. There is no role for retroperitoneal lymph node dissection in prepubertal yolk sac tumors at diagnosis and simple biopsy is adequate.

# Ovary

## CLINICAL PRESENTATION AND EVALUATION

Ovarian tumors are the most common site for germ cell tumors in children and adolescents. Eighty to 90% percent of all ovarian masses are benign (epithelial cyst, mature teratoma), often with predominant cystic components.[10,48] Presenting symptoms often include pain and gradual onset of lower abdominal fullness. Approximately 10% present with an acute abdomen secondary to torsion or tumor rupture.[10] Of all girls presenting with ovarian torsion, only 1.8% to 3% are malignant tumors; however, 33% are benign tumors, including teratoma and cystadenoma.[48]

In nonacute cases, preoperative evaluation should include assessment of AFP and beta-HCG, as well as ultrasonography and usually abdominal and pelvic CT scan. Unfortunately, reliable tumor markers are absent in many tumors. Germinoma is present in one third of malignant tumors, and they have normal markers or mild elevation of beta-HCG, and embryonal carcinomas have normal markers.[2] Benign lesions are primarily cystic, and a 2% risk of malignancy in cystic lesions is frequently quoted based on adult series.[49–51] This, however, is also unreliable, because in the recent intergroup study from the Children's Oncology Group (COG), 57% of malignant tumors had cystic components.[10] A recent study attempting to identify risk factors noted that markers were elevated in only 54% of malignant tumors. The best predictors were a mass with solid characteristics and a mass greater than 8 cm in diameter.[52] They also noted as, in other series, that girls between 1 and 8 years have the greatest incidence of malignancy. In view of these observations, great care should be taken to perform a proper staging operation with lesions with solid components.

1. Collect ascites or peritoneal washings for cytology
2. Examine peritoneal surface and liver; excise suspicious lesions
3. Unilateral oophorectomy
4. Examine contralateral ovary and biopsy if suspicious lesion
5. Examine omentum and remove if adherent or involved
6. Inspection of retroperitoneal lymph nodes, biopsy of enlarged nodes

**FIGURE 37-4** Operative procedure for malignant ovarian germ cell tumor.

**Stage I:** Limited to ovary (ovaries) peritoneal washings negative; tumor markers normal after appropriate half-life decline (AFP 5 days, HCG 16 hours).

**Stage II:** Microscopic residual; peritoneal washings negative for malignant cells, tumor markers positive or negative.

**Stage III:** Lymph node involvement; gross residual or biopsy only; contiguous visceral involvement (omentum, intestine, bladder); peritoneal washings positive for malignant cells; tumor markers positive or negative.

**Stage IV:** Distant metastases, including liver.

**FIGURE 37-5** Children's Oncology Group ovarian staging system. AFP, alpha fetoprotein; HCG, human chorionic gonadotropin.

The staging procedure endorsed by COG is listed in Figure 37-4 and the current staging system in Figure 37-5. The importance of an accurate and complete staging procedure and accurate pathologic evaluation cannot be overemphasized. The recent COG intergroup study of 131 girls reported positive ascites/peritoneal fluid in 23 of 100 girls, and 5 of these would have otherwise been stage I tumors.[10] This is particularly relevant, because the current low- and intermediate-risk COG study manages stage I girls with surgery alone.

The survival rates of children in the most recent intergroup study is listed in Table 37-2. The current therapy for ovarian malignant tumors is noted in Figure 37-2. In the most recent study,[33] the results for stage IV ovarian tumors did not allow them to be included in the current low- and intermediate-risk COG study (AGCT 0132) using reduced chemotherapy.

Some tumors are noted with invasion into surrounding structures, and in these cases, recommendations are for initial biopsy, neoadjuvant chemotherapy, and delayed resection. Bilateral ovarian tumors were observed in 8% of girls on the recent study, and 4 of the 11 contralateral tumors were benign teratomas. The current recommendation for bilateral tumors is to attempt ovarian preservation, if possible, on the least involved side, attempting to find a plane of demarcation between the tumor and normal ovarian tissue. The larger tumor should be removed and sent for frozen section. If the first side is malignant and the contralateral side is greater than 10 cm, it should also be removed.

The treatment algorithm for malignant ovarian tumors is surgery and observation for stage I and surgery and chemotherapy for higher-stage tumors (see Fig. 37-2). The surgery-only arm was based on a German and French series of a total of 39 girls with stage I tumors treated with surgery alone who experience a 67% EFS with salvage of 12 of 13 recurrences with chemotherapy for an overall survival of 97.4%.[53,54] The CCG/POG intergroup study noted excellent results in girls with stage I immature teratoma, with microscopic yolk sac tumor

**TABLE 37-2**
**Event-free Survival (EFS) and Survival in Pediatric Ovarian Germ Cell Tumors, POG/COG Intergroup Study 1990-1996**

| *Stage* | N | *Treatment* | *6-Year EFS (%)* | *6-Year Survival (%)* |
|---|---|---|---|---|
| I | 41 | S + PEB | 95 | 95.1 |
| II | 16 | S + PEB | 87.5 | 93.8 |
| III | 58 | S + HDP/EB vs. PEB | 96.6 | 97.3 |
| IV | 16 | S + HDP/EB vs. PEB | 86.7 | 93.3 |

treated with surgery alone as well as stage I girls treated with surgery and PEB.[55] The current low-risk arm of the study has been closed because of a higher than expected recurrence rate in stage I ovarian tumors. These girls had a less than 70% three-year EFS, thus leading to suspension of the trial; however, with salvage chemotherapy, they have an overall survival of over 95%.[56]

Laparoscopy has been widely used for ovarian cystic disease, and the application of this for malignant procedures has been controversial. The primary concern is adequate completion of the staging procedure (potential understaging) and avoidance of intraperitoneal spill or tumor rupture, which could upstage a stage I to a stage II tumor. The COG germ cell committee and others[10,57] recommend laparotomy for known malignancy; however, this is difficult to determine preoperatively, although preoperative elevated markers and a large solid mass are very suggestive of malignancy. A recent French study suggested that size greater than 7.5 cm or predominately solid components predicted malignancy and thus required laparotomy.[57]

Most primarily cystic lesions, some of which are large, are benign, and a laparoscopic approach is appropriate. One option to avoid spill is to either excise the cyst, as a cystectomy or oophorectomy, and then place it in a retrieval bag, which is then delivered out of the umbilical opening, allowing decompression of the cyst while in the bag without spill and then removal of the bag and cyst. A second option is to glue a bag to the cyst through a small laparotomy, using one of the adhesives, such as cyanoacrylate, as described by Shozu and colleagues.[58] The cyst is incised by cutting through the center of the bag–cyst interface, allowing removal of the fluid without spill, and the decompressed cyst is then delivered from the abdominal cavity. The cyst can then be separated from the normal ovary as a cystectomy, or if not possible or if there is concern for malignancy, an oophorectomy.

# Sacrococcygeal Tumors

## CLINICAL PRESENTATION AND INITIAL EVALUATION

Tumors of the sacrococcygeal region, referred to as sacrococcygeal teratomas (SCTs) in most reports, generally present in two distinct fashions: neonates with large predominantly external lesions, which are detected in utero or at birth and are rarely malignant (Fig. 37-6); and older infants and children

who present with primarily hidden pelvic tumors with a much higher rate of malignancy (Fig. 37-7). Sacrococcygeal teratomas are the most common extragonadal tumor in neonates, accounting for up to 70% of all teratomas in childhood. A 3 to 4:1 female to male ratio is generally reported.[59] Newborns typically present with a mass protruding from the sacral region, and many are detected with prenatal ultrasonography. Abdominal delivery should be considered if the external mass is greater than 5 cm, to avoid dystocia and rupture.[60] In-utero shunting can lead to fetal hydrops, which is associated with high mortality. Adzick and colleagues[61] performed the first successful fetal resection in a fetus that developed placentomegaly and polyhydramnios and, at 25 weeks, underwent

FIGURE 37-6 A newborn with a large ruptured sacrococcygeal teratoma.

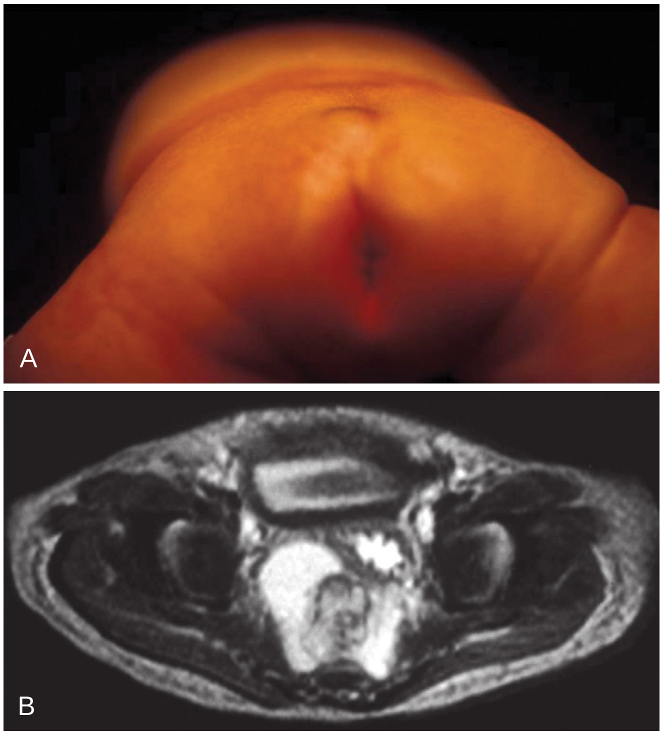

FIGURE 37-7 **A,** Three-month-old boy with a small external mass noted since birth. **B,** Underlying presacral mass noted on magnetic resonance imaging.

fetal resection of a 400-g immature teratoma. After delivery at 29 weeks, the child underwent exploration, with no residual tumor identified.

Makin and colleagues[62] reported a 77% survival among 41 antenatally diagnosed SCTs but noted survival of 50% in those undergoing fetal interventions and survival of only 14% if the intervention was for hydrops. Intervention included nonresection procedures, such as cyst drainage, laser ablation, or alcohol sclerosis. Another study of prenatally detected lesions noted the highest survival (100%) in lesions less than 10 cm with predominantly cystic tumors, whereas survival was only 48% in tumors greater than 10 cm and in those with increased vascularity, vascular steal syndrome, or rapid growth.[63] This is a difficult group, and the University of California San Francisco experience with fetal resection noted a survival of 20%.[64]

Older infants and children typically present with symptoms related to compression of the bladder or rectum. If a mass has been noted at birth and left in place, an increased rate of malignancy has been noted.[65] AFP levels, which can be normally elevated in newborns, should be obtained and then followed to ensure that they return to normal by 9 months of age. An association of the triad of presacral teratoma, anal stenosis, and sacral defects was first reported by Ashcraft and Holder, who also confirmed the autosomal dominant nature of the condition.[66] Currarino proposed that adhesions between the endoderm and ectoderm form, causing a split notochord that results in this association, and the triad now bears his name.[67]

## CLASSIFICATION AND ASSOCIATION WITH MALIGNANCY

Altman and colleagues[68] developed the classification system of SCTs based on a survey of the Surgical Section of the American Academy of Pediatrics (Fig. 37-8). In this study, the malignancy rate increased with the more hidden (type III and IV) lesions. This survey also noted the low rate of malignancy in neonates and young infants ($\leq$2 months of age, 7% girls and 10% boys have malignant tumors) and the higher rates in older infants and children ($\geq$2 months of age, 48% girls and 67% boys have malignant tumors). Several subsequent studies have confirmed this and noted malignancy rates as high as 90%.[65,69]

## SURGICAL MANAGEMENT

In neonates presenting with large external masses, the degree of pelvic and abdominal involvement should be assessed preoperatively with either ultrasonography, CT, or magnetic resonance imaging (MRI), and these studies may also offer a clue as to the characteristics of the vascular supply. An open or laparoscopic abdominal exploration may be required to mobilize the pelvic portion and to divide the middle sacral artery.

The neonatal type I and II lesions can usually be approached with the child in the prone position (Fig. 37-9). Removal of the coccyx is an essential step, because Gross and colleagues[70] reported a 37% recurrence rate if it was not removed. In view of the anterior displacement caused by the large mass, the rectum is often brought back to a more posterior location at the time of closure. Fishman and colleagues[71] described a buttocks contouring closure bringing

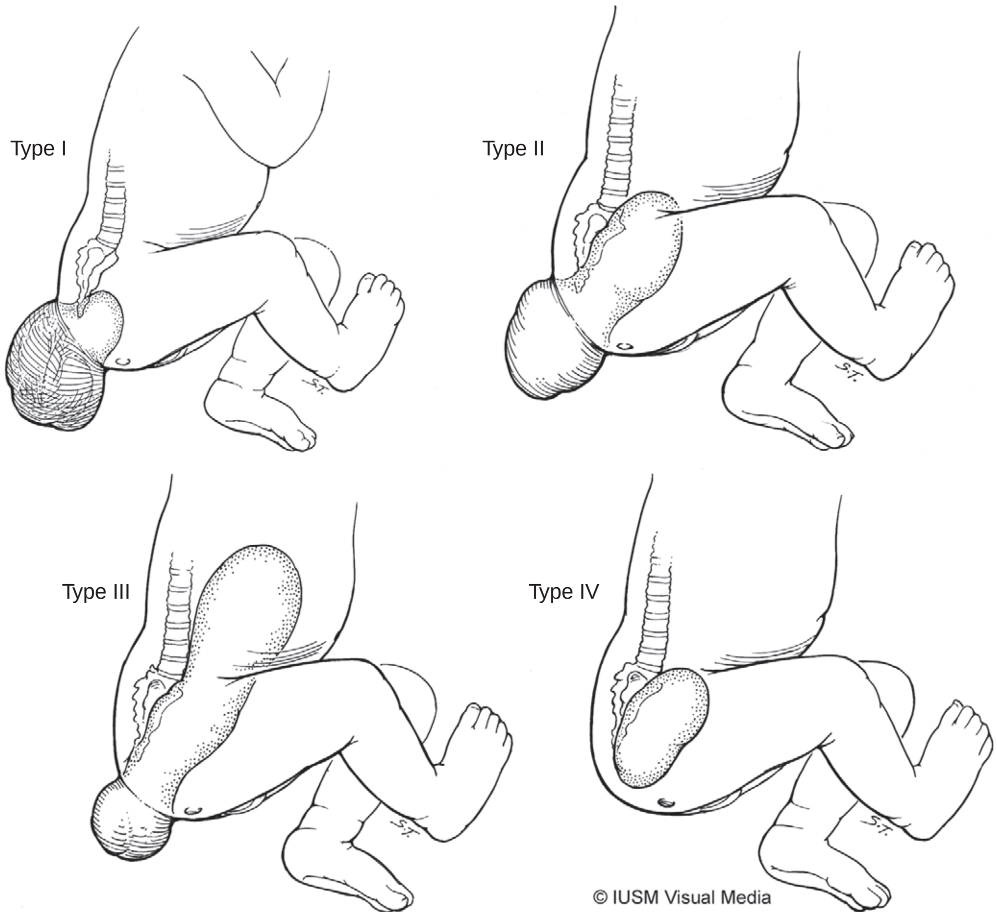

**FIGURE 37-8** Classification of sacrococcygeal teratomas based on Altman's study: Type I (46.7% of reported cases) predominantly external, type II (34.7%) external with intrapelvic extension, type III (8.8%) visible externally but predominantly pelvic and abdominal, type IV (9.8%) entirely presacral. (Adapted from Altman RP, Randolph JG, Lilly JR: Sacrococcygeal teratoma: American Academy of Pediatric Surgical Section Survey—1973. J Pediatr Surg 1974;9:389-398.)

the ventral portion of the lateral flaps to a more central posterior location, thus resulting in a transverse posterior incision and two vertical incisions in the midportion of each buttock. The operative approach in older infants and children is similar; however, due to the presence of malignancy in many of these cases with invasion of adjacent structures or massive size, initial resection is not possible, and an initial biopsy followed by neoadjuvant chemotherapy is the best mode of management (Fig. 37-10). In the CCG/POG Intergroup study, there was no survival difference between initial and delayed rejections, supporting surgical delay in these cases.[72]

## POSTOPERATIVE MANAGEMENT

The staging system for extragonadal tumors is noted in Figure 37-11. Most neonatal tumors are mature or immature teratomas that can be managed by surgery and postoperative observation. Recurrent tumors are noted in 10% to 20% of initially benign tumors, and 50% of these are malignant recurrences.[65,73] The recurrence may be due to a sampling error of the original tumor, incomplete resection of a malignant focus, or transformation of a small benign remnant into a malignant lesion. The large size of the neonatal tumors and frequent cystic components can often result in rupture during resection. Follow-up of these neonates should include serial AFP levels to ensure return to normal by 9 months of age and rectal examination every 3 months until 3 years of age, because the latest reported recurrence has been at 33 months.[65]

The management of the older infants with malignant tumors has been influenced by the chemosensitive nature of these yolk sac tumors. In the intergroup study of 74 infants and children (median age 21 months; 62 girls, 12 boys), 59% had metastatic disease at diagnosis, and the initial procedure was biopsy in 45 patients and resection in 29 patients.[72] All patients received chemotherapy, and postchemotherapy resection was accomplished in all but three patients. Definitive resection required a sacral approach in 63% and a combined abdominal-sacral approach in 35%. The 4-year EFS and survival was 84 ± 6% and 90 ± 4%, respectively, with no significant difference noted between timing of resection or presence of metastatic disease. In view of these results, it is strongly recommended to avoid resection of normal structures at initial exploration.

Long-term follow-up of the newborns and older children is necessary, because neuropathic bladder or bowel abnormalities have been reported in 35% to 41% of survivors.[74,75] A recent report from the U.K. Children's Cancer Group noted that 10 of 95 survivors of sacrococcygeal tumors had a neuropathic bladder, and two had leg weakness.[41] In a large survey of

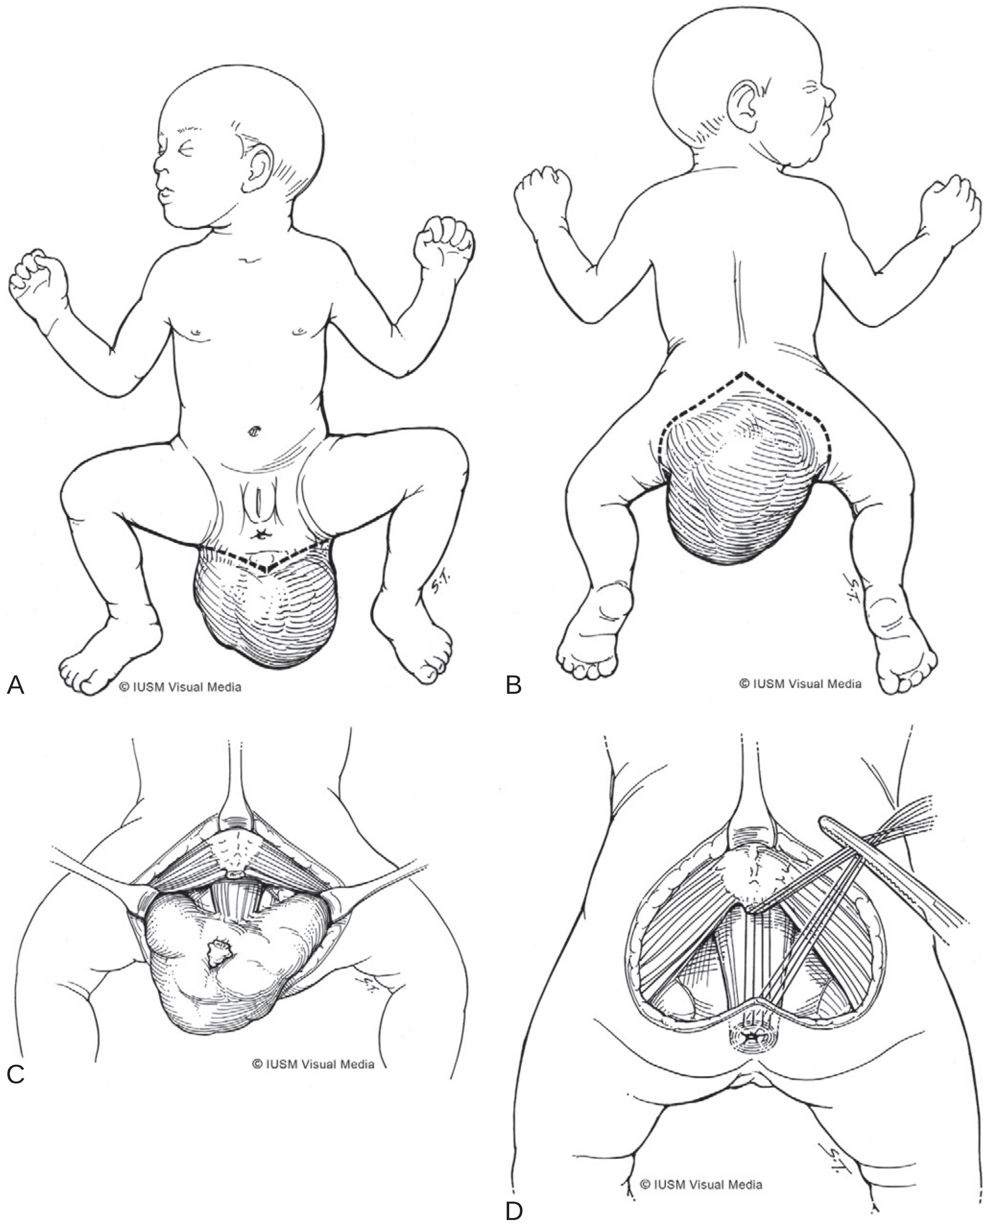

**FIGURE 37-9** **A** and **B,** Operative excision of sacrococcygeal teratoma in a neonate with an inverted-V incision. **C** and **D,** The tumor along with the coccyx is excised with careful preservation of the rectum.

79 patients from the Netherlands, 9.2% reported involuntary bowel movements, 13.2% suffered from soiling, 16% had constipation, and 30% reported difficulty with urinary control,[76] with all of these correlating with decline in their quality of life. Interestingly, the Altman classification of the tumor did not correlate with the occurrence of these long-term complications.

## Mediastinal Germ Cell Tumors

Mediastinal tumors are relatively common in childhood and adolescence and are more common in boys than girls. Germ cell tumors compromise approximately 6% to 18% of mediastinal tumors,[77] and of these, 86% are benign.[78] Mediastinal germ cell tumors are typically located in the anterior mediastinum. Younger children present predominantly with respiratory symptoms. The most common symptoms during adolescence include chest pain, precocious puberty, or facial fullness related to superior vena caval obstruction. Klinefelter's syndrome is also observed in the adolescent group as are hematologic malignancies. The histology of the malignant mediastinal germ cell tumors is more heterogeneous than other sites. In the intergroup study of 38 children, yolk sac was seen in boys less than 5 years of age and in all girls; the older boys had mixed malignant tumors in greater than 50%.[9] Reflective of this, the AFP was elevated in 29 cases and beta-HCG in 16 cases.

Anterior mediastinal tumors pose significant anesthetic risks because of airway compression and may affect the anesthetic from compression as well as the weight of the tumor,

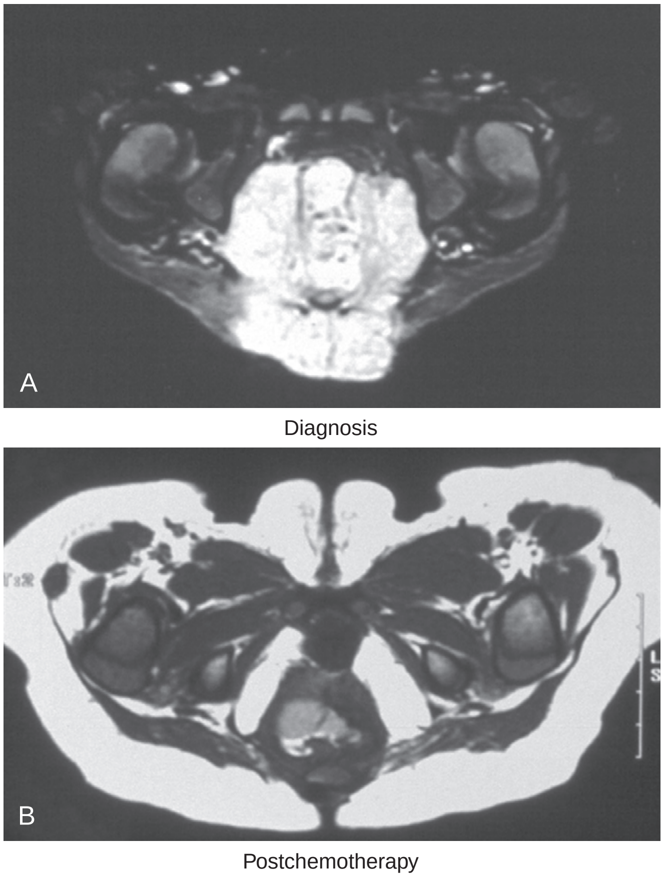

**FIGURE 37-10** **A,** Appearance of a large unresectable malignant yolk sac tumor treated with biopsy and neoadjuvant chemotherapy. **B,** Residual postchemotherapy tumor.

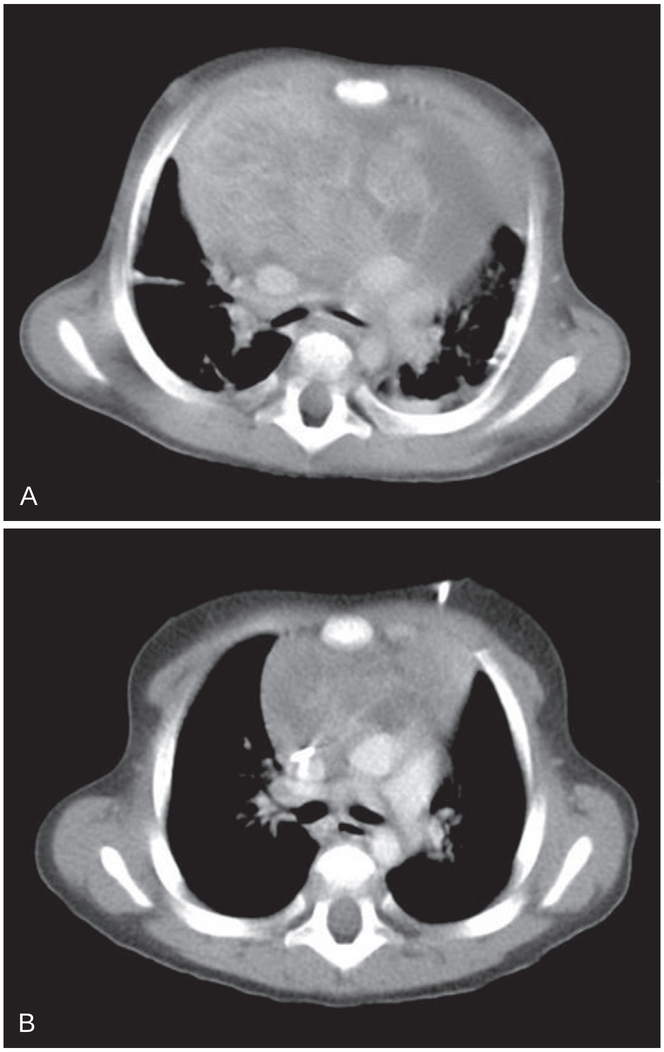

**FIGURE 37-12** **A,** Appearance of a large mediastinal mass causing tracheal compression and cardiac displacement. **B,** Appearance after neoadjuvant chemotherapy.

leading to further compression with loss of spontaneous ventilation. An early report suggested increased risk of respiratory collapse upon induction of anesthesia if the trachea was compressed by one third of the cross-sectional area.[79] Shamberger and colleagues,[80] added pulmonary function tests and observed that general anesthesia was well tolerated if both the tracheal area and the peak expiratory flow rate were greater than 50% of predicted. Alternatives to general anesthesia for diagnostic procedures in children in these situations include aspiration of pleural fluid and needle biopsy or open biopsy under local anesthesia. Open biopsy can be performed using an anterior thoracotomy (Chamberlin procedure) with excision of a segment of costal cartilage.[81]

**Extragonadal germ cell tumors:**

| Stage | Extent of disease |
|---|---|
| I | Complete resection at any site, coccygectomy for sacrococcygeal site, negative tumor margins. |
| II | Microscopic residual: lymph nodes negative. |
| III | Lymph node involvement with metastatic disease. Gross residual or biopsy only; retroperitoneal nodes negative or positive. |
| IV | Distant metastases, including liver. |

**FIGURE 37-11** Staging system for extragonadal germ cell tumors.

In the intergroup study ($N = 38$) 14 children underwent initial resection, with 12 survivors.[9] Twenty-two patients underwent biopsy followed by neoadjuvant chemotherapy and subsequent resection in 18, with 13 survivors. The size of the mass was reduced by a mean of 57% in 12 of the patients and was stable or increased in 6 (Fig. 37-12). Four patients had no further surgery, because of complete radiographic resolution in 1, progressive disease in 1, and death from toxicity in 2. Eight of 10 image-guided biopsies were successful. Of 31 resections, 20 were by median sternotomy and 11 by thoracotomy. Excision was frequently reported as difficult because of adherence to the major arteries and veins as well as the phrenic and vagus nerves and the lung and thymus. The overall survival was 71%, which is higher than the historical series but lower than survivals reported for the other extragonadal sites. The outcome was superior

in the patients with yolk sac tumors, and all of the tumor deaths were noted in adolescent boys with mixed germ cell tumors.

## Abdominal and Retroperitoneal Germ Cell Tumors

Retroperitoneal and abdominal germ cell tumors account for approximately 4% of germ cell tumors in children. Most present in infancy, although several have been indentified antenatally.[82] Eighty percent were less than 5 years of age in the recent intergroup (CCG/POG) study.[83] Mass and pain are the most common presenting symptoms, but fever, weight loss, constipation, and acute abdomen are also reported. An unusual group within this cohort are the infants with choriocarcinoma, which are thought to be primary placental tumors with metastases to the fetal liver. The beta-HCG production can lead to precocious puberty, and these infants usually present with hepatomegaly and anemia in the first 7 months of life.

Most retroperitoneal germ cell tumors are mature and immature teratomas; reports have noted malignancy rates between 0% and 24%, with the highest percentage occurring in infants.[82,84–87] The histologic pattern of the malignant tumors is most commonly pure yolk sac (63%), but also includes choriocarcinoma and mixed tumors. In the intergroup study,[83] 19 of 24 of the malignant tumors had elevated AFP, indicating yolk sac components were present but also illustrating the difficulty of determining malignancy preoperatively. Prior to attempting resection, a search for metastatic disease is appropriate, because nearly 90% of those with malignancy have stage III or IV disease at presentation.[83]

Primary resection should be attempted if preoperative imaging suggests lack of contiguous organ involvement or metastatic disease. Unfortunately, the benign tumors can also encase blood vessels, and the hazardous nature of these operations was demonstrated by two recent reports about several major vascular, biliary, and intestinal injuries.[82,86] In the intergroup study of 25 children, only 5 underwent initial resection, 13 had resection after chemotherapy and biopsy, or there was partial resection in 7.[83] Of note, 4 had no residual tumor after chemotherapy. The outcome with modern chemotherapy has dramatically improved the outcomes of children with these lesions from a historical survival of less than 20%[59] to current 6-year EFS of $82.8 \pm 10.9\%$ and overall survival of $87.6 \pm 9.3\%$.[83] There are other rare abdominal sites that may present later in life, and yolk sac tumors of the pelvis and uterus have been reported in adult patients.[88–90]

## Genital (Vaginal) Germ Cell Tumors

Genital lesions are rare and most commonly involve the vagina in girls. Although early reports of surgery alone reported survival rates of 50%, survival has improved with the addition of platinum-based adjuvant chemotherapy.[91,92] Vaginal lesions generally occur in girls less than 3 years of age who usually present with vaginal bleeding. A mass is typically identified within and often protruding from the vagina and uterus, and the actual site of origin may be difficult to ascertain. The CCG/POG report of 13 genital lesions (12 vaginal, 1 penile) confirmed the efficacy of platinum-based chemotherapy administered in a neoadjuvant fashion, with ultimate preservation of the vagina in 10 of 12 girls.[93] This is best accomplished by initial biopsy, followed by chemotherapy, and subsequent excision of the residual tumor, with the goal of partial vaginectomy. Although there is no role for initial total vaginectomy or hysterectomy, this rarely may be required in chemoresistant cases.

## Cervicofacial Teratomas

This rare site accounts for 5% to 6% of teratomas, which generally present in the neonatal period with large tumors. Most are mature or immature teratomas, but up to 20% are malignant.[94] A review of 20 neonates noted that 35% presented with airway obstruction.[94] A more recent report of seven giant fetal cervical teratomas observed that four developed hydrops (two died, one aborted), with one undergoing fetal resection.[95] Three neonates without hydrops underwent ex utero intrapartum treatment (EXIT) with intubation, tracheostomy, and resection on placental support in one each. If there is no evidence of hydrops, these can be followed to term. If the fetus is sufficiently mature ($\geq$28 weeks) and hydrops is present, the fetus can undergo delivery; however, if the gestational age is less than 28 weeks, fetal resection should be considered.[95]

## Gastric Teratomas

Tumors at this location generally present within the first few months of life with abdominal distention, bleeding, or symptoms of gastric outlet obstruction because of the gastric mass.[96] We have seen older children present with pain and obstructive symptoms as a primary cystic component has enlarged. These tumors occur primarily in males, and there are no reported malignancies at this site. Resection with primary closure of the stomach is the treatment of choice.

CHAPTER 38

# Hodgkin Lymphoma and Non-Hodgkin Lymphoma

Peter F. Ehrlich

## Hodgkin Lymphoma

Hodgkin lymphoma (HL) is one of the few cancers that affect both adults and children with a wide spectrum of histopathologic and clinical presentations. Unlike many other cancers, the adult and pediatric forms have similar biology and natural history. Pediatric HL accounts for 12% of all HL cases and represents 6% of all childhood cancers. Cure rates for pediatric HL are excellent, approaching 90% to 95% (Fig. 38-1).[1,2] Despite these excellent rates of cure, treatment can result in significant short-term and long-term morbidity. The aims of current therapeutic trials are to maintain or improve on outcomes while reducing short-term and long-term complications of therapy.[3]

Hodgkin lymphoma is named after Thomas Hodgkin, a British pathologist, who in 1832 described the disease in a paper titled *On Some Morbid Appearances of the Absorbent Glands and Spleen.*[4] One hundred and fifty years later, with the advent of microscopic histology, Sternberg (1898) and Reed (1902) described the distinctive multinucleated giant cell with the prominent nucleoli that are characteristic of Hodgkin disease (HD) (Fig. 38-2). They showed that these cells, now referred to as Reed-Sternberg cells, are derived from germinal center B cells.[5,6] Radiotherapy was the first reported "curative" treatment for HL in the 1930s.[7] In 1950, Peters published the first long-term series of survivors (20 years) treated with radiotherapy.[8] Single-agent chemotherapy (nitrogen mustard) was used to treat HL in 1946, and multiagent treatment with MOPP (Mustargen [mechlorethamine], Oncovin [vincristine], procarbazine, prednisone) was reported in 1967.[9,10] In the 1960s, the staging laparotomy was increasingly used to identify sites of involvement and for research purposes.[11] In the 1980s, oncologists began to appreciate the long-term morbidity of the chemotherapy and radiotherapy regimens used to treat patients with HL. Thus multimodality therapy designed to maintain outcomes while reducing toxicity were initiated. Currently, biologically based therapies, both immunotherapy and small molecules, are being investigated for use as primary and relapse therapy.

### INCIDENCE AND EPIDEMIOLOGY

Hodgkin lymphoma accounts for 6% of all pediatric malignancies, with an incidence of about 6 cases per 1 million, with a bimodal distribution with peaks in adolescence (15 to 19 years) and after age 55 years. HL is exceedingly rare in children less than 5 years of age.[12] Epidemiologic studies identify three forms of HL: two that involve the pediatric population and one in adults. Childhood HL is found in children less than 14 years old and accounts for 10% to 12% of cases; adolescent young adults (AYA) HL is defined as occurring in those 15 to 35 years of age and accounts for greater than 50% of the cases. It is the most commonly diagnosed cancer among adolescents 15 to 19 years of age. Older adults HL occurs in those older than 55 years of age and comprises 35% of the cases.[13]

Childhood HL is more common in males, and the histology is more likely to be mixed cellularity or nodular lymphocyte predominant. Risk factors include increasing family size, lower socioeconomic status, and exposure to the Epstein-Barr virus (EBV).[14–17] The EBV viral infection appears to precede tumor cell expansion, and EBV may act alone or in conjunction with other carcinogens.

The AYA form has no gender predilection, and the most common form is nodular sclerosis. Risk factors include higher socioeconomic status, early birth order, smaller family size, and EBV. In the AYA forms, it is hypothesized that EBV exposure is delayed (as opposed to the childhood form), suggesting that delayed exposure to EBV or some other unidentified common infectious agent may be a risk factor for AYA HL.[16–19]

Hodgkin lymphoma is derived from a single transformed B cell that has undergone monoclonal expansion. Classic cells include Reed-Sternberg, lymphocytic, and histiocytic cells. There are also many cytokine-producing and cytokine-responding cells that are responsible for the nonspecific signs and symptoms seen with this tumor. Immune system dysfunction is hypothesized to be one of the primary causes for Hodgkin lymphoma. In the childhood form, it is thought to result from immune immaturity, whereas in the adult form, it is thought to result from immune dysregulation. Support for this hypothesis is found in diseases with altered immune states in which an increased incidence of HL is seen, including

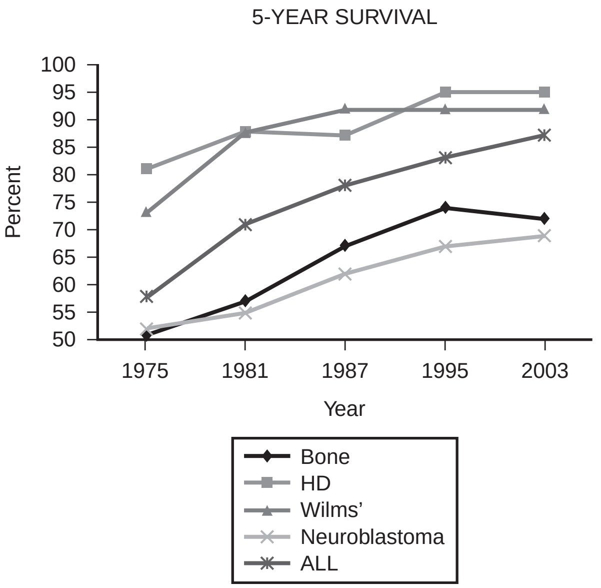

**FIGURE 38-1** Graph shows survival statistics of different pediatric cancers from 1975 to 2003.

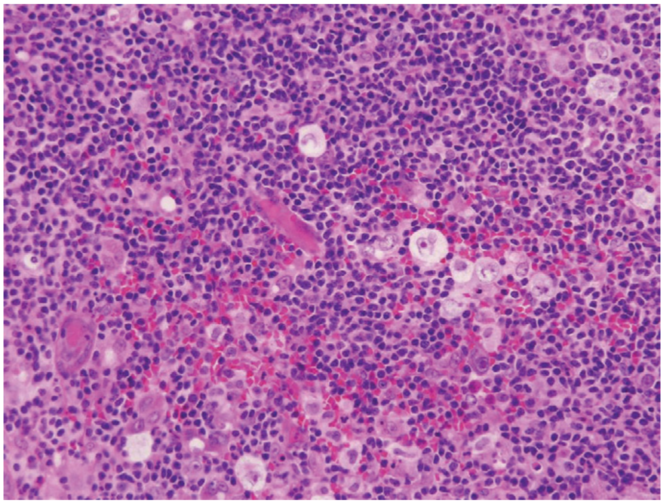

**FIGURE 38-2** High-power hematoxylin and eosin–stained slide of a patient with nodular sclerosis Hodgkin lymphoma with typical Reed-Sternberg cells.

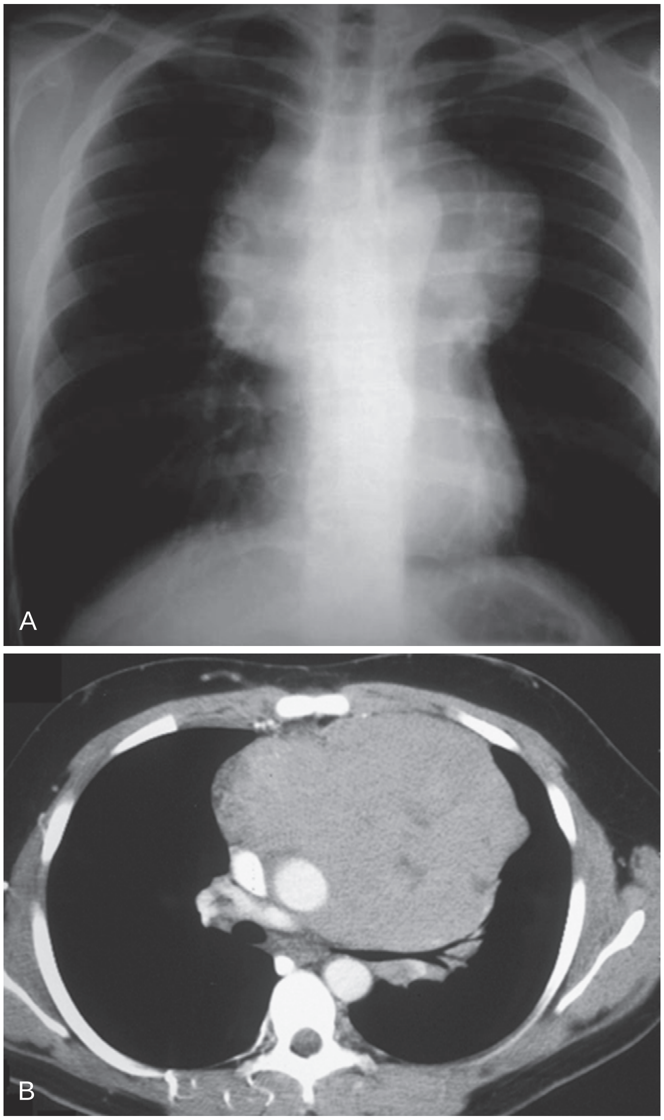

**FIGURE 38-3** **A,** Chest radiograph demonstrating a large anterior mediastinal mass. **B,** Computed tomography scan demonstrating a large anterior mediastinal mass.

patients with human immunodeficiency viral infection, other acquired immunodeficiency states (post–solid organ or hematopoietic stem cell transplantation), and autoimmune disorders or a family history of autoimmune disorders.[20–24]

## CLINICAL PRESENTATION

Hodgkin lymphoma must be considered in any child with lymphadenopathy. Involved nodes are described as firm, nodular, and painless. Children and adolescents most frequently present with cervical and or supraclavicular lymphadenopathy (80%). Patients presenting primarily with enlarged axillary nodes (25% of all cases) or inguinal nodes (5%) are far less common. Associated mediastinal disease is found in up to 75% of adolescents and 33% of children.[13,25–27] Mediastinal involvement must be assessed prior to any operative intervention; involvement may be extensive and produce major complications upon the induction of anesthesia (Fig. 38-3) Patient's may also present with B symptoms, including fever greater than 38° C, soaking night sweats, and weight loss of 10% or more. These symptoms are not specific to HL and can occur in non-Hodgkin lymphoma. The presence or absence of B symptoms, which occur in up to a third of children, has prognostic significance and is reflected in the staging of HL.[13,25] Respiratory symptoms may also result from large mediastinal masses, including dyspnea on exertion or orthopnea. Itching or pruritus is a frequent finding but is nonspecific.[28]

## DIAGNOSIS

A full history and physical examination focusing on nodal areas and the abdomen should be performed. At present there is no specific laboratory test for HL. An excisional biopsy of a suspicious lymph node should be the initial step to diagnosis

**TABLE 38-1**
**Hodgkin Lymphoma Staging: Ann Arbor Classification with Cotswolds Modification**

| | |
|---|---|
| Stage 1 | Involvement of a single lymph node region or lymphoid structure (e.g., spleen, thymus, Waldeyer ring) or involvement of a single extralymphatic site |
| Stage II | Involvement of two or more lymph node regions on the same side of the diaphragm |
| Stage III III1 III2 | Indicates that the cancer has spread to both sides of the diaphragm, including one organ or area near the lymph nodes or the spleen<br>With or without involvement of splenic, hilar, celiac, or portal nodes With involvement of paraaortic, iliac, and mesenteric nodes |
| Stage IV | Indicates that the cancer has spread to both sides of the diaphragm, including one organ or area near the lymph nodes or the spleen |

Modifiers:
*A* or *B:* The absence of constitutional (B-type) symptoms is denoted by adding an "A" to the stage; the presence is denoted by adding a "B" to the stage.
*E:* Used if the disease is "extranodal" (not in the lymph nodes) or has spread from lymph nodes to adjacent tissue.
*X:* Used if the largest deposit is greater than 10 cm large (bulky disease), or whether the mediastinum is wider than one third of the chest on a chest x-ray.
*S:* Used if the disease has spread to the spleen.
The nature of the staging is (occasionally) expressed with:
*CS:* Clinical stage as obtained by doctor's examinations and tests.
*PS*: Pathologic stage as obtained by exploratory laparotomy (surgery performed through an abdominal incision) with splenectomy (surgical removal of the spleen). Note: Exploratory laparotomy has fallen out of favor for lymphoma staging.

of Hodgkin lymphoma. Prior to surgery, a chest radiograph must be obtained to assess the presence of mediastinal disease. If a mediastinal mass is detected, a computed tomography (CT) scan of the chest is mandated to assess the tracheal area, and pulmonary function tests further define the extent of respiratory impairment. In some cases, the procedure may need to be performed under local anesthesia because of the size of the mediastinal mass and the resultant respiratory compromise (see Fig. 38-3). Minimally invasive techniques have been used to biopsy mediastinal masses, if no suspicious extrathoracic lymph nodes are available for biopsy. Care must be taken when using a thoracoscopic or laparoscopic technique to ensure that adequate specimens are obtained. A report from the Children's Oncology Group Hodgkin's Lymphoma Committee demonstrated that up to 50% of mediastinal cases required a second diagnostic biopsy when a thoracoscopic biopsy was performed.[29] thoracoscopic biopsy should also be avoided in children with respiratory compromise.

## HISTOPATHOLOGY

Reed-Sternberg cells are the pathognomonic cells of HD (see Fig. 38-2). The classification systems for HL have evolved over time from the Rye classification to the Ann Arbor Classification and the Cotswolds modification (Table 38-1).[30–32] The current World Health Organization classification system separates HL into two broad categories: classical and lymphocyte predominant. Classical has four subtypes: lymphocyte depleted, nodular sclerosing, mixed cellularity, and classical lymphocyte rich. Classical HL accounts for 90% of all cases. For children, nodular sclerosis is the most common subtype, accounting for 65% of cases. Immunohistochemical studies define a common immunophenotype for classical Hodgkin, characterized by CD15-positive and CD30-positive Reed-Sternberg cells (Fig. 38-4). Classical HL expresses CD30, a marker of activated B-lymphoid and T-lymphoid cells, in almost all cases.[25,28,30] About 87% of classical Hodgkin lymphomas express CD15, the carbohydrate X hapten. Classical Hodgkin lymphoma rarely expresses CD45, also known as common leukocyte antigen, which is expressed by nearly all non-Hodgkin lymphomas and can serve as a useful differential marker between HL and non-Hodgkin lymphoma.

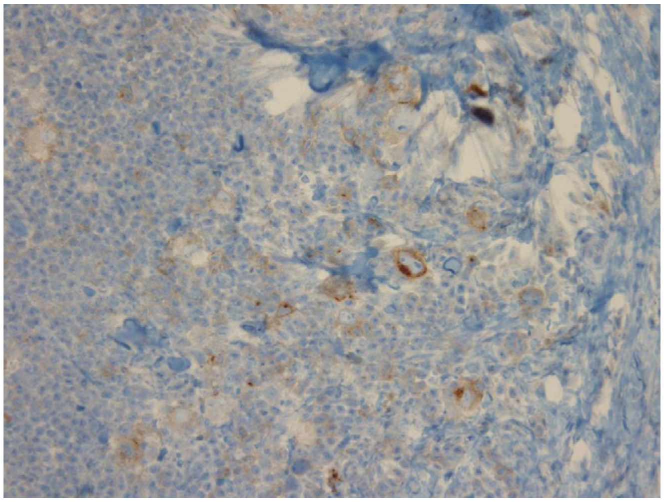

**FIGURE 38-4** CD30-positive staining for Reed-Sternberg cells in a patient with Hodgkin lymphoma.

The lymphocyte predominant (LPHD) subtype accounts for 10% of all cases and is characterized by lymphocytic and histiocytic (L&H) cells that express markers not typically seen in the classical subtype (Fig. 38-5). These cells are also known as "popcorn cells" and are CD20 positive. Other B-cell immunomarkers found in LPHD include CD79a, CD75, epithelial membrane antigen, and CD45. The lymphocyte predominant subtype historically carries the best prognosis. However, since the development of highly effective multiagent and multidisciplinary treatment regimens, all histologic subtypes have become responsive to therapy.

## STAGING

Staging has both clinical and pathologic features. The Ann Arbor staging system and its Cotswolds modification remain the standard for adult and pediatric HL (see Table 38-1).[30,33,34] The original Ann Arbor staging system developed in 1974 was based principally upon the use of staging laparotomy and lymphangiogram, both of which have been abandoned.

Clinical staging requires a complete history and physical examination. Basic tests should include a complete blood cell count with differential, lactate dehydrogenase, alkaline phosphatase, erythrocyte sedimentation rate, or C-reactive protein (CRP), baseline hepatic and renal function tests, and electrolytes. Radiographic studies include a chest radiograph and a computed tomography (CT) scan of the neck, chest, abdomen, and pelvis. Chest radiographs often reveal the presence of a mediastinal mass, and the ratio of its maximal diameter to that of the thoracic cavity on a posteroanterior view is important prognostically. A mass with a ratio greater than 1:3 places

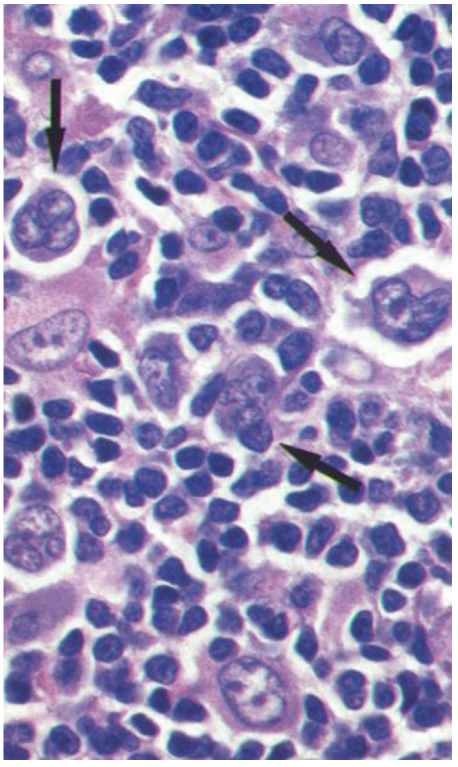

**FIGURE 38-5** High-power hematoxylin and eosin–stained slide of a patient with lymphocyte predominant Hodgkin lymphoma demonstrating classical "popcorn" cells as defined by the arrows.

the patient in the subcategory of bulky mediastinal disease associated with a worse prognosis. Bone marrow biopsy is reserved for those patients with B symptoms or stage III-IV disease. (18F)-2 fluoro-D-2-deoxyglucose positron emission tomography (FDG PET) is replacing gallium scans, and recent studies have assessed the ability of PET scans to replace CT scans and as possible prognostic indicators for response to therapy.[25,28,35–37] Magnetic resonance imaging (MRI) provides a more accurate evaluation of disease in the abdomen compared with CT, with better visualization of fat-encased retroperitoneal nodes, but whether or not this provides clinically significant information has yet to be established.

## TREATMENT

### Risk Classification

Children and adolescents with HL are divided into three risk categories—low-, intermediate-, and high-risk disease—based on clinical and pathologic staging data, histology, stage at presentation, presence or absence of B symptoms, number of involved sites, and/or presence of bulky disease (>10 cm). The exact definitions of each stage will often change between studies and clinical trial consortiums, such as the Children's Oncology Group (COG).[34] In general, *low-risk* disease is defined as classical Hodgkin lymphoma patients, with clinical stage I or II disease showing no B symptoms or bulky nodal involvement and disease in fewer than three nodal regions. *Intermediate-risk* disease includes stage I, II, and sometimes IIIA disease with criteria that vary from trial to trial.[26,30] Some trials have included B symptoms, bulky disease, a large number of involved nodal regions, and extranodal involvement of disease. *High-risk* patients are those with stage IIIB and IVA/B disease.[38–40] LPHD is considered a low-risk disease but is often separated from the classical HL studies.

### Surgery

The role of surgery in the initial diagnosis and staging for HL has been reduced. With the wide application of chemotherapy in all stages of HL, surgical staging has become irrelevant, because the additional information it provides does not alter treatment.[41,42] The surgeon's primary role is to obtain tissue for diagnosis. Biopsies should be taken from the most easily accessible site, and adequate tissue must be obtained and sent fresh to pathology for immunohistochemistry, immunophenotyping, cytogenetics, and flow cytometry. Fine-needle aspiration is generally discouraged, because it is inaccurate and inadequate tissue is obtained to properly stage and classify the patient. Thoracoscopic biopsy or a Chamberlain procedure can be used for diagnosis in patients with only mediastinal involvement. Retroperitoneal lymphadenopathy is often accessible through laparoscopic biopsy. However, thoracoscopic and laparoscopic, as well as core needle biopsies, have a higher incidence of misdiagnosis and can require multiple procedures to obtain an adequate sample.[29] The second role for surgery is to provide central venous access for chemotherapy. Bilateral oophoropexies are also performed in girls who will receive abdominal radiotherapy.

### Chemotherapy and Radiation Therapy

Chemotherapy and radiotherapy (RT) are the mainstay treatments of HL. Although the outcomes for children with HL have improved dramatically, the short-term and long-term toxicity of therapy has been substanial.[43,44] Therefore recent and current therapeutic protocols for HL have focused on maintaining excellent outcomes but reducing toxicity. Ideal chemotherapy regimens use drugs that are individually effective with different mechanisms of action and toxicities, to allow for a maximal dose. The first widespread successful regimen was MOPP (Mustargen, oncovin, procarbazine, and prednisone). In a long-term study of 188 patients from the National Cancer Institute, who were treated with MOPP, the complete remission rate was 89%, and 54% of patients remained disease free at 10 years.[45] In this study, 95% of patients had stage III or IV disease, and 89% had B symptoms. ABVD (Adriamycin [doxorubicin], bleomycin, vinblastine, and dacarbazine) was the second regimen used in the treatment of HD.[46] It was developed for the treatment of patients failing MOPP therapy and contains individually effective drugs with nonoverlapping toxicities.

Historically, radiation therapy was based on the concept of contiguous lymph node basin involvement.[47] The whole nodal region was included as defined by Kaplan and Rosenberg, sometimes additionally covering uninvolved adjacent lymph node region(s), extended field radiotherapy (EFRT).[47] However, radiation therapy is one of the major contributors to early and late toxicity in children with HL. Similar to chemotherapy, treatment has evolved, however, to reduce the radiation necessary. EFRT has been supplanted by involved field radiation therapy (IFRT). Over time, improvements in equipment and targeting have reduced the exposure of uninvolved areas. These practices aim to reduce salivary gland and oral cavity morbidity and to optimally spare the heart from irradiation. A further reduction of RT volume to cover just the nodal

tissue involved by disease, without any attempt to include whole nodal region(s), is termed involved node radiation therapy (INRT).[48] Relapses in patients treated with chemotherapy alone occur primarily in the initially involved lymph nodes.[49] Using FDG PET analysis of residual disease and advances in radiation planning, it is possible now to confine the radiation to the initially involved nodal tissues rather than the whole nodal chain. The hope is that a reduction in irradiation volume will result in a lower incidence of late complications. This goal may be particularly important in young females with anterior mediastinal disease, where exclusion of the hilar and subcarinal nodes from the radiation field would lead to significant reductions in radiation dose to the breasts. This is important because the most common malignancy following treatment for HL is breast cancer. In addition, children have been shown to be particularly susceptible to thyroid toxicity following RT, and the transition to INRT may potentially exclude the thyroid from the treated volume for many patients with supradiaphragmatic HL. Preliminary data reported from British Columbia in Canada indicated no increase in relapses with INRT compared with IFRT or EFRT using a current multiagent chemotherapy regimen.[50]

### Therapy for Low-Risk Disease

Optimal therapy for low-risk Hodgkin disease in children and adolescents continues to evolve. Protocols using chemotherapy followed by low-dose radiation therapy have achieved cure rates of greater than 90% for patients with low-risk Hodgkin disease and represent the standard of care for children and adolescents with Hodgkin disease. Several multi-institutional trials demonstrate that children and adolescents with low-risk HL can be effectively treated with two to four cycles of chemotherapy followed by 15- to 25-Gy IFRT, with series reporting 90% or better event-free survival (EFS), with overall survival (OS) greater than 95%.[51–54] The most recent COG low-risk HL study used a response-based chemotherapy regimen of AP-PC (Adriamycin [doxorubicin], vincristine, prednisone, and cyclophosphamide) with or without IFRT. After three cycles, those with complete response do not receive IFRT. IFRT consists of 21 GY in 14 fractions of 1.50 Gy per day for 14 sessions.[37] This study closed in the fall of 2010.

### Therapy for Intermediate-Risk Disease

Intermediate-risk trials for HL have documented the need for adjuvant radiotherapy in most patients.[54–56] In a German trial, patients who completely responded to induction therapy had radiation therapy omitted, but their event-free survival was lower than expected.[40] In the CCG 5942 trial, intermediate-risk children with complete response were randomized to receive either IFRT or no further treatment.[54] Three-year EFS was 82% with OS of 93%, but the patients who received IFRT had three-year EFS of 88%. Both these studies support the need for IFRT with most intermediate HL patients. The current intermediate-risk COG trial is a randomized trial to see if early complete responders can have a dose reduction of both chemotherapy and radiation therapy without a decrease in their EFS. Induction chemotherapy consists of ABVE-PC (Adriamycin [doxorubicin], bleomycin, vincristine, etoposide, prednisone, and cyclophosphamide) for two cycles. It is a double randomized response–based protocol with both IFRT and chemotherapy intensifications following induction.[36] This study closed in the fall of 2010.

### Therapy for High-Risk Disease

Patients with high-risk tumors require both intensification of chemotherapy and radiation therapy. The German (GPOH) HD-DAL 90 protocol treated high-risk patients with two or four cycles of COPP (cyclophosphamide, vincristine, procarbazine, and prednisone) plus 20- to 35-Gy IFRT. Five-year EFS in high-risk groups was 93% and 86%, respectively.[53] The EFS in the high-risk groups was comparable to that seen in the low-risk group. The Children's Cancer Group (CCG) 5942 protocol treated those with high-risk disease with two courses of intensive multiagent chemotherapy with cytarabine/etoposide, COPP/ABV, and cyclophosphamide, vincristine, doxorubicin, and methylprednisolone/prednisone with granulocyte colony–stimulating factor support. Complete responders were randomly assigned to 21-Gy IFRT or no further therapy. Three-year EFS rates in intermediate- and high-risk patients receiving IFRT were 88% and 91%, respectively.[54] In both the GOPH HD-95 and CCG 5942 trials, the benefit of IFRT in reducing relapse rates was most pronounced among high-risk patients. The most recent studies suggest that outcome of patients with high-risk factors can be improved with intensification of chemotherapy and lowering RT based on response. Pediatric Oncology Group (POG) 9425 study reported 2-year EFS for intermediate- and high-risk disease in a response-based paradigm. In this study, 63% of patients received 9 weeks of chemotherapy and 21 Gy of IFRT because of good response, whereas the others received more intensive therapy.[56] The most current COG high-risk study recently opened. This is a nonrandomized response-based protocol. Induction therapy is with ABVE-PC, and patients will be divided into rapid early responders and slow early responders. Response will be determined by PET scan, and further chemotherapy and radiotherapy targets are based on the PET scan.[57]

### Therapy for Lymphocyte-Predominant Hodgkin Disease

Lymphocyte-predominant Hodgkin disease (LPHD) is recognized as a distinct clinical-pathologic entity, with a favorable outcome, but also associated with a higher risk of late relapse and subsequent development of non-Hodgkin lymphoma (NHL). LPHD comprises up to 10% of cases in adult and pediatric series. Most patients with LPHD reported in the literature have been treated similarly to patients with classical HD, using chemotherapy, RT, or combined modality treatment.[3,58] However, treatment by surgical resection alone has been reported in adult and pediatric patients. The outcomes suggest that patients with low-stage disease may be effectively treated with surgery alone, particularly considering the toxicity of treatment.[59–61] In 2007, European researchers reported 100% survival in 58 LPHD patients treated initially with surgery alone; 50 had a complete response (CR) and received no adjuvant therapy.[62] In this group, 14 (28%) recurred, but 73% required no other therapy at 43 months follow-up. A recently completed COG protocol treated patients with stage I single node disease with surgery only. Results have not been published.[35]

### Novel Therapy

Novel therapies are being investigated for children with HD at diagnosis and relapse. These include rituximab (an anti-CD20 monoclonal antibody) and small molecule agents, such as

bortezomib, a reversible proteosome inhibitor that leads to the blockage of NF-kappa beta being explored in HD. Other agents include histone deacetylase inhibitors, such as MGCD0103; however, none of these agents are being incorporated in standard therapies.[3]

### Treatment Toxicities

Toxicities of treatment include decreased stature, cardiopulmonary dysfunction, thyroid disease, infertility, second malignancies, impaired psychosocial functioning, and decreases in health-related quality of life.[28]

***Growth Problems*** Full-dose (35- to 44-Gy) RT produces bone and soft tissue hypoplasia in prepubertal children. For patients treated with mantle fields, this manifests as spinal and clavicular shortening and underdevelopment of the soft tissues in the neck.

***Cardiopulmonary Dysfunction*** Long-term survivors of HL treated with full-dose RT have an increased risk of atherosclerotic heart disease, valvular dysfunction, and pericardial disease.[62–64] A study reported a 45-fold mortality risk from acute myocardial infarction in children treated before the age of 20 years with more than 30 Gy of mediastinal radiation.[65] Heart disease and valvular disease tends to occur late—8 to 10 years after therapy. Lower doses and cardiac shielding reduce this risk. Pericarditis can occur, especially if the tumor involved the pericardium. Anthracyclines, such as doxorubicin, cause dose-dependent myocardial heart failure and coronary artery disease.[66] In children, a cumulative dose of 300 $mg/m^2$ of doxorubicin increases heart failure rate by 11-fold at 15 years after therapy.[67,68] Contemporary chemotherapy regimens delivering 250 $mg/m^2$ doxorubicin with low-dose IFRT appear to be associated with minimal early cardiac toxicity.[69] Bleomycin results in both short-term and long-term lung toxicity with impaired diffusion capacity and restrictive lung disease.[70] RT can also produce breast hypoplasia and contribute to the pulmonary fibrosis.

***Thyroid*** Hypothyroidism, hyperthyroidism, as well as benign and malignant thyroid nodules have been recognized as problems occurring in long-term survivors of HL.[71,72] In the Childhood Cancer Survivor Study, 34% of 1,791 5-year survivors of HL treated between 1970 and 1986 reported thyroid abnormalities.[72] Thyroid nodules appear late in the follow-up, often 10 or more years after completion of therapy. The relative risk (RR) is 18.3 (confidence interval, 11.4 to 27.6) compared with the general population. Children receiving neck RT also appear to be at greater risk of hypothyroidism than adults.[71]

***Infertility*** Sterility/infertility is a significant risk of alkylating agents, most commonly cyclophosphamide and/or procarbazine.[73] Males in the German GPOH studies receive etoposide in place of procarbazine, because testicular germinal function is more sensitive to alkylating agents than is ovarian function, and current COG protocols limit alkylating agents to doses compatible with preservation of fertility.[35–37,57] Gonadal failure is also a result of pelvic RT. In boys, doses greater than 3 Gy can produce irreversible azospermia.[74] Low-dose IFRT to iliac or inguinal lymph nodes may impair fertility among females if the direct or scattered dose to the ovaries exceeds 2 to 3 Gy. Oophoropexy can help limit the adverse effects of radiation therapy. Also reported in females is a high risk of prematurity and premature menopause.[75]

***Second Cancers (SC)*** The risk of second cancers is significantly increased in the long-term survivors of HL treated with full-dose RT.[76–80] The Late Effects Study Group estimated the 30-year cumulative incidence of SC to be 26.3% among survivors diagnosed before age 16. The two most frequent cancers are breast cancer (20% risk at 45 years of age), followed by thyroid carcinoma (36-fold increased rate).[80] Exposure to alkylating agents, particularly in conjunction with extended-field RT, is associated with an increased risk of leukemia. Leukemias tend to arise 2 to 10 years after therapy. The risk of SC after modern treatment is not yet known, because reduction in exposure to alkylating agents and the use of low-dose IFRT became standard practice within the last 15 to 20 years. The transition from extended-field RT to IFRT significantly reduces the radiation dose to breast and lung tissue.[81] It is thought that modern IFRT should lead to lower SC rates than have been documented in the past.

## Non-Hodgkin Lymphoma

Non-Hodgkin lymphomas (NHLs) comprise a heterogeneous group of tumors that has a constantly evolving classification system. The current World Health Organization (WHO) pathologic classification identifies almost 60 unique subtypes based on morphologic, immunophenotypic, and genetic differences, as well as clinical behavior (Table 38-2). NHL can be broadly divided based on the cell of origin (B cell or T cell) or on clinical behavior (indolent, aggressive, or highly aggressive). There are distinct differences between adult and pediatric NHL, with a strong bias toward precursor B-lymphoblastic and T-lymphoblastic lymphoma, anaplastic large cell lymphoma, and Burkitt lymphoma in childhood.

Indolent lymphomas are slowly progressive but incurable diseases, with a median survival time of 8 to 10 years. Aggressive lymphomas, such as Burkitt and Burkitt-like lymphomas, are rapidly progressive at presentation but curable in 70% to 90% of patients, with outcome strongly dependent on clinical and biological features (as identified by current molecular and immunologic approaches) at presentation.

### INCIDENCE EPIDEMIOLOGY AND CLASSIFICATION

There are 750 to 800 new cases of non-Hodgkin lymphoma each year in the United States.[82] Non-Hodgkin lymphoma (NHL) accounts for 7% of cancer in children and adolescents, with an incidence of 10 per 1 million population annually in the United States.[83] NHL is rare at less than 5 years of age, with an incidence of 2.8 per million cases but increases dramatically after age 20. NHL is more common in males (1.1 to 1.4:1), with a higher frequency in whites than in blacks or Asians. Certain NHL types cluster according to race, for example, the natural killer (NK) T-cell lymphomas are most frequently encountered in Asian populations. A family history of a hematologic malignancy produces an increased risk, but it is not NHL-disease specific.[82]

DNA and RNA viruses are thought to play an important role in the pathogenesis of NHL.[17,82] The Epstein-Barr virus (EBV)

is the most prominent. EBV was first detected in cultured African Burkitt lymphoma cells and is known to be present in greater than 90% of such cases. EBV is important as a trigger for lymphoproliferations/lymphomas occurring in congenital immunodeficiencies, iatrogenically immunosuppressed organ transplant recipients, patients receiving maintenance chemotherapy, and patients receiving combined immunosuppressive therapy for collagen disorders.[84] EBV is also found in HL (mostly the mixed cellularity type), and patients who have had infectious mononucleosis are at increased risk of HL. Other viruses implicated in the pathogenesis of NHL include the retrovirus human lymphotropic virus type 1 (HTLV-1), with adult T-cell lymphoma and human herpesvirus 8 (HHV-8) as a cause of primary effusion lymphoma, a rare type of large cell lymphoma confined to serous-lined body cavities, which occurs with highest frequency in the HIV-positive population. Bacterial overgrowth can also promote the occurrence of a lymphoma. In gastric lymphoma of mucosa-associated lymphoid tissue (MALT) type, *Helicobacter pylori* infection has been shown to be necessary for the development and early proliferation of the lymphoma.[85]

NHLs in children are typically high grade.[86] Ninety percent are from three main groups. These are (1) mature B-cell NHL, which includes Burkitt lymphoma (BL), Burkitt-like lymphoma (BLL), or diffuse large B-cell lymphoma (DLBCL); (2) lymphoblastic lymphoma (LL); or (3) anaplastic large T-cell lymphoma (ALCL). The other 10% are similar to types seen in adults, such as MALT and mature T-cell natural killer (NK) cell lymphoma (see Table 38-2). NHL subtypes have different cell lineages and cell cycle kinetics with different propensities to invade the bone marrow and central nervous system.[87]

## CLINICAL PRESENTATION AND STAGING

Similar to HL, NHL must be considered in any child with lymphadenopathy. However, most children with B-cell lymphoma present with a palpable abdominal tumor or a mediastinal tumor.[88,89] Frequently, the lymphoma presents as a mass in the right iliac fossa and can be confused with appendicitis or an appendiceal abscess. Children may also present with intussusception bleeding, ascites, or a bowel perforation.

As with HL, the presence of mediastinal disease must be assessed, because these masses can be exceedingly large and result in significant morbidity or mortality (see Fig. 38-3). Superior vena cava syndrome and respiratory distress are more common in patients with NHL. In these cases, immediate treatment with corticosteroids with or without cyclophosphamide or radiation may be required. The concern in these situations is that the treatment will make it difficult to establish the pathologic diagnosis. However, there is some thought that treatment for up to 48 hours is beneficial and unlikely to obscure subsequent pathologic diagnosis, but if there is significant resolution of the mass, the tissue may be necrotic.[90] Many children with NHL will present with advanced-stage disease, including bone marrow involvement and malignant pleural or pericardial effusions. Pleural fluid and pericardial fluid often require drainage; cytologic examination of the fluid can be diagnostic.[90] Patients may also present with B symptoms. The presence or absence of B symptoms has prognostic significance and is reflected in the staging of these lymphomas. B symptoms occur in up to one third of children with NHL.[13,25] In NHL, the proper diagnosis allows for classification to the distinct biological subgroups. Specimens should be sent fresh to pathology. Regular histopathology, cytology, immunopathology, cytogenetics using fluorescence in situ hybridization (FISH, to look for chromosomal translocation), polymerase chain reaction (PCR), and growth patterns all are needed to properly classify a case of NHL.[91,92]

### Staging

Staging laparotomy is not performed in non-Hodgkin lymphoma, because all patients require systemic chemotherapy. However, patients may require surgical intervention because of abdominal complications, such as intussusception or bleeding or to obtain diagnostic tissue. In some cases, the disease is localized and a total resection can be performed, in others the

**TABLE 38-3**
**St. Jude's Murphy Staging System for Non-Hodgkin Lymphoma**

| Stage | Description |
|---|---|
| I | A single extranodal tumor or single anatomic nodal area with exclusion of mediastinum and abdomen |
| II | A single extranodal tumor with regional nodal Involvement greater than or equal to two involved nodal regions or localized involvement of extranodal disease on the same side of diaphragm<br>A primary gastrointestinal tract tumor that is completely resected |
| III | Greater than or equal to two nodal or extranodal tumors on opposite sides of the diaphragm<br>Any primary intrathoracic tumor<br>Unresectable primary intraabdominal disease<br>Any paraspinal or epidural disease |
| IV | Involvement of central nervous system and/or bone marrow |

disease is extensive with involvement of the mesenteric root and retroperitoneum.

Although no staging system is entirely satisfactory, the most widely used staging system for NHL is the St. Jude's Murphy system (Table 38-3).[93] The Children's Oncology Group divides NHL into two categories: limited and extensive. Limited disease corresponds to stages I and II in the St. Jude's system, and extensive correlates with stages III and IV.

## NHL SUBTYPES IN CHILDREN AND ADOLESCENTS

A detailed review of all the different types of NHL is beyond the scope of this chapter. The most common subtypes of NHL, accounting for 90% of cases found in children, are presented.

### Mature B-cell NHL: Burkitt Lymphoma, Burkitt-Like Lymphoma, and Diffuse Large B-Cell Lymphoma

B cells originate in the bone marrow from totipotential stem cells that differentiate through many intermediate cell types to eventually become antibody-producing plasma cells (Fig. 38-6). Malignant transformation can occur at any point along the path of differentiation. The clinicopathologic subtypes of NHL are determined by the stage of differentiation at which malignant transformation occurs. Because of their appearance by light microscopy, tumors in this category are also called small, noncleaved cell lymphomas. Because B cells develop in the bone marrow and then migrate to secondary lymphoid organs (lymph nodes, spleen, Peyer patches, liver), one would expect clinical localization of the developing neoplasm in those anatomic sites. Alternatively, B-cell lymphoma should not occur in the anterior mediastinum in the region of the thymus, because normal B cells are not thymic dependent. Usually, but not always, this anatomic distribution is consistent with clinical observations.

***Burkitt Lymphoma and Burkitt-Like Lymphoma*** BL was first described in 1958 in Uganda by a surgeon who observed rapidly enlarging tumors involving the jaw in children.[94] BL and BLL account for about 40% of childhood NHLs (Fig. 38-7).[86] There are three variants of BL: endemic, sporadic, and immunodeficiency related. In the United States, BL most frequently occurs in the abdomen; in western equatorial Africa, it usually arises in the mandible, but abdominal lymphoma is also noted in up to 20% of these patients. BL can also be found in the central nervous system and bone marrow. BL of the anterior mediastinum is extremely rare.[95,96] The gold standard for the diagnosis of BL is c-*MYC* rearrangement.[97] This is based on a characteristic chromosomal translocation, usually involving chromosomes 8 and 14, that was discovered in BL in 1976.[98] In 80% of the translocations, this involves the locus at 14q32, in 15% of cases it is 2p11, and in 5% it is 22q11. BL is the most rapidly growing tumor in

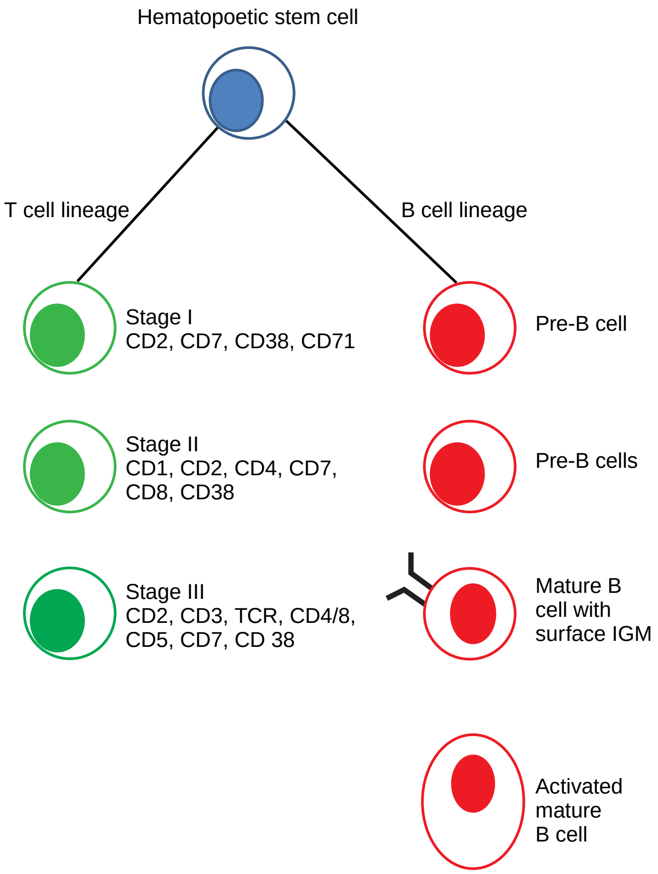

**FIGURE 38-6** A schematic of B-cell and T-cell lineages.

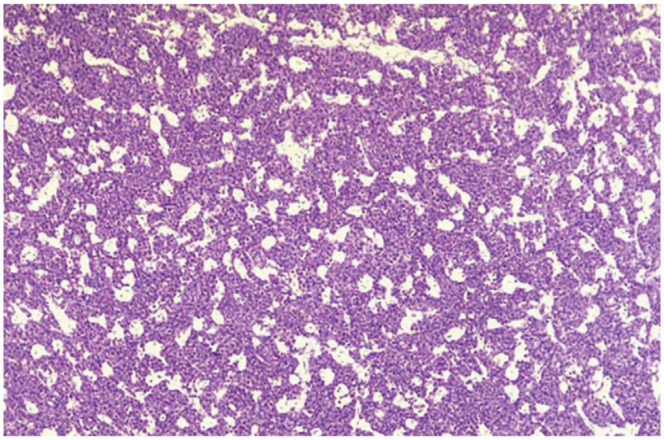

**FIGURE 38-7** A low-power hematoxylin and eosin–stained slide of a patient with Burkitt lymphoma. Shows the typical "starry sky" appearance of the tumor.

children, with a doubling time of approximately 24 hours. The rate of cell death or apoptosis is also high, with the dead cells being taken up by pale histiocytic cells within the tumor that punctuate the low-power view, giving a “starry sky” appearance (see Fig. 38-7).[97] BL cells are mature B-cells that are positive for CD19, CD20, CD22, and CD79a and have a monotypic surface IgM.[99] BLL is an aggressive highly proliferative variant with features that overlap classical BL and DLBCL; BLL is treated by BL regimens.[97] The distinction between BL and BLL is controversial. Because of the rapid growth seen in BL and BLL, when the disease is suspected, the pediatric surgeons are often asked to intervene immediately so that treatment can begin.

***Diffuse Large B-Cell Lymphoma*** DLBCL accounts for 10% of pediatric lymphomas. It is less common in young children and becomes frequent in adolescents. DLBCL is derived from transformed mature B cells of the peripheral lymphoid organs.[100] DLBCL tumors have cells that are 4 to 5 times the size of small lymphocytes. In adults, there is a genetic signature; however, in children this is not the case. The tumors do express c-*MYC*–like BL as well as genes from the NF kappa-beta pathway, but there is no specific marker of DLBCL.[101] The tumors express CD19, CD20, CD22, and CD79a. The three most common morphologic variants are centroblastic, immunoblastic, and anaplastic. Gene expression profiling has identified two subtypes: germinal center B-cell–like (GC) and activated B-cell (ABC). The most common subtype, GC, has a more favorable outcome. A progressively enlarging mass is the most common mode of presentation. Symptoms are based on tumor location. About 20% of pediatric DLBCL present as a mediastinal mass, but the tumors can occur anywhere. Increased lactate dehydrogenase (LDH), pleura effusions, and ascites are less frequently observed than in other NHL. The bone marrow (BM) and the central nervous system (CNS) are rarely involved.[87]

### T-Cell Tumors

***Lymphoblastic Lymphoma*** Lymphoblastic lymphomas (LL) make up approximately 30% of childhood NHL.[12,82,83,86] In pediatric patients with LL, 75% will have a T-cell immunophenotype. The remaining LL patients have a precursor B-cell phenotype more commonly presenting as disease localized in skin and bone rather than T-cell LL. Some oncologists and pathologists feel LL is acute lymphoblastic leukemia in an extramedullarly site. Whether the LL is a T cell or B cell does not affect prognosis. LL tumors have a precursor lymphoblast phenotype (TdT [terminal deoxynucleotidyl] positive) and express T-cell markers, including CD7 or CD5.[12,102.] Although there is no genetic signature, T-cell rearrangements are common, as well as several cytogenetic and molecular changes.[12,103,104] Because thymic residence is a necessary part of T-cell development, most lymphomas presenting in the anterior mediastinum originate from the T-cell lineage. Fifty percent to 70 percent of patients with lymphoblastic lymphoma (T cell) present with an intrathoracic tumor. Abdominal involvement is uncommon and, when observed, usually includes hepatosplenomegaly. Bone marrow infiltration is common in this situation, making the distinction from acute lymphoblastic leukemia difficult. In these cases, survival may be better after treatment with a lymphoblastic leukemia–type regimen. Pleural effusions are often observed, and patients may complain of dyspnea, chest pain, or dysphagia. Superior vena cava syndrome with facial, chest, and upper extremity edema and dilated cutaneous veins over the upper torso and shoulders, or airway compression with severe dyspnea or orthopnea (or both) can also occur. The central nervous system is rarely involved at diagnosis.

***Anaplastic Large T-Cell Lymphoma*** ALCL is a mature T-cell cancer and accounts for 10% of NHL in children. Morphologically, ALCL are characterized by large cells with big cytoplasms and horseshoe- or kidney-shaped nuclei called hallmark cells.[105] More than 90% of ALCL cases are CD30-positive (Ki- antigen) and have the translocation t(2;5)(p23;q35). This results in production of a fusion protein NPM/ALK, although variant *ALK* translocations have been reported.[106] The WHO divides ALCL into systemic (ALK+ and ALK−) and cutaneous lymphomas. ALK− is predominantly found in adults with a poorer prognosis, with OS of 45%. ALK+ prognosis is good, with an 80% OS.[107–109] The cutaneous form is extremely rare in children and only accounts for 1.7% of ALCL; its OS is 90%. Clinically, ALCL has a broad range of presentations, including involvement of lymph nodes and a variety of extranodal sites, particularly skin and bone. Involvement of the CNS and bone marrow is uncommon. As opposed to other pediatric NHL, ALCL is often associated with B symptoms (e.g., fever and weight loss), and a prolonged waxing and waning course can complicate and often delay diagnosis.

***Post-Transplant Lymphoproliferative Disorders*** The 2% to 4% risk of developing cancer after solid organ transplantation (SOT) is about 5- to 10-fold greater than that of the general population. The risk correlates with the intensity and cumulative exposure to immunosuppression.[110] The lowest frequency seen is in renal transplant recipients (1%), and the highest is in heart-lung or liver-bowel allografts (5%). EBV seronegativity at time of transplant and young age at transplant are the two greatest risk factors for subsequent PTLD. In children, post-transplant lymphoproliferative disorders (PTLDs) may occur early, because of their risk for a primary EBV infection.[111] Many of the tumors exhibit an EBV-induced monoclonal or, more rarely, polyclonal B-cell or T-cell proliferation as a consequence of immune suppression.[112] The diagnosis can be difficult and patients tend to present with nonspecific findings, such as episodic and unexplained fever, weight loss, and fatigue. A high index of suspicion is needed to diagnose PTLD. The tumors can occur both within and outside the allograph, including lymphoid tissue, gastrointestinal (GI) tract, lung, and liver. Involvement of the GI tract may present with vomiting, diarrhea, bleeding, intussusception, or obstruction. Perforation may occur at presentation or immediately following initiation of therapy in the presence of transmural necrosis of the lesion.

## TREATMENT AND OUTCOMES

### Chemotherapy for Non-Hodgkin Lymphoma

Non-Hodgkin lymphomas in childhood are in most cases disseminated at diagnosis. Chemotherapy is the primary treatment modality. Each regimen is divided into phases of induction, consolidation, reintensification, and maintenance.

Historically, only 20% to 30% of patients with non-Hodgkin lymphoma survived for 5 years until the pioneering work of Wollner and colleagues in 1975, when the $LSA_2$-$L_2$ (cyclophosphamide, vincristine, methotrexate, daunorubicin, prednisone, cytarabine, thioguanine, asparaginase, carmustine, hydroxyurea) regimen, adapted from the treatment of acute lymphoblastic leukemia, resulted in a 73% salvage rate.[113,114] At the same time, Ziegler and colleagues reported similar success with treatment of these patients using the COMP (cyclophosphamide, Oncovin [vincristine], methotrexate, prednisone) regimen.[115,116] A third important NHL treatment regimen is the Berlin-Frankfurt-Münster (BFM). This is a similar regimen to $LSA_2$-$L_2$.The main difference is the earlier application of L-Asp and high-dose methotrexate (MTX) in the BFM regimen.

The results of the Children's Cancer Group (CCG) randomized trial CCG-551 is considered one of the main studies to alter therapy for NHL in children. It compared $LSA_2$-$L_2$ with COMP. This study stratified treatment modalities by biological subgroups. The three main findings were (1) different chemotherapy regimens exert different effects in different NHL subtypes, (2) differences in treatment efficacy are seen mainly in advanced-stage disease, and (3) in advanced-stage disease, the differences in treatment efficacy are more pronounced in patients with LBL (i.e., patients receiving $LSA_2$-$L_2$ had fewer relapses) and BL (i.e., patients receiving COMP did better), while event-free survival (EFS) rates were not significantly different between treatment regimens in patients with large cell lymphoma.[117] A Pediatric Oncology Group trial further helped with the stratification issue by demonstrating that even in patients with localized disease, different strategies had different effects in histologic subgroups.[118] Despite the different disease process, stages, and stratification, most treatment regimens are based on one of the three regimens described previously with adjustment made for stage, histology, and phases of therapy. For example, LBL protocols are continual exposure to cytostatic agents over a long period of time; BL/BLL and DLBCL are treated with rapid repeated short, dose-intense chemotherapy courses. ALCL have a completely different strategy.[90]

## Surgery

Initial surgical management includes incisional biopsy for diagnosis, followed by intense, multiagent chemotherapy, except for small, easily resectable lesions.[119] Resection of massive retroperitoneal or mediastinal masses is not indicated. In abdominal BL, the extent of disease is a more significant predictive variable than is completeness of surgical resection. The surgical committee of the Children's Cancer Group (CCG) evaluated the role of surgical therapy in 68 patients with non-Hodgkin lymphoma in the CCG-551 study.[60] Tumor burden was the most important prognostic factor. However, in disease that can be completely resected, it may improve EFS and prevent complications such as bowel perforation. In the setting of localized disease, data do support a role for complete resection.[120–122]

## Radiation Therapy

In the treatment of localized non-Hodgkin lymphoma, radiation therapy has been shown to add toxicity with no therapeutic benefit. Several studies continue to show that radiotherapy has a limited role (stage I disease) in the treatment of NHL.[123] Radiation is used for CNS disease with limited effects and is controversial.[124]

## Burkitt Lymphoma and Burkitt-Like Lymphoma and Diffuse Large B-Cell Lymphoma

Most BL and BLL regimens are derived from the $LSA_2$-$L_2$ or BFM regimens with the use of methotrexate (MTX) for CNS disease. Rituximab is currently being studied in clinical trials, because it has shown good results in adult NHL. Because of its high proliferation rate, BL therapy uses cytotoxic drug concentrations over a period and drugs with different mechanisms of action with nonoverlapping toxicities that is sufficient to affect as many lymphoma cells as possible during the active cell cycle, using either fractionated administration or continuous infusion.[125] Treatments use high-dose intensity and short treatment intervals. Although these regimens are effective, they are toxic even with use of granulocyte colony–stimulating factor (G-CSF), because up to 3% can die from treatment complications.[126,127] One particular threat is acute tumor cell lysis syndrome (ATLS). Depending on the size of the tumor, the acute lysis of many tumor cells places a tremendous metabolic load on the kidneys, composed of phosphates, potassium, purines, and protein. Patients may present with elevated serum uric acid, lactate, and potassium levels. This syndrome may be further aggravated during the initial massive cell lysis caused by chemotherapy. ATLS can result in hyperuricemic nephropathy and renal shutdown. Patients with localized resected tumors have nearly 100% EFS with two 5-day therapy courses. Recent trials report overall survival rates of 98%, 90%, and 86% in stage I/II, III, and IV disease, respectively.[128] DCLC also has excellent outcomes when treated on BL and BLL protocols with event-free survival reaching 97%.

## Lymphoblastic Lymphoma

Event-free survival for children with LL ranges from 60% to 90%, with 5-year survival, with lower stages reaching 90%.[129–132] Most current treatments are based on one of two protocols: the $LSA_2$-$L_2$ protocol (cyclophosphamide, vincristine, methotrexate, daunorubicin, prednisone, cytarabine, thioguanine, asparaginase, carmustine, hydroxyurea) or the BFM group strategy. Each uses similar drugs divided into phases of induction, consolidation, reintensification, and maintenance. The main differences between the protocols are earlier application of L-Asp and high-dose MTX in the BFM regimen. Treatment intensity is stratified according to stages I and II versus stages III and IV. Children with stage I/II are rare and achieve EFS rates higher than 90% with reduced-intensity (omission of reintensification in the BFM protocol) and full-length maintenance therapy. Most relapses occur early. Radiation is used for CNS disease with limited effects and is controversial.[124]

A current COG study is looking at the benefit of high-dose MTX with added cyclophosphamide and anthracycline during induction with the regimen from the BFM-95. The study is still open and accruing patients.

## Anaplastic Large Cell Lymphoma

ALCL uses different treatment for local and systemic disease. Patients with localized disease show the best results with pulsed multiagent chemotherapy similar to the regimen used

in mature B-cell NHL reporting overall survival of 93%. Children and adolescents with disseminated ALCL have a poorer survival of 60% to 75%. It is unclear which strategy is best for the treatment of disseminated ALCL. COG is testing the replacement of vincristine with vinblastine in the maintenance phase of the APO regimen (doxorubicin, vincristine, and prednisone.)

## TOXICITIES

The long-term toxicity profile for patients with NHL is very similar to HL. Acutely, the NHL regimens, because of their intensity, tend to be more toxic as described previously.

CHAPTER 39

# Ovarian Tumors

Daniel Von Allmen and Mary E. Fallat

## Ovarian Tumors Incidence

Primary cysts and tumors of the ovaries are uncommon in children. The majority of these masses are not malignant.[1] Gynecologic malignant conditions account for approximately 2% of all types of cancer in children, and 60% to 70% of these lesions arise in the ovary.[2] The North American Association of Central Cancer Registries released data from 1992 to 1997 regarding more than 1.6 million women and children diagnosed with cancer.[3] This report revealed that 1.2% of ovarian cancer cases occurred in females between birth and age 19 years.[3] Lindfors[4] analyzed several large series of ovarian tumors in children and estimated that the annual incidence of combined benign and malignant lesions was 2.6 cases per 100,000 girls younger than 15 years. Using the Surveillance, Epidemiology, and End Results (SEER) registry, 1,037 pediatric patients with malignant ovarian tumors were identified.[5] The age-adjusted incidence of malignant ovarian tumors in those less than 9 years was 0.102 versus 1.072 per 100,000 in those aged 10 to 19 years old. Malignancy is very rare in children less than 5 years old. The predominant pathology was germ cell tumors in all age groups (77.4%) and 61.7% of tumors occurred in patients 15 to 19 years old. The concept that the highest incidence of malignant conditions occurs in the youngest patients has been reassessed. Newer diagnostic imaging techniques have increased the detection of all gonadal masses, and the frequency of ovarian cancer has decreased.

## Epidemiology

A few syndromes or diseases are associated with ovarian pathology. The Peutz-Jeghers syndrome is associated with granulosa cell tumors, ovarian cystadenomas, and sex cord–stromal tumors with annular tubules.[6] Juvenile granulosa and Sertoli-Leydig cell tumors are detected with Ollier disease (multiple enchondromatosis)[7] and juvenile granulosa cell tumors and fibrosarcoma with Maffucci syndrome (enchondromatosis and hemangiomas).[8,9] Sclerosing stromal tumors are associated with the Chédiak-Higashi syndrome (oculocutaneous albinism, pyogenic infections, and leukocyte granule abnormalities that result in deficient phagocytosis).[10] The presence of ovarian cysts had been noted in various dysmorphic syndromes, including those with craniofacial, laryngeal, and digital malformations.[11] The McCune-Albright syndrome (triad of café-au-lait macules, polyostotic fibrous dysplasia, and autonomous endocrine hyperactivity) is generally characterized by gonadotropin-independent sexual precocity resulting from recurrent ovarian follicle formation and cyclic estradiol secretion.[12] Fibromas are associated with the basal cell nevus syndrome.[13]

Nulliparity and increased education are associated with a greater risk of the development of ovarian cancer.[14] Women who have never used oral contraceptives have a greater risk than women who have used them, and hormone replacement therapy slightly increases the risk.[15] Other potential but more controversial risk factors include exposure to ovulation-inducing drugs without successful pregnancy and diets high in meat and animal fats, dairy products, and lactose. The risk is not uniform across histotypes for most of these factors. Prior tubal ligation and hysterectomy may reduce the risk of epithelial ovarian cancer.[16–18] More recent reports suggest that higher body mass index (BMI) may predict a higher risk of ovarian malignancy in women presenting with adnexal masses, and avoidance of obesity and smoking seem protective against development of benign serous and mucinous epithelial ovarian tumors.[19,20] Late age at menarche, earlier age at menopause, the use of vitamin E supplements, and fish consumption tend to be associated with a decreased risk of some histologic subtypes. Occupational physical activity seems protective against all histotypes.[16]

Approximately 5% to 10% of women with breast and ovarian cancer have a genetic predisposition. High percentages of hereditary breast and ovarian cancers arise from mutations in the tumor suppressor genes *BRCA1* and *BRCA2*. Approximately 70% of familial ovarian cancer cases are caused by *BRCA1* mutations and 20% by *BRCA2*. These mutations are inherited in an autosomal dominant fashion. If a woman is a carrier of one of these gene mutations, she has a lifetime risk of developing ovarian cancer as high as 60%.[21,17] Genetic testing of adolescents is controversial.[22] Kodish[23] formulated the argument that physicians should respect the “rule of earliest onset” and defer testing until the age when the onset of disease becomes possible. An alternative view proposed by Elger and Harding[24] is that some mature adolescents may obtain significant psychological relief from knowing their mutation status and may be capable of using this information for reproductive and health decisions. In most cases, surgical intervention is not indicated until age 35 years or older or completion of childbearing. The use of oral contraceptives

has been shown to reduce the risk of ovarian cancer in the general population. Whether the use of these agents in young women with *BRCA* mutations is beneficial remains to be determined.[17]

# Clinical Presentation

The clinical presentation is variable and does not differentiate a benign from a malignant tumor. Abdominal pain is the most common symptom.[22,25] With cysts and other nonneoplastic conditions, the pain can be acute in onset, with a crescendo pattern of severity because of torsion, rupture, or hemorrhage. The clinical picture may mimic appendicitis. A more chronic, insidious pattern of pain, increasing girth, and marked distention over several weeks to months may occur. Secondary symptoms include anorexia, nausea, vomiting, and urinary frequency and urgency. A palpable abdominal mass with or without tenderness is the most frequent finding on physical examination and is detected in more than half of patients with ovarian tumors.[22] These tumors are usually mobile and palpable above the pelvic brim. Bimanual palpation between the lower abdomen and rectum may be helpful in detecting smaller lesions. Vaginal examination is usually reserved for sexually active patients, although vaginal inspection is of value in all patients. An increasing number of ovarian lesions are discovered incidentally by abdominal radiographs or ultrasonography (US) done for other reasons.

Both neoplastic and nonneoplastic ovarian lesions demonstrate endocrine activity in approximately 10% of cases.[13] Ovarian cysts of the simple, follicular, or luteal type may secrete estrogen and can cause precocious isosexual development. The lesions usually function autonomously, and the girls have suppressed gonadotropin concentrations. As a result, they can be distinguished from patients with central precocious puberty (with accelerated skeletal maturation) or premature thelarche (isolated breast development) by estrogen withdrawal and vaginal bleeding after cyst involution or removal. Precocious pseudopuberty may occur because of the production of human chorionic gonadotropin in girls with germ cell tumors, including dysgerminomas, yolk sac tumors (YSTs), and choriocarcinomas. Ovarian tumors most commonly associated with precocious puberty include the sex cord–stromal tumors, such as juvenile granulosa cell tumors or some Sertoli-Leydig cell tumors, which cause elevated levels of circulating estrogen. In the Grumbach syndrome, hypothyroidism presents with precocious puberty and bilateral ovarian cystic masses that resolve with thyroid replacement therapy.

Virilization resulting from androgen excess can occur with Sertoli-Leydig cell tumors, and masculinization is occasionally seen in older girls with dysgerminomas that contain syncytial trophoblastic giant cells. Yolk sac tumors, steroid cell tumors, and polycystic ovaries can be associated with virilization.

# Diagnosis

## LABORATORY TESTS

Many ovarian neoplasms are associated with the secretion of specific tumor markers or hormones. These are outlined in Tables 39-1 and 39-2 and are discussed further in the sections on individual tumors.

### Tumor Markers

Germ cell tumors are associated with various biologic markers that are useful in identifying and managing this group of tumors.[26] Protein markers, including alpha fetoprotein (AFP), beta-human chorionic gonadotropin (beta-hCG), and lactate dehydrogenase (LDH), are the most readily available. They are measured with serum assays or immunohistochemical staining of paraffin-fixed or frozen tumor.

### Alpha Fetoprotein

Because the fetal yolk sac is the source of AFP early in human embryogenesis, elevations of the marker occur with yolk sac tumors.[27] This is also true with hepatoblastoma, hepatocellular carcinoma, and teratocarcinoma.[28] The elevation reflects the presence of fetal tissue from which normal progenitor cells arise. There is wide variability in normal levels of AFP from birth through the first year of life,[29] and AFP is significantly elevated in premature and normal newborns. Its usefulness in the diagnosis of yolk sac tumor or embryonal carcinoma in the first month of life is limited. Its value in tumor identification begins when the AFP level is significantly elevated over the normal range at any particular age. The normal serum half-life of AFP is 5 to 7 days. Its decline after removal of an AFP-producing tumor signifies a response to treatment. The goal of any treatment is to return AFP to normal levels. Tumor recurrence is marked by a sudden elevation of the AFP level.

### Beta-Human Chorionic Gonadotropin

Beta-hCG is a glycoprotein produced by placental syncytiotrophoblasts. It comprises two subunits, alpha and beta; the latter can be reliably assayed.[30] Beta-hCG elevation in a patient with a germ cell tumor suggests the presence of syncytiotrophoblasts, as seen in seminoma, dysgerminoma, choriocarcinoma,

and, occasionally, embryonal carcinoma.[31] Elevations greater than 100 ng/mL are unusual and suggest the diagnosis of choriocarcinoma.[32] Unlike the much longer half-life of AFP, the beta subunit has a half-life of 20 to 30 hours.[32] Its rapid disappearance implies complete removal of a tumor.

### Serum Lactate Dehydrogenase

Serum LDH is a nonspecific marker that is widely distributed in human tissues and is therefore of limited value in establishing tumor type or response to treatment. However, elevated LDH may indicate increased cell turnover and has been used as a nonspecific indicator of malignancy.[33] It is most useful as a prognostic marker for lymphoid tumors and neuroblastoma. The gene for this isoenzyme is located on 12p, and nonrandom structural changes in chromosome 12 have been seen in all histologic subtypes of germ cell tumors, particularly dysgerminoma.

### CA 125

CA 125 is the best available marker for epithelial ovarian cancer, although it lacks sensitivity for stage I disease and specificity for early ovarian cancer. Levels greater than 35 U/mL may indicate malignant or borderline ovarian tumors. However, levels are also occasionally raised in some benign conditions, including endometriosis, uterine myomas, acute and chronic salpingitis, and pelvic inflammatory disease.[34] One small series showed a low sensitivity and specificity of CA 125 for detection of epithelial ovarian malignancy in premenarchal girls.[35]

## VALUE OF FROZEN SECTION FOR INTRAOPERATIVE DIAGNOSIS

Benign, borderline, and malignant lesions have been identified within the same surgical specimen, suggesting evolution from dysplasia to cancer in some cases, although frequency and speed of this process remain unknown. A quantitative systematic review performed to estimate the diagnostic accuracy of frozen sections compared with paraffin sections, including specimens from 3,659 women aged 1 to 95 years concluded that diagnostic accuracy rates were high for both malignant and benign tumors but low in borderline tumors.[36] This has relevance because a fertility-sparing approach can be used in borderline tumors, but surgeons confronted with this potential diagnosis during surgery should also use a standard approach for staging (discussed later in this chapter), because determination of extent of disease has implications for future treatment and prognosis.[36]

## IMMUNOHISTOCHEMISTRY

Immunohistochemistry (IHC) has had a major impact in recent years as an aid to diagnosis in ovarian neoplasia. From a practical standpoint, the time-honored approaches, including gross and microscopic features, thorough sampling, and consideration of patient age and presence or absence of coexisting endometriosis, still take precedence. In general, IHC panels should include markers which are expected to be positive (and negative) in the various tumors in the differential diagnosis. Virtually no antibody is specific for any given tumor, and unexpected positive and negative immunoreactions may occasionally occur. In ovarian pathology, IHC seems to be most valuable in the evaluation of tumors with follicles or other patterns that bring a sex cord–stromal tumor into the differential. The two most useful markers are alpha inhibin and calretinin. Calretinin is a slightly more sensitive marker of ovarian sex cord–stromal tumors as a group, but alpha inhibin, produced by granulosa cells, is a more specific marker, because most other ovarian neoplasms are negative.[37,38]

## CANCER GENETICS

Ovarian germ cell tumors are associated with sex chromosome abnormalities. Although a few case studies suggest otherwise, a large study examining 456 first- or second-degree female relatives of 78 patients with ovarian germ cell tumors did not identify an increased risk for occurrence.[39] Some abnormal karyotypes are associated with abnormal gonads that are predisposed to the development of germ cell tumors.

The application of new cytogenetic technologies has increased our understanding of the genetics and molecular mechanisms involved in the development of germ cell tumors. Nonrandom changes in molecular structure have commonly been reported in chromosomes 1 and 12, as well as in others.[40–42] For example, the chromosomal aberration of trisomy 12 has been identified in many stromal tumors.[43] An isochromosome is a chromosome in which both arms are derived from one of the two arms by breakage at the centromere and subsequent duplication. Isochromosome 12p [i(12p)] has been identified in all types of germ cell tumors,[44–47] including testicular germ cell tumors in men.[46] The presence of three or more copies of i(12p) has been associated with treatment failure.[41] Nonrandom endodermal sinus tumors in children involve the deletion of segments of chromosome 1p and 6q. Deletion of the terminal portion of 1p has been identified in other tumors, indicating that it may be a locus of one or more tumor suppressor genes not yet characterized. Endodermal sinus tumors in children may show cytogenetic differences from adults with no evidence of i(12p), but with deletions involving 1p, 3q, and 6q.[48] The c-*MYC* oncogene has been found in a few endodermal sinus tumors, and the current Children's Oncology Group protocol will begin to correlate amplification with survival and response to therapy.[49] Further studies are required to determine the significance of these findings. Many germ cell tumors in children express P-glycoprotein, a membrane-bound protein that can decrease the response to chemotherapy; this may explain why these tumors are frequently resistant to treatment.[50]

### Role of Tumor Markers in the Incidentally Identified Ovarian Mass

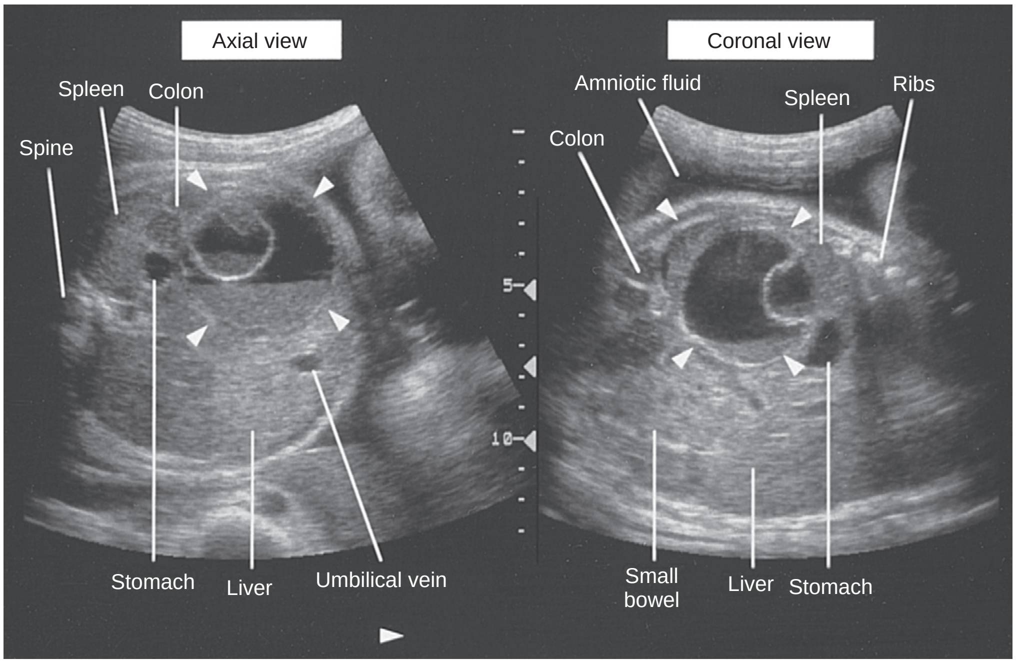
If a mixed cystic and solid ovarian mass is discovered incidentally on an imaging study, a preoperative AFP, beta-HCG, and CA-125 assay should be done. If normal, the mass should be removed with ovarian sparing, if possible. If any of these are elevated, a chest CT should be included in the evaluation to look for metastatic disease. Follicle-stimulating hormone (FSH), luteinizing hormone (LH), thyroid-stimulating hormone (TSH), estradiol and lactate dehydrogenase (LDH) serum levels should be added to the preoperative testing if there are signs of precocious puberty.[51]

## IMAGING TECHNIQUES

Various radiographic studies play an important role in the clinical evaluation of pediatric ovarian lesions. Prenatal US can usually differentiate ovarian lesions from intestinal duplication, hydronephrosis, duodenal atresia, choledochal cyst, urachal remnants, hydrometrocolpos, and intestinal obstruction (Fig. 39-1). Mesenteric and omental cysts are more difficult to distinguish from simple ovarian cysts, because the ovary is an abdominal rather than a pelvic organ in an infant.

US is the diagnostic study of choice for the initial evaluation of potential ovarian pathology in all age groups. Adequate urinary bladder distention is mandatory to displace gas-filled intestinal loops out of the pelvis and to ensure adequate sound wave transmission through the ovaries. Ovarian volume changes with age from less than 0.7 $cm^3$ in girls younger than 2 years to 1.8 to 5.7 $cm^3$ in postpubertal patients.[52] Morphologic characteristics also change. In children younger than 8 years, the ovaries are generally solid, ovoid structures with a homogeneous echogenic texture. During and after puberty, the ultrasonographic spectrum of the gonad undergoes cystic changes that parallel ovulatory follicle activity in the organ. Ovarian cysts are generally anechoic, thin-walled masses with through transmission. With torsion, fluid debris or septation may be present.[53] Most benign tumors are complex masses that are hypoechoic with peripheral echogenic mural nodules, which may exhibit acoustic shadowing. Malignant tumors are

A



B

**FIGURE 39-1** **A** and **B,** Two views of an ultrasonogram of a fetus in the third trimester. A large, complex ovarian cyst containing fluid debris, internal septation, and solid components can be seen (*arrowheads*). An ovarian neoplasm was identified during surgery after birth. (Courtesy Gary A. Thieme, MD, Prenatal Diagnosis Center, University of Colorado School of Medicine.)

often larger in diameter and appear as complex soft tissue masses with ill-defined, irregular borders and central necrosis, thick septations, or papillary projections on US. Doppler color-flow imaging and transvaginal US are also valuable in postpubertal patients to determine morphologic characteristics of ovarian lesions.[54,55] When vessels are located in the central, septal, or papillary projections, together with a diffuse vascular arrangement, the tumors are likely to be malignant.[56] Other discriminating factors include the presence and nature of solid components and free intraperitoneal fluid. Based on the premise that angiogenesis is a neoplastic marker for malignancy, newer methods of ultrasonography using high-resolution color Doppler with extended flow (e-flow) have resulted in better discrimination of malignancy because of higher sensitivity in detection of blood flow in minute vessels.[57]

Computed tomography (CT) and magnetic resonance imaging (MRI) are useful when the origin of the pelvic mass cannot be established by US or when assessment of the full extent of a noncystic lesion is necessary. The characteristic finding of a benign tumor on CT is a fluid-filled mass with fat and calcifications.[58] Focal solid components arising from the tumor wall are common (Fig. 39-2). Malignant lesions are large and predominantly solid with occasional cystic areas as well as fine or coarse calcifications. Direct extension of tumors to adjacent pelvic structures or to the liver and lungs can also be demonstrated by CT, which provides more accurate staging of disease than US. Adnexal torsion in association with any tumor has a distinct appearance on CT, which is demonstrated by dynamic scanning after the administration of contrast medium. The appearance is generally characterized by lack of enhancement of mural nodules, which indicates interruption of blood flow, and demonstration of thick, engorged blood vessels that drape around the tumor and indicate markedly congested veins distal to the site of torsion.

MRI is well suited for imaging pelvic lesions, because it is not influenced by extensive subcutaneous fat and offers superb soft tissue contrast resolution.[59] The technique is especially valuable in determining whether a mass is ovarian or uterine in origin, and it contributes to the characterization of adnexal masses based on criteria suggestive of benignity (fatty components, shading on T2-weighted images) or malignancy (vegetations or solid portions within cystic masses).[60] MRI accuracy can reach 91%. The long imaging times required may cause peristalsis and respiratory motion to obscure peritoneal and intestinal surfaces, and sedation may be needed in small children. Ovarian torsion with hemorrhagic infarction can be detected on MRI by the finding of a high-intensity rim at the periphery of the mass on the T1-weighted image.[61]

Positron-emission tomography (PET) scanning is a newer modality that may play a role in the differentiation of malignant from borderline ovarian tumors.[62] PET and PET-CT have a potential role in evaluating patients for recurrent ovarian cancer, particularly those with negative CT or MRI findings and rising tumor marker levels. Fused PET-CT scans obtained with combined scanners can help localize pathologic activity and differentiate this activity from physiologic radiotracer uptake.[63]

## Disease Classification and Staging

Ovarian lesions are generally divided into nonneoplastic and neoplastic entities; the former category includes functioning cysts, and the latter includes benign and malignant tumors. The clinical system presented here is modified from the most recent version of the World Health Organization's proposal for

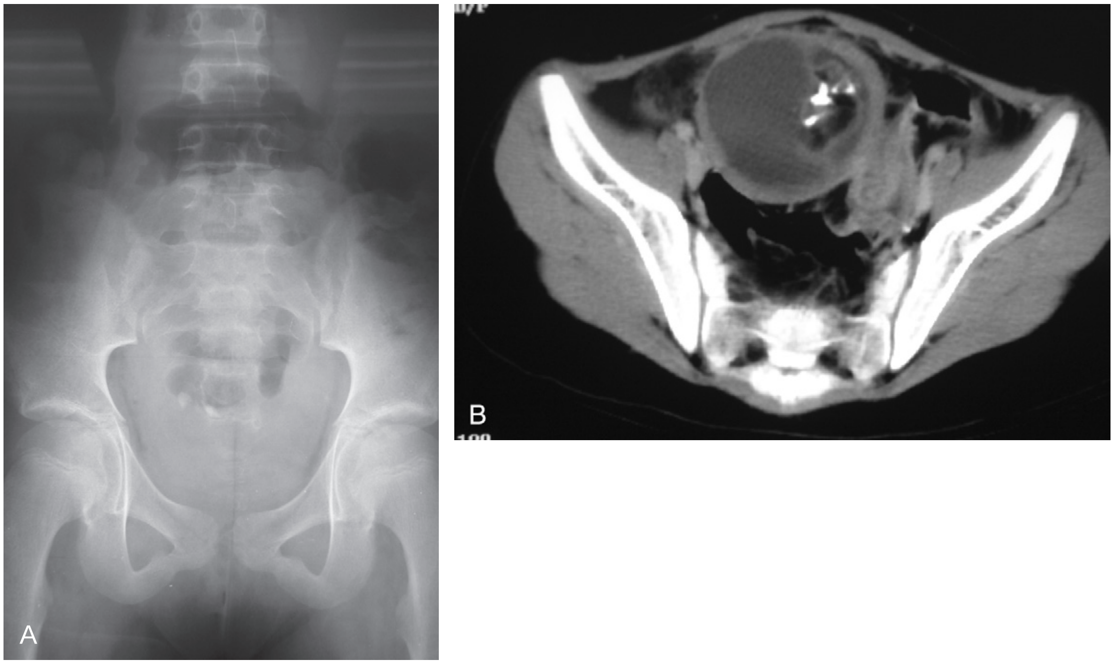


FIGURE 39-2 **A,** Plain abdominal radiograph of a 16-year-old girl with a unilateral ovarian teratoma; the pelvic mass contains toothlike calcifications. **B,** Computed tomography scan of a large, calcified abdominal mass. The mass has a large cystic component, with solid, thickened walls that are eccentric in appearance. The tumor was a thin-walled fibrous cyst with extensive hemorrhagic infarction throughout the entire cyst wall. Histology was consistent with a benign cystic teratoma.

From WHO International Classification of Diseases (ICD), 2007. Available at http://www.who.int/classifications/icd/en/. Accessed June 6, 2010. WHO International Statistical Classification of Diseases and Related Health Problems, revision 10, 2007.

the international histologic classification of diseases and its adaptation for oncology (Tables 39-3 and 39-4).[64–66] Nonneoplastic and neoplastic lesions may arise from surface epithelium, germ cell components, or support stroma. Neoplastic lesions are listed based on the tissue of origin.

Proper management of ovarian neoplasms requires accurate staging of the initial extent of disease. In malignant cases, recent advances in therapy have resulted in increased survival rates and preservation of fertility. Surgical staging with histologic confirmation must be done to supplement the clinical assessment of disease status. Precise staging is based on clinical examination, surgical exploration, tissue histology, and fluid cytology. In the United States, staging of epithelial ovarian cancer is performed at the time of surgery using the International Federation of Gynecology and Obstetrics (FIGO) staging system of 1988 (which was evaluated and not changed in 2009) (Table 39-5).[67,68] This system is ideal, because it accurately correlates clinical findings with survival in a continuum. However, the FIGO staging protocol does not describe the thoroughness of the lymphadenectomy required for ovarian cancer staging, and it has been suggested that the number of lymph nodes obtained at surgery has prognostic and clinical significance.[68]

Because ovarian neoplasms are relatively uncommon, evaluation and treatment protocols developed from multi-institutional collaborative studies have been valuable. Stromal and germ cell tumors have been assessed in studies from the Children's Cancer Group (CCG), the Pediatric Oncology Group (POG), and the Gynecologic Oncology Group (GOG).[49,69–71] In children, the intergroup POG 9048/9049 and CCG 8882/8891 studies used a system that incorporated both surgical and pathologic findings.[70] This concept has been preserved by the Children's Oncology Group (COG) (Table 39-6). Uniform surgical guidelines that incorporate standard approaches to these lesions have been formulated, although the approach to ovarian neoplasms has become more conservative with time.[72,73] Preoperative assessment should try to exclude obvious malignancy by the collection of serum tumor markers and carefully performed pelvic US to determine whether the ovarian mass is complex in nature.

(From International Classification of Diseases for Oncology, ed 3 (ICD-O-3). Creation date: 1976; last date change: 2000.

Elevated tumor markers and a complex mass on US strongly suggest a malignancy, and an abdominal and pelvic CT scan should be obtained. For potentially malignant lesions, an adequate abdominal incision is used, and violation of the tumor capsule is avoided. Alternatively, if tumor markers are negative and the mass is thought to be benign (e.g., a mature cystic teratoma) a laparoscopic approach can be considered.

Initial resection in pediatric patients should virtually always be conservative. Pelvic washings, unilateral ovarian cystectomy, intraoperative frozen section, and careful visual

**TABLE 39-5**
**Staging of Carcinoma of the Ovary: International Federation of Gynecology and Obstetrics (FIGO)**

| Stage | Extent of Disease |
|---|---|
| | Primary tumor cannot be assessed |
| 0 | No evidence of primary tumor |
| I | Tumor confined to ovaries |
| IA | Tumor limited to one ovary, capsule intact |
| | No tumor on ovarian surface |
| | No malignant cells in ascites or peritoneal washings |
| IB | Tumor limited to both ovaries, capsule intact |
| | No tumor on ovarian surface |
| | No malignant cells in ascites or peritoneal washings |
| IC | Tumor limited to one or both ovaries, with any of the following: |
| | capsule ruptured, tumor on ovarian surface, malignant cells in ascites or peritoneal washings |
| II | Tumor involves one or both ovaries with pelvic extension |
| IIA | Extension to or implants on uterus or tubes or both |
| | No malignant cells in ascites or peritoneal washings |
| IIB | Extension to other pelvic organs |
| | No malignant cells in ascites or peritoneal washings |
| IIC | IIA or IIB with positive malignant cells in ascites or peritoneal washings |
| III | Tumor involves one or both ovaries with microscopically confirmed peritoneal metastasis outside the pelvis or regional lymph nodes metastasis |
| IIIA | Microscopic peritoneal metastasis beyond the pelvis |
| IIIB | Macroscopic peritoneal metastasis beyond the pelvis 2 cm or less in greatest dimension |
| IIIC | Peritoneal metastasis beyond the pelvis more than 2 cm in greatest dimension or regional lymph nodes metastasis |
| IV | Distant metastasis beyond the peritoneal cavity |

**TABLE 39-6**
**Clinicopathologic Staging of Ovarian Germ Cell Tumors: Children's Oncology Group (COG)**

| Stage | Extent of Disease |
|---|---|
| I | Limited to ovary (peritoneal evaluation should be negative); no clinical, radiographic, or histologic evidence of disease beyond the ovaries (Note: The presence of gliomatosis peritonei does not change stage I disease to a higher stage.) |
| II | Microscopic residual; peritoneal evaluation negative (Note: The presence of gliomatosis peritonei does not change stage II disease to a higher stage.) |
| III | Lymph node involvement (metastatic nodule); gross residual or biopsy only; contiguous visceral involvement (omentum, intestine, bladder); peritoneal evaluation positive for malignancy |
| IV | Distant metastases, including liver |

inspection of the contralateral ovary are appropriate in the initial management of benign lesions or tumors of low malignant potential. Pelvic washings are part of the staging system for ovarian tumors and should be performed immediately on entry into the abdomen (by either laparoscopy or laparotomy) in an attempt to avoid contamination in the event of intraoperative tumor rupture. Because the final pathology will not be known until either frozen section or histologic evaluation of paraffin-embedded tissue, peritoneal washings should be performed in all patients with complex adnexal masses in case of an unsuspected malignancy. If there is no evidence of free fluid upon entering the abdomen, lactated Ringer solution can be used to irrigate the pelvis and paracolic gutters, then aspirated and sent as washings.

Malignant germ cell and stromal tumors are almost never bilateral in early-stage disease; so, unilateral salpingo-oophorectomy with a staging procedure is adequate first-line management. Excellent responses have been reported with chemotherapy, even in children with extensive tumors, and maintenance of childbearing capability is possible with this approach. In bilateral or more advanced disease, the current success of in vitro fertilization techniques has prompted the consideration of uterus-sparing procedures during the initial operation.[74,75] The expected biologic behavior of the tumor and its response to adjuvant therapy generally dictate the ultimate extent of surgery required. The value of laparoscopic examination in the assessment of pelvic disease is well established, because it will allow identification and management of ovarian masses as well as identification of nonovarian lesions.[76,77] The American Association of Gynecologic Laparoscopists reviewed more than 13,000 procedures performed for persistent ovarian masses.[78] Stage I ovarian cancer was detected in 0.4% of cases. Although these results are encouraging in adult women, there is concern about the difficulty of establishing the true nature of an ovarian tumor by gross examination in children, because experience with such an evaluation is so infrequent. Nevertheless, techniques are being established to avoid tumor spillage that may expand the use of this method. Experienced surgeons have performed more extensive staging procedures and lymph node dissections using the laparoscope.[79] Studies evaluating the laparoscopic approach have been retrospective and suggested that staging is safe, feasible, and a valid alternative, but there has been no prospective trial to date comparing the laparoscopic to open approach.[68]

# Treatment

## NONNEOPLASTIC OVARIAN TUMORS

Ovarian cysts are known to arise from mature follicles. Fetal FSH, LH, estrogens (maternal, placental, and fetal), and placental hCG all stimulate the ovarian follicle, and mature follicles can be found in more than half of newborn ovaries.[80] A postnatal decrease in hormonal stimulation often leads to a self-limited process. Autopsy studies of prepubertal girls have documented active follicular growth at all ages and in normal oocytes, granulosa cells, and cysts in various stages of involution.[81,82] By convention, physiologic follicles are differentiated from pathologic ovarian cysts on the basis of size, and any lesion larger than 2 cm in diameter is no longer considered a mature follicle.

Nonneoplastic cysts are benign and generally asymptomatic. Although surgical intervention is rarely indicated, these lesions occasionally have clinical manifestations, based on size or associated functional activity, that warrant differentiation from true ovarian neoplasms. When an operation is necessary, a conservative approach should be undertaken with the goal of ovarian preservation.

### Follicular Cysts

Follicular cysts represent about half of nonneoplastic ovarian lesions. They are unilateral, unilocular, and histologically benign and often have a thin, yellowish, clear liquid content. Cohen and associates[83] detected cysts in 84% of all imaged ovaries in 77 patients from birth to 24 months of age. The prevalence was similar in each 3-month age bracket. Parallel findings were noted in premenarchal girls between 2 and 12 years of age,[84] with a generally equal distribution across the age spectrum. Occasionally, ovarian cysts persist and enlarge and are capable of secreting estrogen, thereby leading to precocious isosexual development.[85]

The size of an ovarian lesion has been a major factor in determining clinical management.[80] Simple cysts, regardless of size, are more likely to regress. Larger cysts (>5 cm) have a greater risk of torsion. Larger cysts in children have a greater association with sexual precocity. Complex cysts may already have torsed or may be neoplastic. Complex cysts should be resected, rather than observed, in prepubertal children. Complex cysts in adolescents are most often due to hemorrhage into a functional cyst and can be managed conservatively with symptom control. Operation is indicated for persistent cysts or persistent symptoms despite conservative management.

Ovarian cysts noted in the prenatal period can be expected to spontaneously regress during the first year of life, and in utero therapy is seldom justified.[86,87] Cysts that develop in utero are most often lined by luteinized cells, whereas those in older children are more often lined by granulosa cells.[32] These lesions may occasionally be complicated by torsion, intestinal obstruction, or perforation and cyst rupture.[80,88] Bagolan and colleagues[89] and Giorlandino and colleagues[90] confirmed that echogenic cysts with fluid debris, retracting clot, or septation were associated with torsion and hemorrhage. In newborns, torsion is often a prenatal event, and viable ovarian tissue may not be identified, even with the most expeditious neonatal surgical intervention (Fig. 39-3). Most authors now advocate increasingly conservative measures for neonatal ovarian lesions.[80] Small, asymptomatic cysts are generally observed for regression with serial US. Cysts 5 cm in diameter or larger and those with a long adnexal pedicle are more likely to undergo torsion and may be excised with ovarian preservation or aspirated.[91] However, in one randomized study of postmenarchal patients, cysts greater than 5 cm in diameter and those with a complex appearance on imaging studies were followed for a short time with serial pelvic US. High regression rates were seen with those followed expectantly.[35] Although practitioners often reflexively prescribe oral contraceptive pills (OCPs), hormonal therapy has not been shown to improve the regression rates of ovarian cysts compared with those followed expectently.[92] Exploratory laparotomy or laparoscopy has been recommended for patients with cysts that do not resolve or increase in size within 2 to 3 months[92] and for cysts associated with acute or severe chronic abdominal pain or intra-abdominal complications.

FIGURE 39-3 This newborn female infant had a prenatal diagnosis of an intra-abdominal cystic mass. Postnatal imaging showed a low-attenuation cystic structure with a curvilinear calcification along one wall. Laparotomy disclosed a torsed ovarian cyst and ovary, attached by only a small residual stalk. The fallopian tube was preserved. Pathology showed a thin-walled cyst containing dystrophic calcifications.

In prepubertal children, the occurrence of acute symptoms and endocrine activity are more problematic. Surgical intervention is recommended for any cyst that increases in size or fails to regress on follow-up US or if there is evidence of a neoplasm on imaging studies.

As many as 75% of girls with juvenile hypothyroidism have large multicystic ovaries and may show varying degrees of sexual precocity and/or galactorrhea resulting from increased secretion of pituitary gonadotropins and prolactin.[93] Multiple follicular cysts should be distinguished from polycystic ovary syndrome, which is the most common cause of delayed puberty and heavy anovulatory bleeding in adolescent females.[94]

In nonneoplastic ovarian cysts, surgical preservation of as much normal ovarian tissue as possible is a high priority.[95] A plane of dissection can usually be established between the normal gonadal tissue and the cyst after injecting saline with a fine-bore needle beneath the visceral peritoneum. If the surgical manipulation necessary to completely remove the lesion would threaten significant viable ovarian tissue, the cyst should be unroofed and debulked, and the cyst wall excised to the extent possible, while protecting the ovary. Unilateral oophorectomy is indicated only if there is a reasonable certainty that no viable gonadal tissue can be salvaged. The ipsilateral fallopian tube should be spared, because fertilization is still possible from the contralateral normal ovary.

### Corpus Luteum Cysts

True functioning corpus luteum cysts develop only in adolescents who are actively ovulating. Although these cysts may be bilateral and become quite large, they usually regress spontaneously with the cyclic decline in serum progesterone. The gross appearance of the external surface is often bright yellow, although it may take on a hemorrhagic appearance when filled with bloody fluid. The cyst lining is composed of luteinized granulosa and theca cells and is capable of actively producing estrogen and progesterone. These cysts may cause acute pelvic pain if they rupture or undergo torsion. Failure of the corpus luteum to involute may cause menstrual irregularity and dysfunctional uterine bleeding. Surgical goals for corpus luteum cysts parallel those for other follicular lesions. Surgical intervention is indicated in the presence of cyst accident or persistence, demonstrated by repeat pelvic US performed 4 to 6 weeks after the initial assessment. Hasson[96] was able to treat 17 of 19 patients who had corpus luteum cysts with laparoscopic aspiration, fenestration, or cyst wall excision. Clinical symptoms resolved in all but one patient. Cyst recurrence was rare.

### Parovarian Cysts

Parovarian cysts are usually small and rarely symptomatic. They do not arise from ovarian tissue but are usually considered with this group of lesions because of their proximity to the gonad. These cysts originate from the epoophoron and are located in the leaves of the mesosalpinx. Parovarian cysts cannot be distinguished from ovarian follicular cysts using any radiographic imaging technique. During an operation, their gross features are virtually identical to those of follicular lesions, but they can usually be accurately distinguished because of their anatomic position. When surgical treatment is required, both standard open and minimally invasive techniques have been used.[96,97] Large parovarian cysts (>3 cm) should be completely enucleated from the mesosalpinx in such a way that the fallopian tube and ovary are not damaged.[98] Those less than 3 cm may be treated with puncture and bipolar coagulation of the cyst wall.[98]

### Endometriosis

Endometriosis is a disorder in which the endometrial glands and stroma are implanted on the peritoneal surfaces of extrauterine sites. The proposed mechanisms for the pathogenesis of this disease include menstrual flow obstruction with retrograde menstruation, mechanical transplantation and implantation of endometrial elements, and coelomic metaplasia.[99–101] The interval between the onset of menarche and the diagnosis of endometriosis may be as short as 1 month, and the incidence of disease in teenage girls may be far higher than previously anticipated or described.[102] Extensive disease and the presence of endometriomas is uncommon in children and young adolescents unless it is associated with an obstructive müllerian anomaly.[103] An endometrioma or endometrioid cyst may occur in the ovary and can be diagnosed by ultrasonography. Endometrioid *cysts* are filled with dark, reddish-brown blood and may range in size from 0.75 to 8 inches. Several surgical treatments are available for endometriomas, including simple puncture, ablation, removal of the cyst wall, or drainage and medical therapy, followed by later removal. Complete removal is the procedure of choice to decrease recurrence of disease. The revised American Fertility Society classification of endometriosis is widely accepted as the staging system for the disease and was developed as a prognostic tool for patients with infertility.[104] For patients with pelvic pain and a suspected diagnosis of endometriosis, medical therapy with nonsteroidal antiinflammatory drugs or oral contraceptives should be considered. Both medications act to suppress prostaglandins, which are known to be important in the pathophysiology of dysmenorrhea. These drugs along with gonadotropin hormone antagonists, used for a 6-month period, are the most commonly used medications.

## NEOPLASTIC OVARIAN TUMORS

Most neoplastic ovarian tumors develop from cell lines derived from one of three sources: the germinal epithelium covering the urogenital ridge, the underlying stromal elements of the urogenital ridge, or the germ cells that arise from the yolk sac. Cells from each of these lineages may develop into an ovarian neoplasm by de-differentiation, proliferation, and eventually malignant transformation.[105] Malignant ovarian tumors probably arise from their benign counterparts because of either direct or indirect hormonal stimulation.[106] Histologic and biologically intermediate forms between benign and malignant epithelial lesions have been identified and designate tumors of low malignant potential.

Age influences the relative frequency of the various types of ovarian neoplasms. In adults, most tumors are derived from the epithelial line and adenocarcinomas predominate. In children, germ cell tumors are most common and represent approximately 60% to 77% of cases.[105] Epithelial lesions account for approximately 15% of tumors in the younger age group.[95,107] Although germ cell tumors predominate in each age group, the peak incidence of sex cord–stromal tumors occurs in the first 4 years of life, and epithelial tumors are more common in older teenagers. Neoplasms that are rare in children include endometrioid and clear cell tumors (which are usually malignant); Brenner tumors, which are usually benign; disseminated malignant lymphoma; and metastatic lesions to the ovary.

### Surface Epithelial-Stromal Tumors

Epithelial tumors account for 70% of all ovarian neoplasms, but they are much less common in children. In most series, they account for approximately 15% of all surgically resected ovarian masses.[108] Norris and Jensen[109] reported that 67 of 353 ovarian tumors (19%) in children were epithelial in origin and 12% were malignant. The tumors are usually serous or mucinous.[13] Twenty percent of serous tumors are bilateral, and very few are malignant.[13,110] Mucinous tumors are usually unilateral, and 10% are malignant.[13] Deprest and colleagues[111] calculated a 16% malignancy rate for ovarian epithelial neoplasms derived from a collected series that reported more than 1700 pediatric patients with various types of ovarian tumors. Ovarian carcinoma is different in children than in adults. The proportion of mucinous tumors in children was 40% compared with 12% in adults, and 30% were of borderline malignant potential compared with the adult rate of fewer than 10% for these more favorable lesions. As previously discussed, serum CA 125 is a useful tumor marker in malignant epithelial ovarian tumors.[68] However, in premenopausal patients, it may also be raised in several benign gynecologic conditions, including endometriosis, pelvic inflammatory disease, fibroids, and pregnancy.

Proper staging of epithelial tumors is important and differs from the staging algorithm used in pediatric germ cell tumors, which are far more common. Epithelial tumors are staged using the adult FIGO system (see Table 39-5).[67,68] Stage IA tumors may be treated with unilateral salpingo-oophorectomy. The opposite ovary should be examined externally and a biopsy should be taken of any surface abnormalities. Most young patients with stage IB tumors (tumors limited to both ovaries) may be adequately treated by bilateral gonadectomy, but the uterus should be preserved to allow future fertilization.[74,112] In ovarian cancer of a more advanced stage, maximum cytoreduction is important and has been associated with an improved outcome.[113] Total abdominal hysterectomy and bilateral salpingo-oophorectomy with omentectomy and resection of as much gross intraperitoneal disease as possible is necessary. Systemic chemotherapy after appropriate surgery has been beneficial in cases of advanced ovarian carcinoma. Combinations of cisplatin, cyclophosphamide, and paclitaxel are standard agents, while newer biologic therapies hold some promise to improve the overall poor outcome in advanced-stage disease.[114]

Fortunately, advanced-stage disease is uncommon in pediatric patients as tumor stage is the most important prognostic factor.[68]

### Tumors of Low Malignant Potential

Ovarian epithelial tumors of low malignant potential or borderline ovarian tumors (BOTs) differ from epithelial cancer in two major ways: They occur in younger patients, and they have a better prognosis than ovarian cancer. They have been described for all subtypes of ovarian cancer.[111] The serous and mucinous tumors are by far the most common and resemble their benign counterparts. These borderline tumors are differentiated from standard adenocarcinoma in that they lack stromal invasion by neoplastic epithelial elements (Fig. 39-4). Up to 50% of these tumors are bilateral, and they demonstrate a characteristic indolent clinical course. However, recurrences may occur as long as 10 to 15 years after surgery for the primary tumor, and they may be in the form of invasive cancer.[115,116]

In adults, 91% of borderline mucinous tumors present with stage I disease and have a 5-year survival rate of 98%. Serous tumors have a similar outcome. The extensive review of Massad and colleagues[117] noted an overall survival of 98% for stage I tumors, 94% for stage II, and 79% for stages III and IV. In children, Morris and colleagues[118] noted that 75% of the cases presented with stage I disease, and overall survival was 100%. The combined 10-year survival rate for all stages was 73%. In a more recent adolescent study, 26/28 cases were stage I, two cases were stage II, and all patients were alive at 5 years.[116]

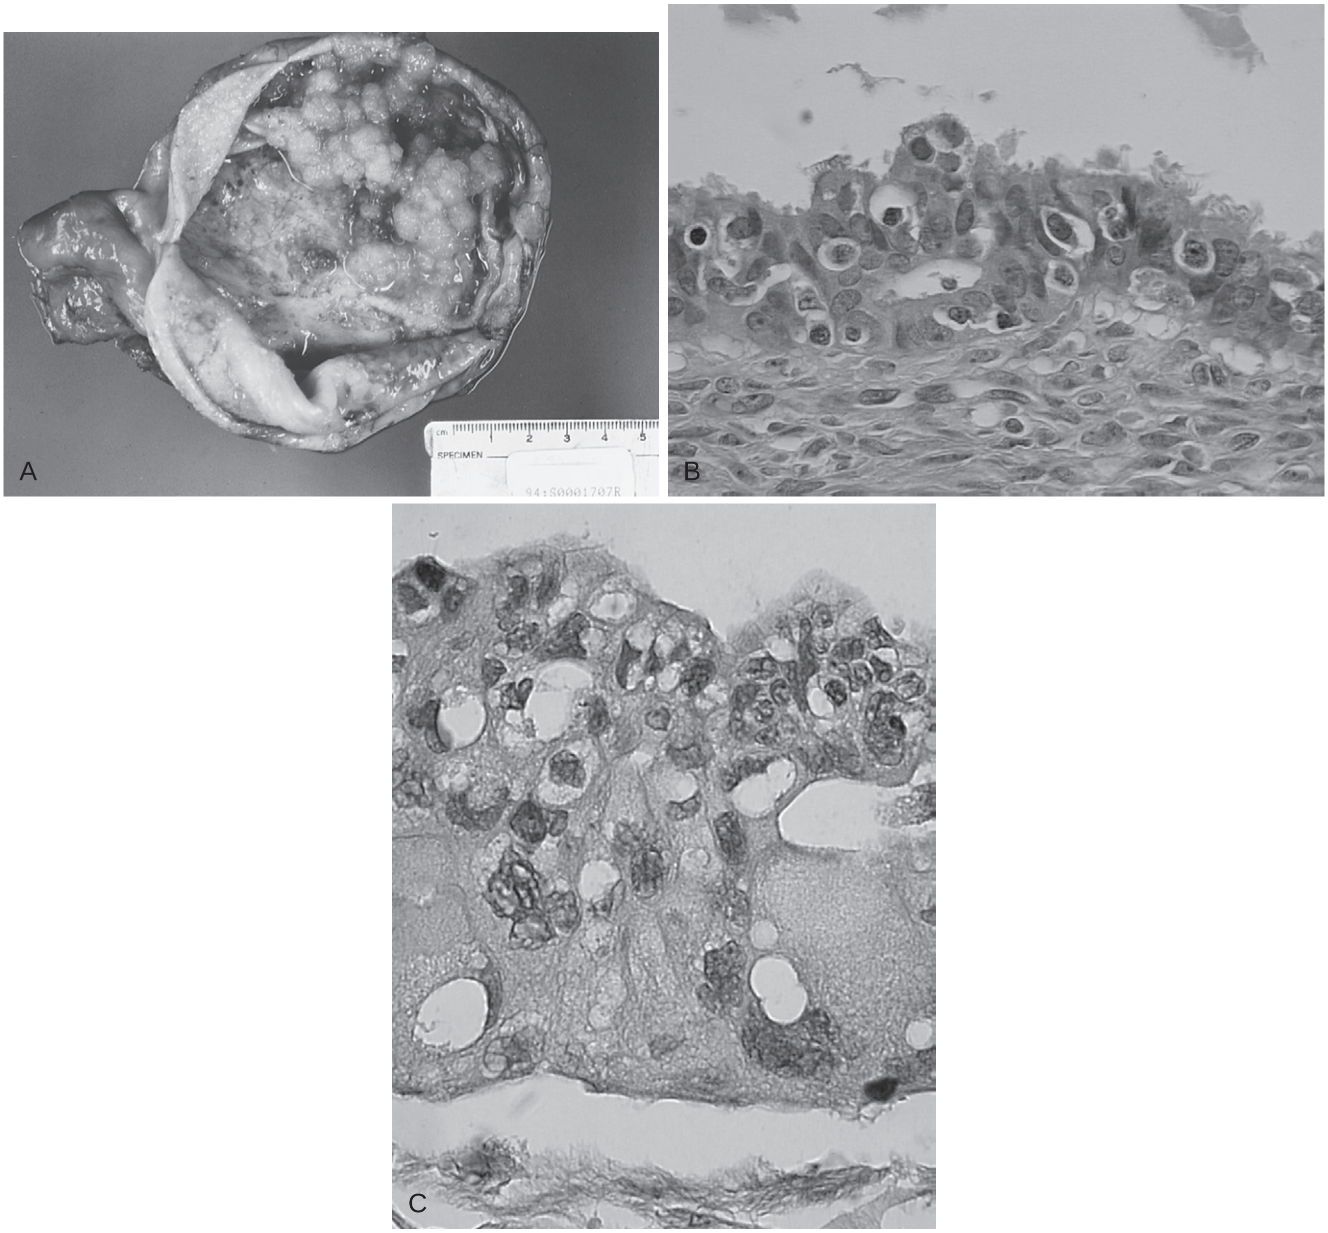

**FIGURE 39-4** **A,** Ovarian tumor from a 17-year-old girl with massive bilateral ovarian lesions. The opened specimen shows a cavity filled with clear fluid, and the wall is lined by numerous nodules and papillary protuberances. **B,** Histologic section of the lesion shows serous papillary tumor of low malignant potential (hematoxylin-eosin stain). **C,** Higher-power photomicrograph of a section of the lesion shows mucinous tumor of low malignant potential (hematoxylin-eosin stain).

Surgery is the primary method of therapy. Unilateral salpingo-oophorectomy is adequate for all low-stage tumors and has been standard treatment; however, some studies have shown that ovarian cystectomy can be performed in young patients with careful follow-up.[119] These patients require close follow-up with pelvic exams, CA 125 assay, and ultrasonography every 3 to 6 months, because patients managed with ovarian cystectomy have a higher risk of recurrence than those managed more aggressively.[120] Morice and colleagues have demonstrated this to be 36.3%, 15.1%, and 5.7% after cystectomy, oophorectomy, and hysterectomy/bilateral oophorectomy, respectively.[119] Despite the difference in recurrence risk, there was no demonstrated impact on overall survival, because all patients were salvaged with further surgery. Conservative treatment should therefore be considered in young patients who wish to preserve their fertility and will comply with routine follow-up.[121]

Bilateral tumors will require bilateral oophorocystectomy or salpingo-oophorectomy. Uterine-sparing procedures are probably not appropriate for advanced-stage disease. The pathologic features that identify poor prognosis are being sought,[115] but currently there are no clear candidates. At present, surgery remains the most effective therapy for these patients with the place of adjuvant therapy yet to be established.[122] No individual treatment strategy has led to consistently superior outcomes, but the favorable biology of this tumor minimizes the importance of the limited clinical benefit from adjuvant therapy.

## Sex Cord–Stromal Tumors

Sex cord–stromal tumors probably arise from uncommitted mesenchymal stem cells that reside below the surface epithelium of the urogenital ridge.[123,124] This totipotential tissue may differentiate into several different cell lines, including granulosa-theca cells in the ovary and the Leydig-Sertoli cells in the testicular interstitium. Sex cord–stromal tumors are referred to as functioning ovarian tumors, because they produce systemic hormonal effects. They account for 5.7% to 17% of malignant tumors in series of ovarian neoplasms in children.[5] Before 9 years of age, most sex cord–stromal tumors are feminizing, and after 9 years of age, there is a predominance of virilizing neoplasms.[32]

***Granulosa-Theca Cell Tumors*** Granulosa-stromal cell tumors are the most common type of sex cord–stromal neoplasms, and the most common type of functioning ovarian neoplasm. The juvenile granulosa cell tumor is a specific subclassification of these lesions; 44% of these occur in the first decade of life and 97% are seen by 30 years of age.[125] Isosexual pseudoprecocious puberty is the presenting sign in the majority of premenarchal girls who have this tumor (Fig. 39-5).[123] Most patients have elevated serum and urinary estrogen levels, whereas gonadotropin levels are low. This profile assists in differentiating children with these tumors from those with true sexual precocity, gonadotropin-secreting lesions, or feminizing adrenal tumors. The peptide hormones

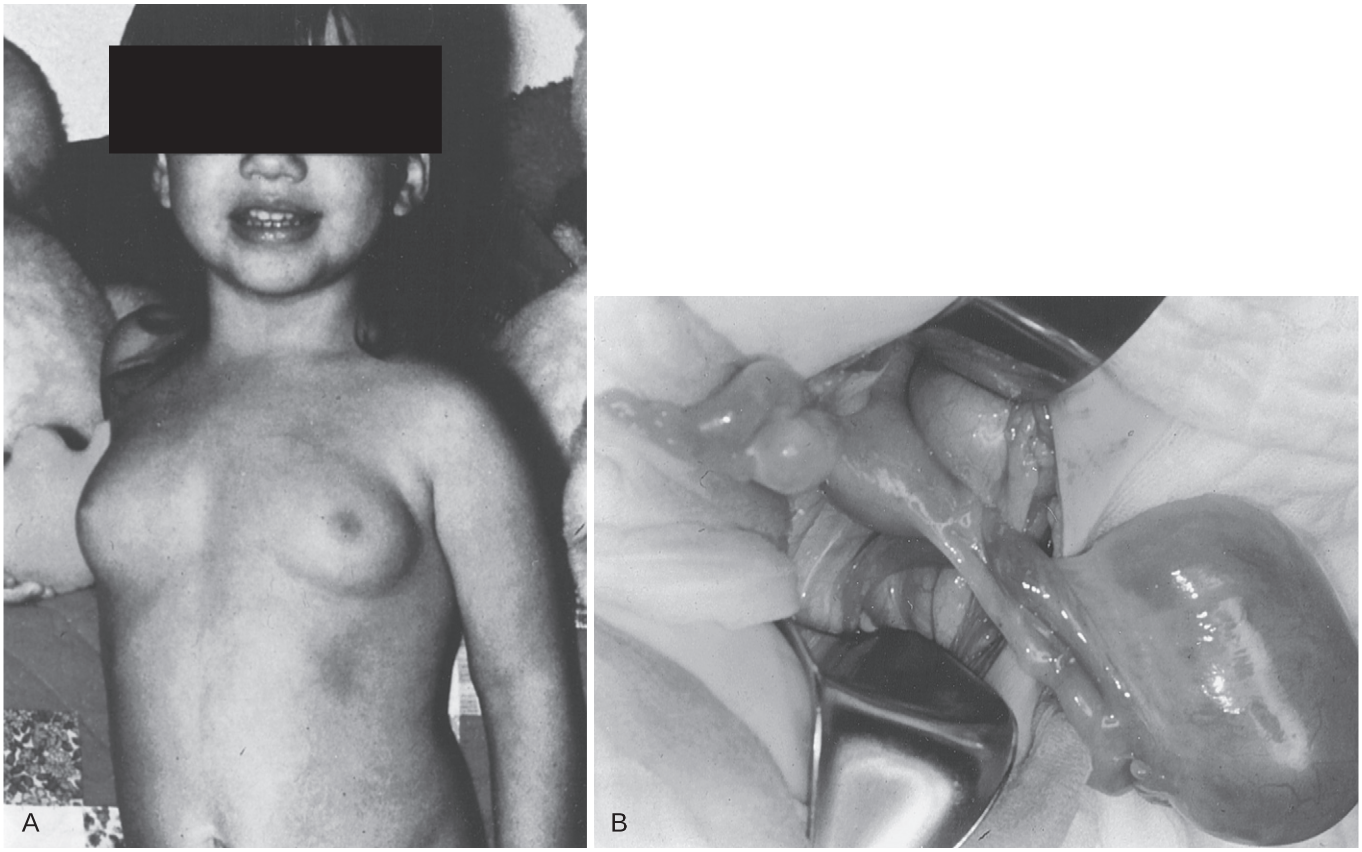

**FIGURE 39-5** **A,** Three-year-old girl demonstrating isosexual pseudoprecocious puberty. **B,** Surgery revealed a benign juvenile granulosa cell tumor. Unilateral salpingo-oophorectomy was performed to remove the tumor.

inhibin and antimüllerian hormone are produced by ovarian granulosa cells and may be useful tumor markers for diagnosis and follow-up of granulosa cell tumors.[126]

Clinical findings include premature thelarche, vaginal discharge or bleeding, labial enlargement, development of pubic or axillary hair, increased somatic growth, and advanced bone age. Clitoral enlargement is a rare manifestation of virilization and tumor androgen production. Postpubertal girls may present with an abdominal mass, relatively nonspecific symptoms of abdominal pain, or increased girth. Amenorrhea and other menstrual irregularities may occur.

In addition to differences in clinical presentation, juvenile granulosa cell tumors demonstrate a pattern of histologic features and biologic behavior that are very distinct from the adult counterpart. The juvenile variety is usually a relatively large lesion that averages 12.5 cm in diameter.[127] At laparotomy, it appears as a yellow-tan or gray solid neoplasm with cystic areas that often contain hemorrhagic fluid. In contrast to the adult tumors, the juvenile type has abundant eosinophilic or luteinized cytoplasm with atypical nuclei and a higher mitotic rate. Deoxyribonucleic acid (DNA) content and cell cycle kinetics analyzed by flow cytometry do not necessarily correlate with the prognosis in children as they often do in adults.[128]

Although the adult form is generally an indolent, slow-growing lesion of relatively low malignant potential, the biologic behavior of the juvenile tumor is more aggressive and correlates well with tumor size, disease stage, presence of rupture, and degree of nuclear atypia and mitotic activity. The lesion was unilateral in 122 of 125 cases reviewed by Young and colleagues.[129] If the adult tumor recurs, it is usually more than 5 years after diagnosis. Malignant granulosa cell tumors in young patients tend to recur much more quickly.

Granulosa cell tumors are staged similarly to other ovarian lesions (see Table 39-5). In children, these tumors are associated with a favorable prognosis, because more than 90% of affected children present with stage I disease. In a German series, 69% of patients were less than 10 years of age, and 82% of patients less than 5 years of age presented with endocrine symptoms. Survival of FIGO stage IA patients was 100%, stage IC was 76%, and stage II/III was 67%. Platinum-based chemotherapy is recommended for tumors of stage IC and above.[93]

***Fibromas and Thecomas*** Fibromas and thecomas account for 14% of sex cord–stromal tumors in pediatric patients.[13] Although they are extremely uncommon in females younger than 20 years of age, fibromas are usually associated with the basal cell nevus syndrome and are frequently bilateral, multicentric, and calcified. Most ovarian thecomas occur in menopausal women; however, two variants of this lesion have been reported in the second decade of life. Calcified thecomas invariably cause amenorrhea or other menstrual irregularities and hirsutism.[130] If these tumors contain a substantial number of lutein cells, they are appropriately called luteinized thecomas and can occur in younger girls associated with androgenic manifestations.

On gross examination, fibromas are firm, solid masses with a whorled, trabeculated appearance on cross section. The lipid content of thecomas imparts a pale yellow to orange color on sectioning the tumor. These lesions are benign, and unilateral oophorectomy is adequate treatment. In the case of bilateral fibromas, all gross tumor tissue should be removed with particular attention to sparing normal-appearing ovarian tissue.[131] Tumor recurrence is rare and managed by reoperation. Virilizing symptoms usually resolve after resection of the tumor.

***Sclerosing Stromal Tumors*** Sclerosing stromal tumors have recently been recognized as distinct tumors that are separate from fibromas and thecomas. These tumors are seen in girls, with 30% of documented cases occurring in the first 2 decades of life. Estrogen secretion has occasionally been reported, whereas androgen manifestations are quite rare. The typical presentation includes the presence of a pelvic mass and pelvic pain in a young patient with a history of menstrual irregularity. This lesion has also been associated with the Chédiak-Higashi syndrome.[10]

Sclerosing stromal tumors are unilateral, usually larger than 5 cm in diameter, and benign. At laparotomy, these tumors are well-circumscribed, firm, whitish-yellow masses with clearly demarcated areas of edema and cyst formation. Histologically, the tumor is characterized by a pseudolobulated pattern with cellular foci clearly demarcated from the edematous and collagenized areas.[132] Gross tumor removal is generally adequate for treatment.

***Sertoli-Stromal Cell Tumors*** Sertoli-Leydig cell tumors account for less than 0.5% of all ovarian tumors but represent 10% of the sex cord–stromal neoplasms.[13] Although most of these tumors are masculinizing, some are nonfunctional or even associated with estrogenic effects. Therefore the older terms, *arrhenoblastoma* and *androblastoma* are no longer favored. One third of cases occur in patients younger than 20 years of age. These tumors are almost always unilateral and present as stage IA at diagnosis. Survival is excellent, with tumor-related deaths in only 5% of affected individuals.[32] Similar to granulosa cell tumors, the gross appearance of Sertoli-Leydig cell tumors varies widely, but these lesions are less often filled with hemorrhagic fluid and rarely have a unilocular thin-walled cystic appearance. Current classifications now recognize five histologic patterns based on the degree of differentiation and presence of heterologous, endodermal, or mesenchymal elements. Tumor stage and histologic appearance are important prognostic factors. Sertoli-Leydig cell tumors with heterologous elements are more common in younger patients and may be difficult to distinguish from immature teratomas.[32] There are two phases of the masculinizing effects of androgen overproduction. Initially, defeminization takes place with amenorrhea, breast atrophy, and loss of female body habitus. This may be followed or overlapped by masculinization characterized by hirsutism, clitoral hypertrophy, and deepening of the voice. In prepubertal girls, masculinization and accelerated somatic growth predominate. Postpubertal girls usually have menstrual irregularities, acne, body habitus masculinization, and hirsutism. The virilizing effects are caused by testosterone accumulation resulting from a deficiency in catabolizing enzymes. Gonadotropin levels are low, and excretion of urinary 17-ketosteroids and pregnanetriol is normal. Because the testosterone level is often directly related to tumor tissue volume, this hormone is a biologic marker for monitoring disease behavior.[133] Tumor markers most likely to be elevated are alpha fetoprotein (AFP) and CA 125.[134] LDH may be elevated or normal. The hormonal

profile of these lesions assists in differentiating them from exogenous androgen sources, adrenal tumors, true hermaphroditism, and polycystic ovaries. Similar to granulosa cell tumors, the Sertoli-Leydig cell lesions may be associated with multiple enchondromas caused by nonhereditary mesodermal dysplasia (Ollier disease).[124]

Surgical therapy should be conservative for patients with low-stage disease. Unilateral oophorectomy or adnexectomy is adequate for such disease and will preserve later childbearing capacity. If tumors are bilateral, poorly differentiated or have ruptured or demonstrate aggressive behavior, a more aggressive approach similar to that used for granulosa cell tumors is necessary. Oral contraceptives and gonadotropin-releasing hormone agonists may provide some ovarian protection both during and following chemotherapy.[135]

***Sex Cord Tumors with Annular Tubules*** Sex cord tumors with annular tubules (SCTAT) are rare but distinct variants of sex cord–stromal tumors. They have potential for bidirectional differentiation into granulosa or Sertoli cells.[13] These lesions are observed in patients with Peutz-Jeghers syndrome.[6] When associated with this syndrome, the lesions are small, multifocal, and usually bilateral. The tumors are often calcified and are invariably noted incidentally during autopsy or in an ovary removed for reasons unrelated to neoplasia. Although patients with these tumors occasionally have menstrual irregularities suggesting hyperestrogenism, surgical therapy is rarely indicated. When these tumors occur in the absence of Peutz-Jeghers syndrome, the clinical difference is significant. Such lesions occur in older patients with a mean age of 34 years, although cases have been reported in patients from 6 to 76 years of age. In the younger patients, the tumor is unilateral and almost always larger than 5 cm in diameter; 20% are malignant. Even with aggressive therapy, 50% of patients with these tumors die.[136]

***Steroid Cell Tumors*** Steroid cell tumor is the now preferred name for lesions previously called lipid cell tumors. This name is more appropriate because of the morphologic features of the tumor, its propensity to secrete steroid hormones, and because many such lesions contain little or no lipids. The group is subclassified into three major categories according to the cells of origin: (1) stromal luteoma is a small steroid cell tumor contained in the ovary arising from the stromal lutein cell; (2) Leydig cell tumor contains the classic intracytoplasmic Reinke crystals and arises from histologically similar precursor cells found in the ovarian hilus; (3) steroid cell tumors not otherwise specified account for approximately 60% of cases and typically occurs in younger patients.

The first and second categories of lesion are usually encountered in postmenopausal women and are only rarely reported in patients in the first 3 decades of life. Most of the cases in the third category and in prepubertal children have been associated with androgenic, heterosexual pseudoprecocity. The tumors are rarely estrogenic, but isosexual pseudoprecocious puberty has been reported.[137] The androgenic tumors show elevated testosterone and androstenedione levels, increased urinary 17-ketosteroid excretion, and decreased gonadotropin levels. In children, these lesions are virtually always benign and of a low stage. Unilateral salpingo-oophorectomy is adequate treatment, but close follow-up is essential. Most of the hormonal symptoms should progressively resolve after removal of the tumor, although younger children may develop true precocious puberty after resection, because chronic androgen exposure appears to induce an early maturation of the hypothalamus.[138]

### Germ Cell Tumors

The path of descent of the primordial germ cells is imperfect; as a result, some of the cells may occasionally miss their destination and be deposited anywhere along this migration route. Germ cells have been found in the pineal area of the brain, mediastinum, retroperitoneum, the sacrococcygeal area, and the ovary and testis. If malignant transformation occurs at any of these sites, a gonadal or extragonadal neoplasm will develop. Because these nests of cells are totipotential in nature, a wide variety of tumors are seen. The specific type of tumor depends on the degree of differentiation that has occurred. This has been characterized by Telium.[27] According to this schema, if no differentiation occurs, a germinoma develops; with differentiation, embryonal carcinomas occur; and with extraembryonic differentiation, these lesions become choriocarcinomas or endodermal sinus tumors. If embryonal differentiation occurs, then the teratoma or most mature of these tumors is seen.

Germ cell tumors are rare in children and adolescents, but when they occur, the gonad is the most frequent site. The ovary is the site of origin for 30% of all germ cell tumors in children.[139,140] Epithelial and stromal ovarian tumors prevail in adults; germ cell tumors predominate in children. Several large series of ovarian neoplasms report an incidence of germ cell tumors ranging from 67% to 77%.[5,141] This group of tumors develops from the same totipotential primordial germ cell, but each neoplasm has different behavioral characteristics, and will be presented individually and then as a group relative to overall management decisions.

***Germinoma*** The term *germinoma* is used to include a group of tumors with common histologic characteristics. It is the primary malignant tumor found in dysgenetic gonads. This tumor may be referred to as a seminoma if found in the testis, a dysgerminoma in the ovary, and a germinoma in an extragonadal site. Germinomas are believed to arise from the totipotential germ cells that were present at the undifferentiated stage of gonadal development.[142] Germinomas represent the most frequent ovarian malignant neoplasm seen both in children and adults.[32] They account for 26% to 31% of malignant ovarian tumors in children.[143,144]

Germinomas are most often seen in prepubertal girls and young women, with 44% of cases occurring before 20 years of age and 87% by 30 years of age.[145] The typical patient is genotypically and phenotypically normal. These often large tumors may reach massive proportions and lead to abdominal pain and symptoms of pelvic pressure, or symptoms related to obstruction of the gastrointestinal or urinary tract. Occasionally, girls with these tumors present with an acute abdomen as a result of torsion, rupture, or hemorrhage into the tumor. Ascites may be present. In pure dysgerminoma, LDH is elevated in 95% of patients, but other markers are negative. In the mixed form of these tumors, other markers may be positive, including neuro-specific enolase, beta-hCG, and CA 125, depending on which germ cell component is present.[146,147] Ovarian dysgerminomas may also be associated with a paraneoplastic syndrome causing hypercalcemia, which typically resolves with

removal of the tumor but may persist for several days.[148] On gross examination, these tumors appear bulky, encapsulated, solid, and yellowish in color (Fig. 39-6); they can be bilateral in 5% to 30% of cases.[142,149,150] Germinomas have a rather uniform microscopic appearance consisting of large, round cells that have vesicular nuclei and clear-to-eosinophilic cytoplasm. These cells resemble primordial germ cells. Lymphoid infiltrates may be present.

The management of germ cell tumors begins with surgical excision. Conservative surgery with a unilateral salpingo-oophorectomy, thorough inspection of the contralateral ovary with biopsy of suspicious lesions, and careful staging (as outlined in the section on surgical approach) is mandatory. Although these tumors are very radiosensitive, surgery alone is adequate treatment in stage I disease. In more advanced disease, radiation has been abandoned in favor of effective

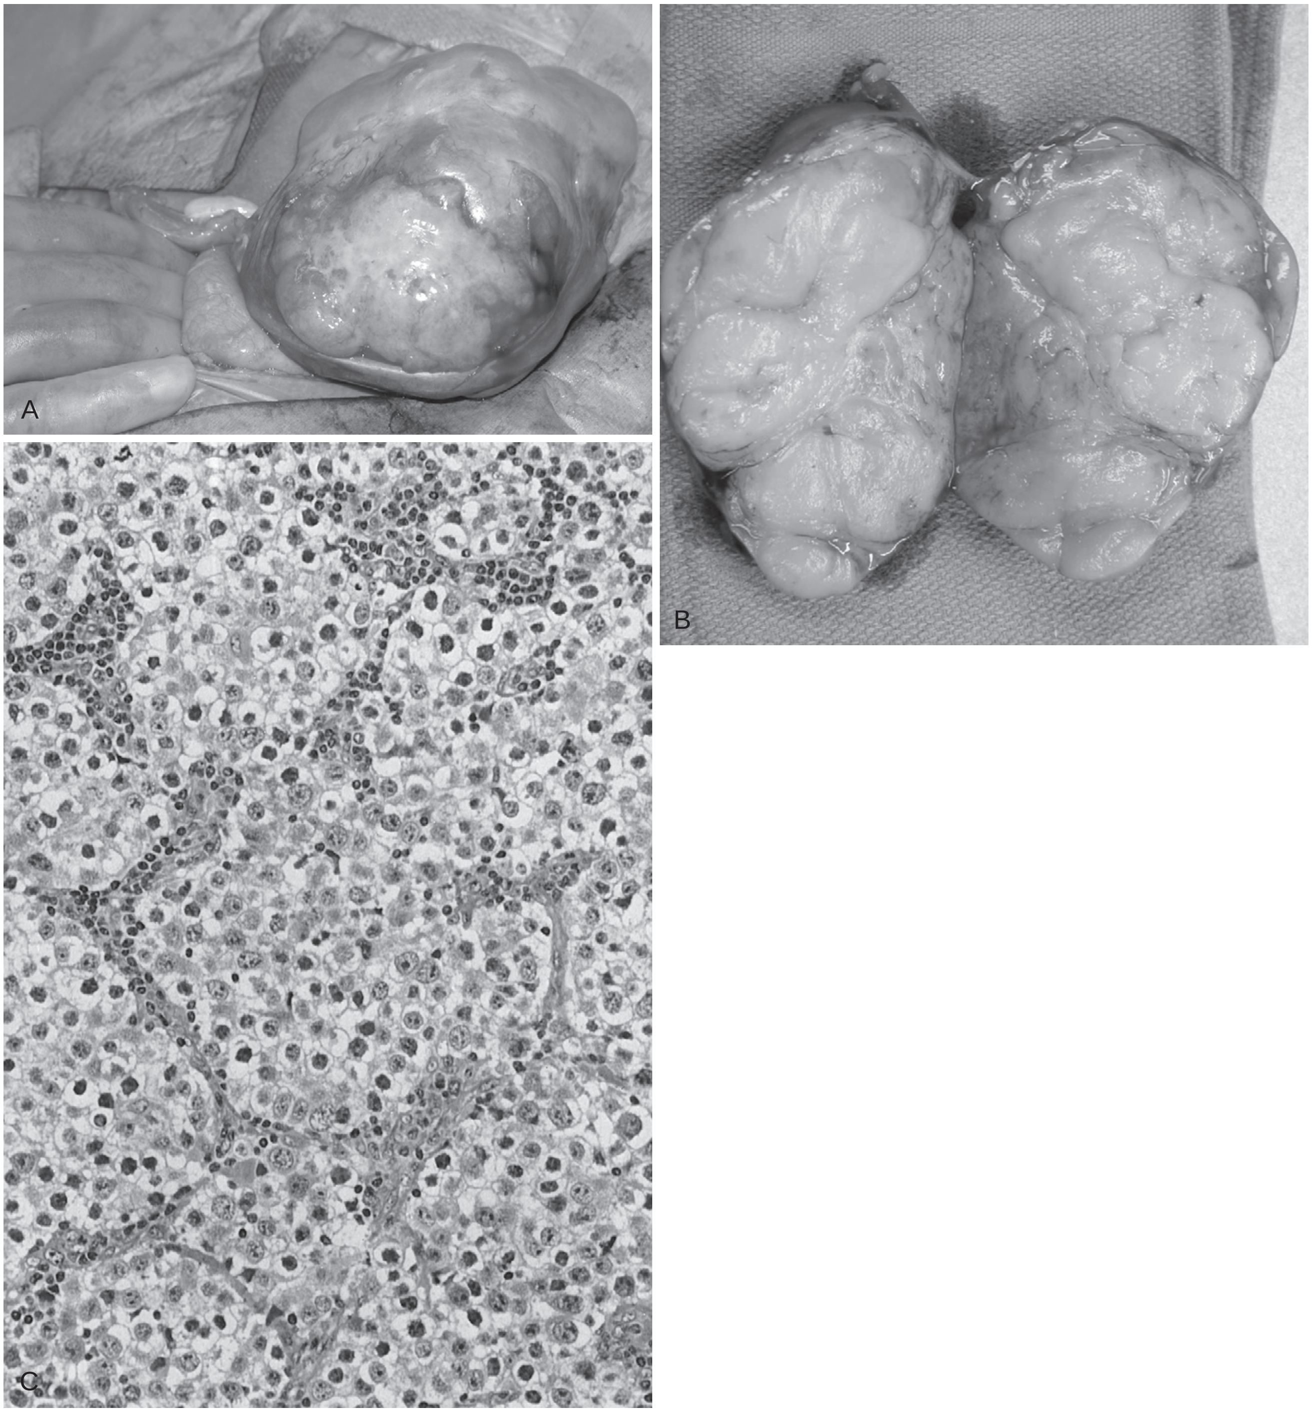

**FIGURE 39-6** **A,** This encapsulated mass from a 5-year-old girl with acute abdominal pain proved to be a dysgerminoma. The child's contralateral tube and ovary are seen to the left of the tumor. A small portion of the ipsilateral tube and uterus were in the surgical specimen but uninvolved with tumor. **B,** The cut surface of the tumor is characterized by lobules divided by thin, fibrous septae. **C,** Micrograph of a dysgerminoma demonstrating polygonal, clear tumor cells divided into small lobules by fibrous septae that contain scattered lymphocytes.

multiagent chemotherapeutic programs that include platinum, etoposide, and bleomycin, which is now standard therapy.[146,151,152]

***Endodermal Sinus Tumors*** Endodermal sinus or yolk sac tumors are aggressive malignant neoplasms that, either alone or as a component of a mixed germ cell tumor, are the second most common histologic subtype of malignant ovarian germ cell tumors in children and adolescents.[32,153] In neonates and young children the primary location of these tumors is in the sacrococcygeal area. In older children and adolescents, it is found most frequently in the ovary. The origin of this particular tumor has been debated, and many microscopic patterns of this tumor have now been described. Nogales suggested that this tumor originates from the primary yolk sac, a structure that develops very early in embryogenesis and consists of multipotential primitive endoderm.[154] This tissue is capable of differentiating epithelial somatic tissues as well as secondary yolk sac tissue (a terminal, temporary structure with limited differentiating capacity) and mesenchyme. Yolk sac tumors with pure endodermal sinus subtypes are less mature than the differentiated glandular or hepatoid subtypes.[155] Symptoms are generally present for less than a month and are related to the presence of an intra-abdominal mass. Sixty-three percent of patients present with abdominal pain and/or abdominal distention.[156] Elevation of the biologic marker AFP is the hallmark of this tumor.

The gross appearance of these tumors during surgery is pale yellow-tan and slimy, with foci of cystic areas and necrosis.[157] The tumors are soft and friable when handled. Most tumors show a distinct histologic subtype with differentiation toward vitelline or yolk sac structures.[158] Microscopically, the most common papillary pattern has the so-called endodermal sinus structures (Schiller-Duval bodies) or perivascular sheaths of cells. Most well-differentiated yolk sac tumors also contain extracellular and intracellular droplets that are resistant to periodic acid–Schiff diastase staining and positive for AFP.

***Embryonal Carcinomas*** A relatively uncommon isolated germ cell tumor is embryonal carcinoma, which may resemble an anaplastic carcinoma with extensive necrosis. Embryonal carcinoma is more often found in association with other germ cell tumors and is referred to as a mixed germ cell tumor. One subtype of this tumor, the polyembryoma, is capable of producing both AFP and beta-hCG, resulting in clinical endocrinopathies, including menstrual irregularities and isosexual precocious puberty. The histologic appearance is characterized by bodies that resemble tiny embryos.[159]

The workup and surgical approach to this tumor is similar to that for an endodermal sinus tumor. Isolated, unilateral disease is managed by unilateral salpingo-oophorectomy. Advanced local disease necessitates hysterectomy for local control along with multiagent chemotherapy.[160]

***Choriocarcinomas*** Choriocarcinomas are extremely rare in the pure form but may be present in mixed germ cell tumors as well. They are endocrinologically active, highly malignant germ cell tumors that occur in girls and women. Estrogen is produced both by the tumor and by the ovary itself in response to release of gonadotropin by the neoplastic chorionic tissue. The beta-hCG level is elevated, and AFP is normal. The clinical presentation is influenced by the age of the patient. In a review of 30 cases, Goswami reported a mean age of 13.9 years, with the predominant presenting symptom being abdominal pain. Ten cases occurred in prepubertal girls, three of whom developed isosexual precocious puberty, and in one case a mature teratoma was identified in the contralateral ovary.[161] These usually large, solid tumors generally adhere to surrounding tissues, and distant metastatic disease is associated with this tumor. Operative excision can be a formidable task, because the tumor may be friable, quite vascular, and often invades contiguous structures.[162] If the lesion is localized, surgery is limited to unilateral salpingo-oophorectomy. However, this rarely is the case, and a more extensive extirpative procedure is usually required that involves removing the tumor, the opposite ovary, the uterus, and as much metastatic tissue as possible.

These tumors appear grossly as nodular with a friable consistency. The tumor is purple with variegated areas of dark brown and yellow secondary to hemorrhage and necrosis. Microscopic evaluation of these tumors reveals cytotrophoblasts and syncytiotrophoblasts with evidence of extensive necrosis and hemorrhage. Metastatic implants are friable and have a similar gross and microscopic appearance as the primary lesion. Survival is based on stage at diagnosis and treatment. Platinum-based and methotrexate-based multiagent chemotherapy are described treatment regimens, and platinum-based (bleomycin, etoposide, and cisplatin) chemotherapy has improved survival. Goswami reports an 82% survival in patients treated with chemotherapy versus 28% in those treated with surgery alone.[161]

***Teratomas*** Teratomas are a group of neoplasms composed of tissue elements that are foreign to the organ or anatomic site in which they are found.[163] Classically, these tumors are defined as being composed of tissue derived from the three germ layers: ectoderm, mesoderm, and endoderm. All three germ layers do *not* have to be present in each tumor, but some embryonic tissues must be found in an abnormal location. These tissues show elements of disorganization as well as various levels of maturation. As such, teratomas are histologically classified as mature and immature tumors and those with monodermal components.[164,165] The development of a somatic malignancy within a teratoma is a rare event in childhood, and is thought to occur within differentiated teratomatous elements rather than from totipotent embryonal cells.[32]

**Mature Teratomas** Most teratomas in children are of the mature type. The majority of mature ovarian teratomas have entered, but have not completed meiosis, suggesting that they arise from germ cells arrested in meiosis I.[32] There is little or no tendency to malignant degeneration of preexisting benign elements or the coexistence of malignant cells in a benign teratoma.[107] In neonates, mature teratomas are found most commonly in the sacrococcygeal area followed by the head and neck.[146,164,166] The ovary becomes an important site later in childhood, especially during adolescence. Ovarian teratomas are predominantly cystic in nature.[107] Overall, benign cystic teratomas are the most common ovarian neoplasms in children[162] and can be bilateral in as many as 10% of patients.[107,165,167]

Symptoms of mature teratomas can be acute or chronic. Acute symptoms that mimic appendicitis are seen when torsion, hemorrhage, or rupture of the mass occurs. Gradual onset of symptoms may be related to the presence of an intra-abdominal adnexal mass, which may cause pressure on adjacent organs.[165] Rarely, a ruptured teratoma may lead to a chronic inflammatory

response with the development of a mass of intestine and omentum adhering to the anterior abdominal wall; this condition is associated with pelvic adenopathy, which mimics a malignant tumor.[168] On examination, findings are primarily related to the mass itself. These tumors are located in the abdomen in infants and young children. They are found in the pelvis of adolescents, although large tumors may be palpated in the abdomen, and there may be associated tenderness.

Plain abdominal radiographs demonstrate calcifications in up to 67% of cases.[169] Ultrasonography is a commonly used diagnostic test. The positive predictive ability of ultrasonography approaches 100% when two or more characteristic findings for mature cystic teratoma (MCT), such as shadowing echodensity and regionally bright echodensity, are present.[170] Magnetic resonance imaging has been reported to be more useful than CT scan in the diagnosis of mature cystic teratoma due to its ability to clearly define soft tissue components.[171]

Conservative ovarian surgery in childhood and adolescence is important for the development of normal puberty and future fertility. This must be balanced with complete removal of the mature cystic teratoma. Traditional management of children with mature cystic teratomas has been oophorectomy by laparotomy. However, laparoscopic removal, either by cystectomy or oophorectomy affords a safe alternative option when done by an experienced laparoscopist.[73] Campo and colleagues, in a randomized controlled trial, demonstrated that the use of an endobag in the removal a mature cystic teratoma at the time of laparoscopy decreased spillage from 46% to 3.7% of cases.[172] Aspiration of a giant predominantly cystic lesion in order to facilitate removal through a smaller incision runs the risk of upstaging the patient by spillage of the cyst contents if malignant components are identified. Techniques have been described to minimize this risk while allowing a less invasive approach to large cystic lesions.[173,174] Every effort should be made to spare the ovary when a teratoma is suspected based on radiographic findings and normal tumor markers. Very large or bilateral teratomas can be successfully enucleated in an attempt to preserve hormonal and reproductive functions (Fig. 39-7).[165,175,] If this is not possible, the gonad and tumor alone should be removed, leaving the ipsilateral fallopian tube in place.

Miliary, intraperitoneal glial implants (gliomatosis peritonei) are occasionally encountered in association with mature teratomas.[176] These implants are rarely suspected before surgery. They appear as white or gray nodules, usually 1 to 3 mm in diameter, and are usually confined to the omentum, pelvic peritoneum, or adjacent or adherent to the tumor itself. Several explanations have been offered for the development of these implants.[177] The most recent data using microsatellite DNA analysis suggest that the glial implants arise from subperitoneal cells, presumably pluripotent müllerian stem cells and not from the teratoma.[178,179] Implants can have a disturbing appearance and biopsy is necessary, but no specific treatment is indicated when they are well differentiated, and their presence does not change management of the primary tumor. However, if adjacent components are immature, the lesions may progress and require adjuvant therapy.

**Immature Teratomas** Immature teratomas are germ cell neoplasms that are composed of tissue derived from the three germ cell layers. These teratomas are clinically distinct from benign or malignant teratomas, because they also contain immature, neuroepithelial elements (see Fig. 39-7). Immature teratomas can coexist with the more mature solid or cystic benign teratomas or with malignant teratomas, in which case treatment is determined by the malignant component.[180] Immature teratomas are graded based on the relative quantity of immature elements and the presence and quantity of the neuroepithelial components. The grade of the primary tumor is significant and is one of the major determinants of the likelihood of recurrence following resection. Multiple grading systems have been proposed based on the system developed by Thurlbeck and Scully.[181] The criteria outlined by Gonazez-Crussi identified the percentage of incompletely differentiated (embryonal) elements in the tumor as follows: grade 0, 0%; grade I, less than 10%; grade II, 10% to 50%; grade III, greater than 50%.[163,182]

The treatment of immature teratomas has gone through an evolution from aggressive treatment with surgery followed by multidrug chemotherapy to conservative surgical approaches with no adjuvant therapy. In a study of 58 pure immature teratomas published in 1976 by Norris,[180] survival was 82% for patients with grade I tumors, 62% for grade II, and 30% for grade III. Based on this study, along with others, use of multiagent chemotherapy for grade III immature teratomas was advocated. The protocol for extracranial nontesticular germ cell tumors of the German Society for Pediatric Oncology and Hematology (GPOH), which was initiated in 1983, recommended adjuvant chemotherapy for grade II and III immature teratomas of all nontesticular sites.[183] Using this approach, the relapse rate was 13.3% for patients with mature and immature lesions. In a follow-up study from the German registry, immature lesions had a higher rate of recurrence than mature lesions when completely resected (8/78 vs. 3/104), as in the previous study, but the recurrence rate overall dropped from 13.3% to 9.5%. Complete resection was associated with a relapse rate of only 4.2% in both studies, and the malignant relapses were explained by microfoci of yolk sac tumor present in the primary tumor as shown retrospectively in single cases by reevaluation of the primarily resected teratoma.[184] The hypothesis that recurrent tumor stems from microfoci of malignant cells present in the original mass is supported by an intergroup study in the United States in which yolk sac tumor elements were detected in 29% of immature teratoma specimens (73 immature teratoma, 21 with YST-microfoci). It was suggested that the true incidence of such microfoci might be underestimated in these typically large masses, as a result of sampling errors.

The combined report from the Children's Oncology Group and the Pediatric Oncology Group in 1999 included 31 patients with pure immature teratomas of the ovary treated with surgery alone. Eighty-six percent of the tumors were grade I or II and the 3-year event-free survival (EFS) was 97.8%, with only one patient developing recurrent disease. That patient was salvaged with a combination of surgery and platinum, etoposide, and bleomycin. The authors advocate surgical excision alone, with close follow-up as appropriate therapy for all ovarian immature teratomas.[185] Based on the excellent survival and avoidance of the risks of chemotherapy, immature teratomas are treated in the United States with fertility-preserving surgery and observation without adjuvant chemotherapy.[185,186]

**Monodermal Teratomas** A monodermal teratoma refers to an ovarian tumor composed exclusively or almost exclusively of ectoderm or mesoderm or endoderm, for example, neuroectoderm.[187]

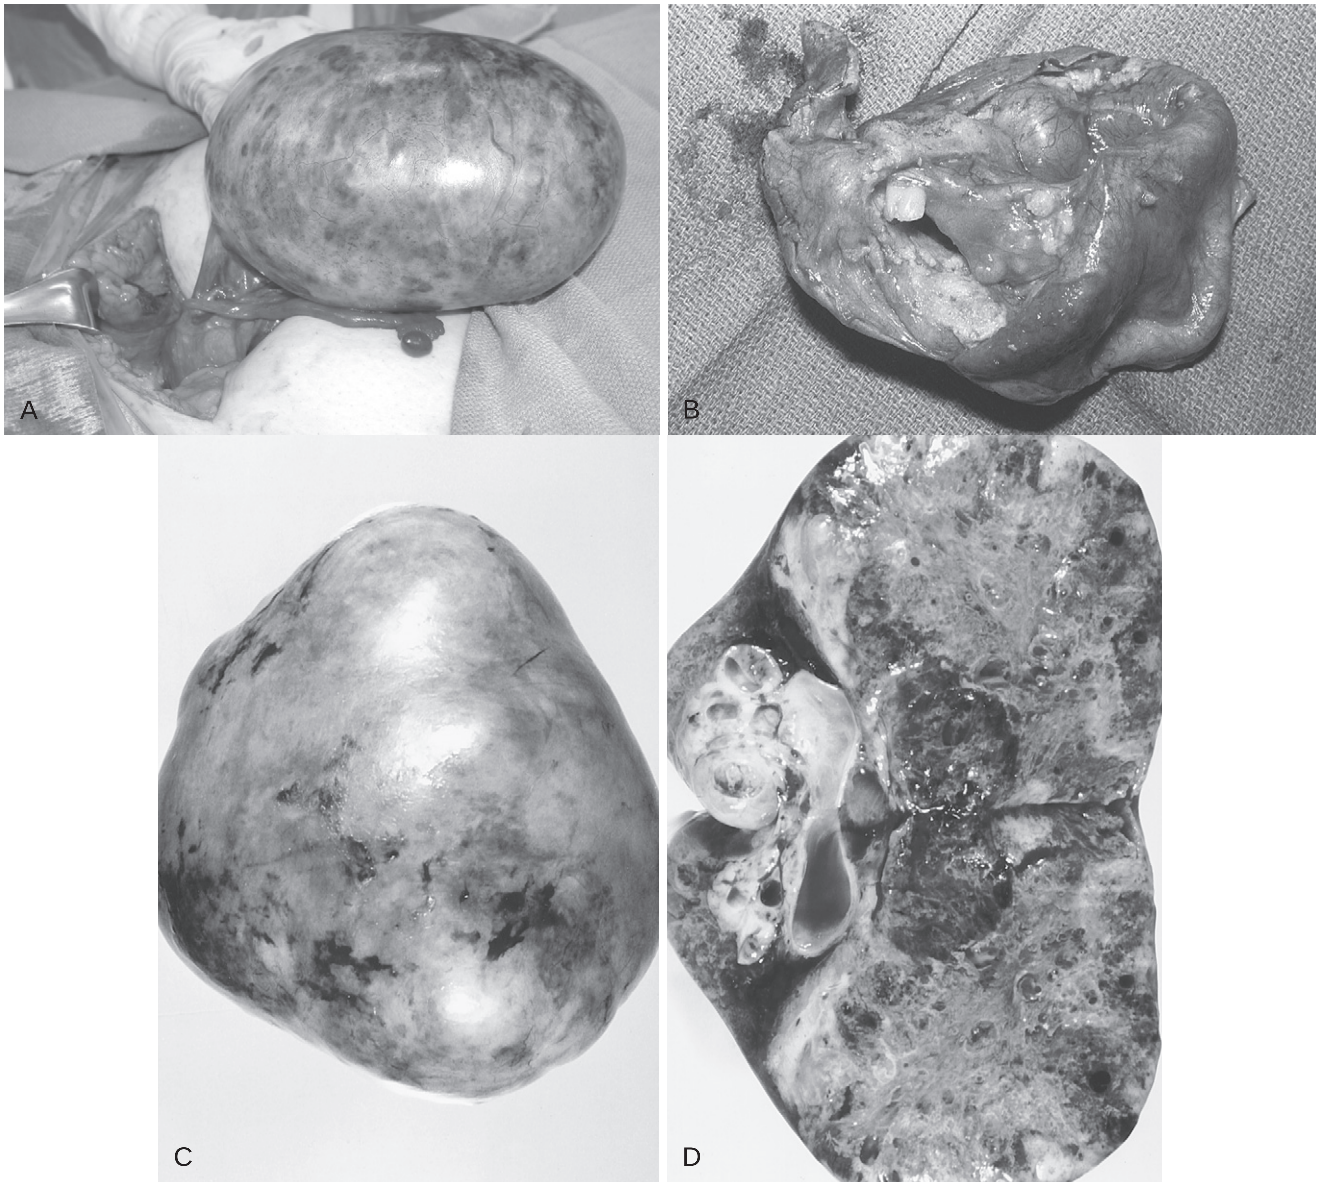

**FIGURE 39-7** **A,** Large ovarian dermoid tumor in a 14-year-old girl with acute severe abdominal pain upon awakening. The fallopian tube is seen below the tumor. **B,** Opened gross specimen of ovarian dermoid showing multiple tooth- and jawlike calcifications. **C,** Characteristic gross appearance of an immature teratoma in a 5-year-old girl who presented with a left ovarian mass. The tumor is a solid and cystic globoid mass with a smooth, shiny surface. **D,** Cut section of an immature teratoma shows a variegated, solid, cystic appearance with focal areas of hemorrhage.

## Gonadoblastomas

Gonadoblastoma, a tumor first described by Scully[188] in 1953, is relatively rare and occurs most commonly in patients with dysgenetic gonads. Most patients are virilized or nonvirilized phenotypic females. In the only large series reported, Scully[189] reviewed 74 cases and found that 89% were chromatin negative and the most common karyotype was 46XY or 45X/46XY. Troche, in a literature review of 140 cases of neoplasms arising in dysgenetic gonads, found that 80% also had these karyotypes.[190] Patients are usually older adolescents or in the third decade of life with a history of primary amenorrhea. Androgen production by the tumor causes virilization. When a workup for amenorrhea or virilization is undertaken, an abnormal karyotype with a Y chromosome or chromosome fragment can be found in as many as 90% of patients.[190] These often small tumors may then be identified during examination or exploration. They may also be found incidentally during excision of gonadal streaks or dysgenetic gonads.[191,192] These tumors become invasive early and gonadectomy is recommended as soon as 46XY gonadal dysgenesis is diagnosed.[18,190]

Gonadoblastomas are composed of germ cells and sex-cord derivatives that are similar to granulosa and Sertoli cells, although immunohistochemical and ultrastructural findings are more supportive of Sertoli-like differentiation.[193] Lutein or Leydig-like stromal cells occur in two thirds of cases and probably reflect a stromal reaction to gonadotropin stimulation.[193] These tumors are considered precursors to germ cell tumors in dysgenetic or streak gonads, because they may coexist with dysgerminomas and other germ cell tumors in more than half of the patients.[190] The tumor may be difficult to identify on gross examination because of overgrowth by the

malignant component and other changes, including calcification, fibrosis, or both. In fact, calcification may be the only remnant of the gonadoblastoma, and the presence of calcification in a dysgerminoma should raise the suspicion of an underlying gonadoblastoma. The malignant potential of this tumor is determined by the underlying malignant component and should be treated accordingly. The outcome for patients with these tumors may be improved, because abnormal sexual development prompts early evaluation of the patient and subsequent diagnosis of the tumor. The prognosis of nongerminomatous germ cell tumors has improved with the advent of bleomycin, etoposide, and cisplatin protocols, and survival rates of 70% to 90% have been reported.[32]

### Mixed Germ Cell Tumors

Germ cell tumors in children are often composed of more than one pure histologic type. Benign but questionably malignant tumors (i.e., immature teratomas) and frankly malignant tumors (germinomas, choriocarcinomas, endodermal sinus tumors, and embryonal carcinomas) may be present. Management of mixed tumors is geared toward the most malignant component of the mass.

## Surgical Guidelines for Ovarian Germ Cell Tumors

The goal of surgery is to completely evaluate the extent of disease, safely and completely resect the tumor, and spare all uninvolved reproductive organs. Preservation of reproductive potential is a high priority during surgery for ovarian lesions in children. Laparoscopic procedures are being increasingly performed for evaluation of pelvic masses, and there are now data to demonstrate that the benefits of a faster recovery time and shorter hospital stay seen in adults are also applicable to children.[73,194] If a suspected ovarian malignancy is detected at the time of laparoscopy, complete surgical staging and resection by conventional laparotomy is recommended. Benign lesions require only tumor resection by ovarian cystectomy or unilateral oophorectomy.

Benign tumors, frankly malignant tumors, and those with mixed histologic characteristics often cannot be distinguished based on gross appearance alone. If in doubt, staging is recommended, because treatment and prognosis of malignancies depend on accurate staging. The current intergroup COG protocol includes thorough inspection, palpation, and biopsy of any suspicious peritoneal and liver nodules (including the subphrenic spaces).[49] Both ovaries are inspected. If a tumor is found in an ovary and malignancy is suspected, it should be removed by unilateral oophorectomy if the fallopian tube is not involved. A salpingo-oophorectomy is indicated if the fallopian tube is involved. The contralateral ovary should be inspected, and nodules or suspicious areas should be biopsied. A contralateral salpingo-oophorectomy should be avoided unless malignancy is confirmed.

Staging procedures for malignancies differ somewhat for different cell types, which can result in inadequate staging of unsuspected epithelial tumors. Staging guidelines for germ cell tumors proposed by the Children's Oncology Group (see Table 39-6) include peritoneal fluid aspiration/washings, inspection of the omentum and contralateral ovary with biopsy of suspicious lesions, biopsy of clinically suspicious lymph nodes, and removal of the primary tumor. Epithelial tumors are staged by the FIGO system (see Table 39-5), which requires peritoneal biopsies, peritoneal washings/aspiration, omentectomy, removal of the primary tumor, and an ipsilateral lymph node dissection. The need for a lymph node dissection is not based on the gross appearance of the nodes, because up to 30% of clinically normal nodes can be positive for metastatic disease.

## Chemotherapy for Ovarian Germ Cell Tumors

Forty years ago, no effective therapy for germ cell tumors existed. Based on the early success of management of testicular germ cell tumors using multiagent platinum-based chemotherapy, ovarian tumor treatment evolved along similar lines. The addition of chemotherapy reduced the risk of recurrent disease for adult patients with completely resected ovarian germ cell tumors.[195] Current regimens for ovarian germ cell and sex cord–stromal tumors is platinum-based therapy, and the regimen of cisplatin, etoposide, and bleomycin (PEB) has become the preferred protocol. An 8-year study from the GOG that closed in 1992 evaluated PEB, and 91 of 93 patients were free of recurrent germ cell tumors, with a median follow-up of 38.6 months.[196]

Several chemotherapeutic regimens were also historically tried in children, and the best results were achieved with PEB.[197,198] In a pilot study, Pinkerton and colleagues[199] demonstrated the effectiveness of substituting cisplatin with carboplatin, a less toxic drug; carboplatin was then combined with bleomycin and etoposide. Eight of eight patients with ovarian germ cell tumors survived with this regimen. Using a platinum-based regimen, only 1 of 17 girls with resected ovarian nonseminomatous germ cell tumors in FIGO stage IA relapsed in an analysis of European trials by Gobel and colleagues.[200]

In 1991, the Children's Cancer Group (CCG) experience of 93 children with malignant germ cell tumors included 30 ovarian tumors.[151] By study design, immature teratomas and dysgerminomas were not included. Using a cisplatin-based regimen, the 4-year, event-free survival rate was 63%. Tumor size affected prognosis. If the tumor was larger than 16 cm in diameter, the outcome was worse. Patients in whom complete tumor resection could not be done during the original procedure were more likely to have subsequent adverse events than if the tumor was completely removed ($P = 0.08$). In 1994, Nair and colleagues[201] reported their findings in 107 children with germ cell tumors, including 43 girls with ovarian tumors. Of these, 22 received multiagent chemotherapy. A complete response was seen in 6 of 11 patients treated with platinum, vinblastine, and bleomycin, compared with 10 of 11 patients who completely responded to treatment with PEB (with etoposide replacing vinblastine). The risk for chemotherapy-related complications is low relative to the effectiveness of the PEB regimen and compared with prior regimens that included vinblastine.[202] Others have shown that the PEB regimen is superior to other chemotherapy regimens.[160]

Current efforts in the United States are geared toward reduction of therapy for low- and intermediate-risk tumors. A phase III study undertaken by the Children's Oncology

Group (COG-AGCT0132) stratified malignant germ cell tumors into three risk groups (low, intermediate, and high risk) defined by stage and primary site. Based on data from the POG 9048/CCG 8891 study, demonstrating that patients with stage I ovarian and extragonadal immature teratoma with malignant elements appeared to do well following complete surgical resection,[69] all patients with stage I ovarian tumors were categorized as low risk and were initially treated with surgery, followed by close observation and monitoring. That arm of the study has subsequently been amended to include stage I ovarian tumors in the intermediate-risk group because of a higher-than-expected failure rate with observation alone. Overall survival remains greater than 95%. The intermediate-risk group will consist of patients with stage I to III gonadal tumors. Such patients have been shown to have a 3-year EFS of about 90% with standard-dose PEB.[49,71] These patients will be treated with a modified standard PEB regimen, consisting of three cycles of compressed PEB every 21 days. Saxman and colleagues[203] reported that long-term survival was equivalent for men treated with germ cell cancer for three or four cycles of PEB. Patients who are partial responders (PR) may then have surgical resection of residual tumor. Therapy is discontinued upon pathologic complete response and normal markers, or continued for an additional three cycles in children who remain PR. High-risk patients, defined as those with stage IV disease, showed some improvement in survival with a high-dose platinum regimen that was offset by increased toxicity. Patients with recurring germ cell tumors may be salvaged using high-dose chemotherapy with autologous stem cell transplantation.

## Miscellaneous Tumors

Small cell carcinoma of the ovary is an extremely rare condition with a very poor prognosis.[204] These tumors are very aggressive and are the most common undifferentiated ovarian carcinoma in young patients. They have been encountered in patients from 9 to 44 years of age, with a mean age of 23 years.[205] Paraendocrine hypercalcemia occurs in two thirds of cases, but patients rarely have clinical manifestations of this abnormality. Serum parathormone levels are normal. Virtually all tumors are unilateral, although only 40% have been detected at stage 1A. Only one third of patients with stage 1A tumors survive long-term, and survival of patients with more widespread disease is rare.[13] Unilateral salpingo-oophorectomy has been associated with long-term survival in some patients with stage 1A tumors. Asynchronous appearance of tumor in a contralateral conserved ovary has been encountered, and bilateral adnexectomy may be a more appropriate surgical option. Despite various treatment modalities including resection, radiation therapy, and intensive chemotherapy, the average life expectancy remains low at 18 months.[205]

Primary ovarian sarcomas are a heterogenous group of aggressive tumors associated with poor survival. Most cases occur in older women; however, a recent review of 151 cases described 10 of 29 patients with rhabdomyosarcoma who were younger than 20 years of age.[206] These patients presented with nonspecific symptoms of abdominal discomfort or swelling with occasional urinary or gastrointestinal complaints secondary to mass effect. Accurate staging is critical. Hysterectomy with bilateral salpingo-oophorectomy and debulking of as much diseased intra-abdominal tissue as possible has been done. Radiation therapy was administered for residual pelvic disease, and several chemotherapeutic regimens have been used. In contrast to rhabdomyosarcomas arising at other sites, the outcome for patients with ovarian lesions has generally been poor, perhaps because of the advanced stage of disease at diagnosis. Nevertheless, the most recent chemotherapeutic regimens used in cooperative group studies have been highly effective, and it is reasonable to assume that more conservative surgical resection will provide adequate treatment for these rare tumors.

Stromal sarcomas and low-grade endometrial stromal sarcomas of the ovary have been occasionally reported in the second decade of life. These lesions are believed to arise from ovarian endometriosis, coelomic mesenchyme, or neometaplasia of stromal cells. Lesions are usually discovered because of nonspecific pelvic discomfort, although early infiltration into adjacent tissues may cause intestinal or ureteral obstruction. Tumor infiltration may not be grossly apparent, so initial surgical resection should be aggressive with total hysterectomy and bilateral salpingo-oophorectomy. Progesterone administration may provide effective adjunctive therapy, although this has to be continued indefinitely because stromal sarcomas have been reported to reappear and spread dramatically when the medication is stopped. Radiation therapy has been used for local residual disease, although recurrence is common. The role of chemotherapy for these tumors has not been defined.

Cases of genuine ovarian fibrosarcoma in children are extremely rare. Patients present with pelvic pain and a palpable mass. Fibrosarcoma has been associated with Maffucci syndrome.[8] Although the outcome has been uniformly poor in older patients, survival of younger patients who have undergone aggressive surgical resection, including hysterectomy and bilateral salpingo-oophorectomy, has been reported. Success with subsequent radiation or chemotherapy has not been reported.

Primary leiomyosarcoma of the ovary is extremely rare in children. These tumors may arise de novo from any of the smooth muscle sites in the ovary or may represent malignant degeneration of leiomyoma, a benign counterpart.[207] As with most of these rare tumors, presenting symptoms are nonspecific and discovery may occur in the advanced stage of disease. Aggressive surgical therapy is recommended, because no adjuvant therapy has proven to be effective.

## Secondary Tumors

Although secondary ovarian malignancy is rare, the ovaries are a potential metastatic site for a wide variety of childhood malignancies (Table 39-7).[127,208] Distinguishing primary neoplasms from secondary neoplasms is important to prevent inappropriate therapy or adverse sequelae. Metastatic spread to the ovary occurs through four main pathways: (1) hematogenous spread, (2) lymphatic spread, (3) transcoelomic dissemination with surface implantation, and (4) direct spread.[208] Recently described highly malignant tumors that have a predilection for the pelvic region are intra-abdominal desmoplastic small round cell tumors.[209]

Lymphoma can occur in the ovary in children either as a primary tumor or a manifestation of systemic disease. Most

of the reported cases have been of the small, noncleaved cell type (Burkitt or non-Burkitt category), although T-cell non-Hodgkin lymphoma and anaplastic large cell lymphoma have also been reported.[210] Pais and colleagues[211] reviewed 23 cases of ovarian involvement in patients with relapsing leukemia. Abdominal pain was the most common symptom, and a mass could usually be palpated. Although most patients in whom leukemia treatment failed had systemic and not local disease, ultrasonography revealed a characteristic appearance and was effective in detecting ovarian involvement.[212] Survival was based on aggressive systemic multiagent chemotherapy and not on the degree of surgical resection of the ovarian lesion. Routine pelvic radiation therapy was of no benefit.

Reports have noted granulocytic sarcoma of the ovary occurring in patients with acute or relapsed acute myelogenous leukemia.[213] Although aggressive systemic chemotherapy is critical to survival, an ovarian mass should be investigated immediately to determine its nature (i.e., benign or malignant and exact cell type). In this instance, surgical resection of the ovary and any other involved gynecologic organs or pelvic tissue must be done. Radiation therapy has been used for residual disease in the pelvis. Although the ultimate outcome of granulocytic sarcomas is probably more related to effectiveness of chemotherapy, local measures of tumor control cannot be overlooked when this tumor is detected.

# Unclassified Benign Tumors

Although the ovary is highly vascularized, hemangiomas are extremely rare; a recent review found only 40 published cases.[214] Their occurrence is relatively evenly distributed between infancy and postmenopausal age groups. The lesions are usually quite small, asymptomatic, and discovered incidentally. Bilateral occurrence is rare, and the tumors are almost always cavernous. Benign-appearing ultrasonographic features have been described.[215] When the tumors are large, associated symptoms include abdominal pain, distention, and bloody ascites. Torsion or rupture may cause an acute surgical emergency. No malignant tumors of this type have been described, and oophorectomy or adnexectomy is curative if needed.

Primary ovarian leiomyomas are also extremely rare, although they have been reported in teenage girls.[216] Most reported cases are clinically silent; however, the lesion may be large enough to cause increased abdominal girth and pelvic pain. Tumor markers are normal, and imaging studies are generally unable to differentiate this benign solid tumor from a malignant process. Unilateral salpingo-oophorectomy is curative. The ovarian myxoma is a rare benign tumor characterized by conspicuous vascularity and mesenchymal proliferation that requires only a conservative surgical procedure.[217]

Struma ovarii is a benign variant of a germ cell tumor that typically occurs in older women but has been reported in teenagers. It is composed of more than 50% benign thyroid tissue, which is functional in 5% to 12% of cases. Rarely, the tumor contains malignant components and, in some cases, represents the patients' only functioning thyroid tissue. CA 125 levels may be elevated, but other markers are usually normal. Treatment is resection of the mass.[218] In another thyroid-related condition known as the Van Wyk and Grumbach syndrome, long-standing hypothyroidism can lead to large ovarian cysts. TSH levels are extremely high and several theories hypothesize a crossover hormonal effect on FSH or direct stimulation of the ovary by TSH. CA-125 and LDH levels may be elevated. The ovarian cysts resolve with thyroid replacement therapy.[219]

# Summary

The diagnosis and management of ovarian lesions in infants and children remains a challenge because of the wide variety of possible pathologies, some of which are extremely rare. Nonneoplastic lesions are being detected more commonly as imaging techniques continue to improve. Neoplastic lesions are more readily diagnosed and completely characterized with advances in biochemical, immunohistologic, and cytogenetic technology.

Because of the relative rarity of ovarian tumors in children, clinical approaches may be based on experience with similar adult lesions. However, it is critical to recognize the differences exhibited by the juvenile forms of many of these entities, which often present at a less advanced stage and have a more favorable natural history and response to therapy. Preservation of reproductive and endocrine function is of paramount importance in the treatment of ovarian lesions in infants and children. Careful observation or nonoperative therapies may be appropriate for many nonneoplastic conditions. Most benign neoplasms are adequately managed with conservative surgical approaches. Even frankly malignant tumors increasingly yield to multimodal therapy, which can include less radically ablative surgery and still result in long-term survival and possible preservation of fertility for young patients.

CHAPTER 40

# Testicular Tumors

Bryan J. Dicken and Deborah F. Billmire

Historically, prepubertal malignant testicular tumors were managed using the same treatment protocols as their adult counterparts, with radical orchiectomy and retroperitoneal lymph node dissection (RPLND) weighing heavily in the treatment pathway.[1,2] However, with growing clinical evidence, it became clear that prepubertal tumors differed from the postpubertal population not only in presentation but differed in terms of clinical behavior, incidence, histologic diagnosis, and prognosis.[1–6] In recognition of the differences in this population of patients, the Prepubertal Testis Tumor Registry (PTTR) of the urologic section of the American Academy of Pediatrics was established in 1980 to better delineate the natural history of these lesions and to document their response to therapy.[1,2,4] Since its inception, several important features have emerged that have significantly altered the management of testicular tumors in the pediatric population. The management has been further clarified by a series of recent multicenter clinical trials of the most common malignant tumors of the prepubertal testis.[7–12]

The results of the PTTR confirmed that testicular tumors in children are rare, making up approximately 1% to 2% of all pediatric solid tumors, with an incidence of 0.5 to 2/100,000 among whites, while African-American males appear somewhat protected, with an incidence of 0.25/100,000.[1–3,13] Asian/Pacific Island males have a 1.4-fold increased risk of testicular tumors compared with whites.[14] In contrast to adult testicular cancer, which has experienced a marked increase in incidence, pediatric testicular tumor incidence has been stable during the past 30 years.[15] Testicular tumors are 10 times more frequent in the postpubertal cohort compared with boys younger than 12 years of age.[1] Furthermore, epidemiologic data from several sources suggest a bimodal distribution, with a small distinct peak in the first 3 years of life, followed by a large peak in adolescents (15 to 18 years).[2,3] The majority of testicular tumors in the postpubertal age group are malignant, with 90% to 95% demonstrating histologic features of either seminoma or mixed germ cells.[2,6] Initially, the PTTR reported that the yolk sac tumor (62%) was the most common prepubertal testicular tumor, with benign tumors occurring much less commonly.[1,2,13] However, a landmark paper by Metcalfe and colleagues[13] suggested that the PTTR registry and the Armed Forces Institute of Pathology American Tumor registry are subject to reporting bias, with overreporting of malignant tumors and failure to capture the benign tumors. In a series of articles that followed, 74% to 87% of tumors identified were benign, with teratoma making up 43% to 48%, while malignant yolk sac tumors constituted only 15%.[1,5,6,13] Recognition of this fact led to a marked reassessment of the management of testicular tumors in the prepubertal population.

## Risk Factors for Testicular Cancer

Although a number of risk factors have been proposed regarding the occurrence of testicular tumors, to date only a few may be considered as “established” based upon a sufficient level of evidence.[16] Other associations that have historically been considered important etiologically have since been refuted. Only four factors have sufficient evidence that links them “highly” with testicular cancer: (1) undescended testis (cryptorchidism), (2) contralateral testicular germ cell tumor (GCT), (3) familial testicular germ cell tumor, and (4) gonadal dysgenesis.[16,17] Associations that may be considered “likely” include infertility, twin-ship, and testicular atrophy. Clinical factors with equivocal/low association include scrotal trauma, inguinal hernia, mumps orchitis, testicular torsion, maternal estrogen exposure, and occupational exposure. Parameters that have historically drawn attention but have since been shown to be irrelevant include obesity, vasectomy, smoking, hydrocele, varicocele, alcohol, and circumcision.[16]

Cryptorchidism occurs in 2% to 5% of term infant males; however, by 12 months of age, this number is reduced to 1%.[18] To date, cryptorchidism is the only factor that has level I evidence linking it with testicular cancer. A meta-analysis of 20 case control studies showed a strong association between undescended testis (UDT) and testicular cancer, with an overall relative risk of 4.8.[16] Similarly, Walsh and colleagues[19] showed boys who underwent orchiopexy after 10 years of age had a 3.5-fold increased risk of testicular cancer, compared with those that had the procedure at an earlier age. In a population-based prospective observational study, Pettersson and colleagues followed 16,983 men treated for UDT for a mean period of $12.4 \pm 7.4$ years.[20] This study demonstrated two important findings. There was an increased risk of testicular cancer for the entire cohort (relative risk [RR] = 2.23) versus normal population figures, and the incidence of cancer was significantly higher (RR = 5.4) in those who were

treated after the age of 13 years.[20] The lowest incidence of cancer was seen in children who underwent orchiopexy before the age of 6 years (RR = 2.02). Orchiopexy before the age of 10 to 12 years results in a twofold to sixfold relative risk decrease in testicular cancer in children with unilateral UDT.[21] Because of the increased risk of malignancy, patients with UDT seen after age 10 may still be candidates for orchiopexy with close surveillance; however, consideration of testicular biopsy may be useful in directing therapy. The decision of timing for orchiopexy should include consideration not only of an effort to reduce the incidence of testicular cancer, but also a consideration of the possibility of spontaneous descent and the evidence regarding preservation of fertility. Canavese and colleagues demonstrated an inverse relationship between age at orchiopexy and total sperm counts and sperm motility, and they recommended orchiopexy during the first year of life.[22] Taking all factors into account, consideration should be given to orchiopexy in all children if complete descent has not occurred by 12 months of age.[21]

## Clinical Presentation

The most common presentation of a testicular tumor is a nontender scrotal mass, accounting for 50% to 85% of cases.[5,6,13,23] The presentations of children that were subsequently diagnosed with a prepubertal tumor have included trauma and persistent swelling (3%), hydrocele (10%), epididymitis (13%), incidental discovery during surgical repair of a congenital or acquired disorder (53%), testicular pain/torsion (21%), and bruising.[5,6,13,23] Tumors may also be diagnosed by ultrasonography during investigations for UDT or nonresolving acute hydroceles.

Physical examination should differentiate between those problems arising from the cord (varicocele, spermatocele, epididymitis) and those arising from the testicle (trauma, orchitis, tumor). There may be bruising or a hydrocele present that may confound the diagnosis, because both of these findings may coexist with a tumor. This is particularly true in cases where preceding trauma draws attention to the scrotal area. Careful evaluation of the child's pubertal status relative to their chronologic age is important, because stromal cell tumors may present with precocious puberty (Leydig cell) or gynecomastia (Sertoli cell).

## Diagnosis

In addition to a history and physical examination, all boys with testicular masses, and those with a tense hydrocele or with a suspicious examination, should undergo a scrotal ultrasound. Although preoperative ultrasound is highly sensitive for distinguishing intratesticular from extratesticular tumors, it has poor specificity to distinguish between benign and malignant lesions.[5,13,24] Tumor size (volume) on ultrasonography has not been shown to be indicative of benign or malignant tumors.[5] Sonographic features suggestive of benign tumors (epidermoid cyst) include intratesticular cystic lesions with a hypoechoic center, representing central keratinizing debris, and an outer hyperechoic rim. Features of a teratoma may include an entirely intratesticular cystic, septated mass with intervening solid components with calcifications (bone or psammoma bodies).[13] This contrasts with malignant lesions, which tend to be more solid in appearance. In cases where malignancy is suspected, computed tomography (CT) of the chest, abdomen, and pelvis should be obtained to exclude metastatic disease to the most common sites—lung and retroperitoneum.[2,4]

## Tumor Markers

Serum tumor markers are essential in the workup and postoperative monitoring of children with testicular tumors. Human chorionic gonadotropin (HCG) and α-fetoprotein (AFP) are important markers for certain malignant germ cell histologies.[2] AFP is secreted by yolk sac tumors in up to 90% of cases, and β-HCG is secreted by choriocarcinoma. HCG has a half-life of 24 hours, whereas AFP has a half-life of 5 days. In the prepubertal age group yolk sac tumors are the most common malignant histology, and AFP is very important, whereas HCG is rarely elevated. An important consideration is that AFP is normally very high in infancy, and remains elevated for up to 8 months, decreasing to adult levels around 1 year of age.[2,23] Older boys are more likely to have malignant germ cell tumors of mixed histology, and both AFP and HCG may be elevated. For those patients with elevated tumor markers at diagnosis, serial AFP and HCG should be monitored monthly in the first postoperative year, then every other month in the second year to follow current recommendations.[25] Patients presenting with precocious puberty and a testicular mass should prompt assessment of a urinary 17-ketosteroid, serum luteinizing hormone (LH), follicle-stimulating hormone (FSH), and testosterone. Unlike precocious puberty induced by a pituitary lesion, in which the LH, FSH, and testosterone are high, testicular tumors display a low LH and FSH and a high testosterone.

## Classification and Stage

Table 40-1 lists the histologic diagnoses for prepubertal testicular tumors from several institutions, and the diagnoses are compared with the 2002 AAP tumor registry.[1,13,26] This table demonstrates the reporting bias of the national tumor registry and the population-based distribution of all testicular tumors. Table 40-2 outlines the Children's Oncology Group (COG) testicular tumor staging system.[7]

### PRIMARY TESTICULAR TUMORS

#### Epithelial-Based Tumors

***Epidermoid Cysts*** The epidermoid cyst is a benign tumor, accounting for 2% to 14% of testicular tumors in the prepubertal population.[1,5,13] They are hormonally inactive and typically present as a smooth, firm intratesticular mass. The tumor consists of a cystic structure filled with keratinizing squamous epithelium, contributing to a characteristic ultrasound appearance: central hypoechoic mass, a surrounding echogenic rim, or a mixed internal echogenicity.[27,28] Epidermoid cysts are rare, making up only 1% of testicular tumors.

**TABLE 40-1**

**Differences in Distribution of Testicular Tumors Based on Tumor Histology among Study Sites**

| *Tumor Type* | *2002 Registry %* (N = *395)* | *Pohl %* *(N = 98)* | *Metcalfe %* (N = *51)* | *Ciftci %* (N = *51)* |
|---|---|---|---|---|

**TABLE 40-2**

**Staging of Testicular Malignant Germ Cell Tumors**

| **Testicular Stage** | |
|---|---|
| I | Limited to testis, completely resected by high inguinal orchiectomy; no clinical, radiologic, or histologic evidence of disease beyond the testis; tumor markers normal after resection |
| II | Transscrotal orchiectomy; microscopic disease in scrotum or high in spermatic cord; retroperitoneal node involvement (<2 cm) and/or increased tumor markers after resection |
| III | Gross residual disease, retroperitoneal lymph node involvement (>2 cm), or malignant cells in pleural or peritoneal fluid |
| IV | Distant metastases involving lung, liver, brain, bone, distant nodes, or other sites |

From Cushing B, Giller R, Cullen JW, et al: Randomized comparison of combination chemotherapy with etoposide, bleomycin, and either high-dose or standard-dose cisplatin in children and adolescents with high-risk malignant germ cell tumors: a pediatric intergroup study—Pediatric Oncology Group 9049 and Children's Cancer Group 8882. J Clin Oncol 2004;22:2691-2700.

These cysts lack atypia and mitotic activity. Although some epidermoid cysts show loss of heterozygosity for certain chromosomal loci, there is currently debate as to whether they represent a true neoplasm.[29]

## Stromal Tumors

***Sex Cord-Stromal Tumors*** The stromal tumors consist of three subtypes: Leydig cell, Sertoli cell, and juvenile granulosa cell tumors. This group of tumors accounts for 8% to 11% of pediatric tumors.[1,13] The vast majority of stromal tumors are benign, compared with a 10% rate of malignancy in postpubertal males.

Leydig tumors and granulosa cell tumors are universally benign in children. Leydig cell tumors tend to present in boys 5 to 10 years of age and with precocious puberty.[2] The precocious puberty is a peripherally driven etiology; therefore, the hormone profile consists of a low luteinizing hormone (LH), low follicle-stimulating hormone (FSH), and elevated testosterone. Granulosa cell tumors are rare in children and occur almost exclusively in the first 6 months of life. Chromosomal anomalies of the Y chromosome are common, and granulosa cell tumors have occurred in association with ambiguous genitalia.[2] Because of the benign nature of both Leydig and granulosa cell tumors, both can be treated with either orchiectomy or tumor enucleation in the prepubertal population.[30]

Approximately 10% of adult Sertoli cell tumors are malignant, whereas malignancy is rare in prepubertal males. Review of the PTTR showed a median age of presentation of 6 months, with no cases of malignancy reported in children less than 5 years of age.[31] Therefore complete excision of the tumor is adequate treatment in infants and young children. Presently there are no histologic criteria to predict tumor behavior in older children; however, a full metastatic evaluation should be considered if there is microscopic invasion of the spermatic cord,[31] or worrisome findings, such as a large tumor, necrosis, vascular invasion, cellular atypia, or increased mitotic activity.[2] Large cell calcifying Sertoli cell tumors are histologically distinct tumors occurring in older children and adolescents. One third of these patients have an associated genetic syndrome or endocrinopathy, most commonly, Peutz-Jeghers and Carney syndromes (myxoma of the skin, soft tissue, heart or breast, lentigines of the face and lips, cutaneous nevi, pituitary adenoma, and schwannoma).[2] They have been universally benign in patients less than 25 years of age and may be treated with testis-sparing procedures. Bilateral or multifocal disease is present in 25% of cases, increasing the need for this approach.

## Germ Cell Tumors

***Teratoma*** Testicular teratoma is the most common germ cell tumor in prepubertal males according to recent literature.[1,5,6,13] These tumors are invariably benign, unlike the adult population, where 90% to 95%[6] of germ cell tumors are malignant.[32] Teratomas are typically pure; derived from ectoderm, mesoderm, and endoderm; have diploid DNA; and a normal 46 XY karyotype.[29,32] The tissue arrangement is often organized with a gross solid cystic appearance. Dermoid and epidermoid cysts analogous to the prepubertal teratomas occur in the postpubertal testis. The testicular dermoid, like the ovarian dermoid, contains hair within a cystic tumor, and microscopic replication of skin without cellular atypia or widespread mitotic activity. The adjacent testis has normal spermatogenesis.[29] The finding of pilosebaceous units in an epidermal surface, occasionally with a lipoid reaction resulting from leakage of oil from the sebaceous glands, is a prerequisite for diagnosis of a testicular dermoid.

***Yolk Sac Tumor*** The yolk sac tumor comprised approximately 60% of the tumors historically reported in the AAP registry.[2] However, recent population-based studies, including benign testicular tumors, now report the incidence of yolk sac tumors to be 8%[13] to 15%.[1] Most of the yolk sac tumors occur in boys less than 2 years of age, but they are rare in the first 6 months of life. This is important in differentiating this tumor from the juvenile granulosa cell tumor (see previous section).[32] The majority of patients (84.5%) identified in the PTTR presented with localized stage I disease.[33] Prepubertal patients are less likely than adults to have metastasis limited

to the retroperitoneum. In a review of the PTTR of the American Academy of Pediatrics, 15.5% of boys with yolk sac tumors presented with metastatic disease. The reported sites included retroperitoneum (27%), retroperitoneal and hematogenous spread (18.8%), chest (24%), lung and an additional hematogenous site (12%), scrotum (3%), and 2% were not documented.[33]

Elevated AFP levels in excess of age-adjusted levels in the context of a testicular mass should raise suspicion of a yolk sac tumor, and the child should be managed with a standard radical inguinal orchiectomy (see later).

Grossly, the tumor is a soft solid, white to grey, or pale yellow mass with cystic degeneration containing areas of necrosis and hemorrhage. Microscopically, the yolk sac tumor characteristically contains solid papillae with a connective tissue core containing a central vessel projecting into cystic spaces; these structures are referred to as Schiller-Duval bodies.[32] The tumor invariably stains positive for AFP and placenta-like alkaline phosphatase.

***Embryonal Carcinoma*** Embryonal carcinoma is a relatively common testicular germ cell tumor after puberty; 10% are pure embryonal tumors, and a substantial number of tumors will have a mixed embryonal component.[29] This tumor demonstrates distinctive sheets, glands, and papillary structures composed of primitive epithelial cells with crowded pleomorphic nuclei. In poorly differentiated tumors, positive immunostains for CD30 and OCT3 with a c-KIT–negative profile are helpful in confirming an embryonal carcinoma.[32] Embryonal carcinoma is treated with orchiectomy. Tumors composed of more than 80% embryonal cell carcinoma or with elevated preoperative AFP (>10,000 mg/mL), vessel invasion in the primary tumor, and tumors of stage T2 or greater are considered high risk and are treated with postoperative chemotherapy and close follow-up.[34]

***Gonadoblastoma*** Gonadoblastoma has classically been identified in patients with mixed gonadal dysgenesis (45,X/46,XY), and is likely related to the presence of the testis-specific protein-Y–encoded gene (TSPY).[35] The ectopic location of the testis adds to this risk. The most commonly encountered invasive tumor in the intersex gonad is the seminoma. The development of these invasive tumors is always preceded by the presence of an in situ neoplastic lesion—intratubular germ cell neoplasia unclassified (ITGNU) or gonadoblastoma.[35,36] ITGNU is commonly referred to as carcinoma in situ (CIS). Because gonadectomy is performed prophylactically in early childhood in patients with gonadal dysgenesis, most of the encountered germ cell tumors are benign or CIS lesions. The overall prevalence of germ cell tumors in dysgenetic gonads is 15%, which is much lower than the previously reported prevalence of 33%.[35] The tumor presents with virilization of a phenotypic female harboring an XY karyotype.[37]

Gonadoblastoma typically arises from an intraabdominal testis in a young patient with gonadal dysgenesis. It is usually small, bilateral in 30% of cases, malignant in 10%, and histologically resembles a seminoma. Available data suggest the gonad of origin to include dysgenetic testis in 20%, streak gonad in 26%, and an undifferentiated gonad in 54%.[36] Extension beyond the testis has not been reported. Management has traditionally involved bilateral gonadectomy because of the risk of degeneration into an invasive seminoma. However, the recognized role of testosterone in gender differentiation has led to a more conservative approach to the contralateral gonad, which may involve a contralateral orchiopexy to allow gender development, followed by annual scrotal examinations and ultrasonography after age 10 years until puberty. At puberty, testicular biopsy should be carried out to evaluate for CIS in the remaining testicle.[38] If no evidence of CIS is identified, annual follow-up with testicular ultrasonography until age 20 is recommended. If CIS is identified at puberty, orchiectomy should be considered.[38]

***Choriocarcinoma*** Choriocarcinoma is among the rarest of the gonadal germ cell tumors, representing 0.3% of testicular tumors.[29] These tumors elaborate β-HCG, and may be associated with a number of hormonal manifestations. These include precocious puberty from β-HCG–induced Leydig cell stimulation, gynecomastia, and hyperthyroidism because of the similarity of the β-HCG subunits to thyroid-stimulating hormone.[29] Testicular choriocarcinomas frequently have distant metastasis at the time of presentation rather than a scrotal mass. Histologically, they are composed of syncytiotrophoblastic cells with mononucleated cells around foci of hemorrhage. They stain positive for β-HCG and placental lactogen.[32]

### Rhabdomyosarcoma

Although technically a paratesticular tumor, rhabdomyosarcoma should be included in the differential diagnosis of scrotal tumors. It is the most frequent tumor of paratesticular origin, accounting for 4% to 25% of scrotal masses.[13] The tumor has a bimodal distribution, peaking between 3 to 4 months of age and 15 to 19 years of age. The infant tumor has a more indolent behavior than the tumor presenting in the adolescent age group (90% vs. 63% failure-free survival).[39] Despite its aggressive behavior, the prognosis of paratesticular rhabdomyosarcoma has improved dramatically from 10% to 77% overall survival with the introduction of vincristine, dactinomycin, and cyclophosphamide (VAC) chemotherapy.[39,40] The most common subtype is embryonal rhabdomyosarcoma, which accounts for 97% of paratesticular tumors.

The tumor consists of small round blue cells and presents as a scrotal mass in 80% of patients. Ultrasonography is highly effective in demonstrating its paratesticular location and distinguishing it from the tumors of testicular origin.[13] CT or MRI of the retroperitoneum should be performed prior to surgery for staging purposes. Thirty to 40 percent of boys will have micrometastasis to the retroperitoneum. The tumor should be resected by a radical inguinal orchiectomy. A retroperitoneal lymph node dissection (RPLND) is recommended for all patients 10 years of age or older for accurate staging, and in patients less than 10 years with radiologic evidence of retroperitoneal involvement.[39] A metastatic workup should include a chest CT, liver function tests, bone scan, and bone marrow biopsy.

## SECONDARY TESTICULAR TUMORS

Lymphoma and leukemia are the dominant secondary tumors of the testis. Acute lymphoblastic leukemia (ALL) is a common cause of a prepubertal testicular mass. Microscopic

involvement of the testis has been found at autopsy in 66% of patients with ALL.[32] Malignant lymphomas account for 5% of testicular tumors; 10% to 15% are bilateral at presentation.[32]

The management of leukemia and lymphoma are the same. The presence of a palpable mass in a patient with newly diagnosed leukemia/lymphoma should prompt a scrotal ultrasonography. This usually demonstrates a homogeneous hypoechoic mass. Current literature discourages testicular biopsy in patients prior to initiating chemotherapy, because there is no survival advantage.[41] In contrast, a patient with persistent or newly enlarged testis undergoing chemotherapy, particularly in leukemia, implies a relapse while on therapy. This should prompt a biopsy to direct subsequent therapy. This typically involves additional chemotherapy to eradicate residual disease in sanctuary sites and possible systemic residual disease and radiation to the affected testis.

In 25% of cases, testicular lymphoma is a manifestation of widespread systemic involvement, another 25% present with Ann Arbor stage II disease (involvement of lymph nodes below the diaphragm), and the remaining 50% have disease confined to the testis (Ann Arbor stage I).[32]

Metastasis to the testis in children is rare. The most frequent metastasis has been carcinoma from the prostate, colon, kidney, stomach, pancreas, and malignant melanoma in adults, while neuroblastoma and Wilms tumor predominate in children.[32] Most of these tumors have distinctive features that allow easy identification.

# Surgical Management

## TESTIS-SPARING SURGERY

In the last 2 decades, multiple reports have confirmed that many testicular tumors in the prepubertal population can be managed more conservatively than in adults, because the distribution of prepubertal tumors favors a benign histology. This realization has confirmed the safety and feasibility of testis-sparing surgery, especially when the lesion is evaluated preoperatively by ultrasonography and serum AFP and intraoperatively by frozen section analysis. Metcalfe and colleagues[13] have provided a practical treatment algorithm incorporating the common benign tumors for nonradical surgery (Fig. 40-1).

In general, before puberty, teratoma, gonadal stromal tumors (Leydig cell and Sertoli cell) and epidermoid cyst can be managed with a testis-sparing approach (Fig. 40-2). Postpubertal patients with teratoma or stromal tumors should be treated as adults, with radical orchiectomy because of their more malignant behavior.

Testis-sparing surgery is carried out through an inguinal incision. The cord is mobilized after opening the external oblique aponeurosis to the level of the internal ring. The cremasteric fibers are dissected from the cord structures to allow circumferential control of the cord. The cord should be occluded at the level of the internal ring with a noncrushing clamp. The testis is then delivered through the inguinal incision, and the wound is protected. The tunica vaginalis is opened directly over the mass, and an excisional biopsy of

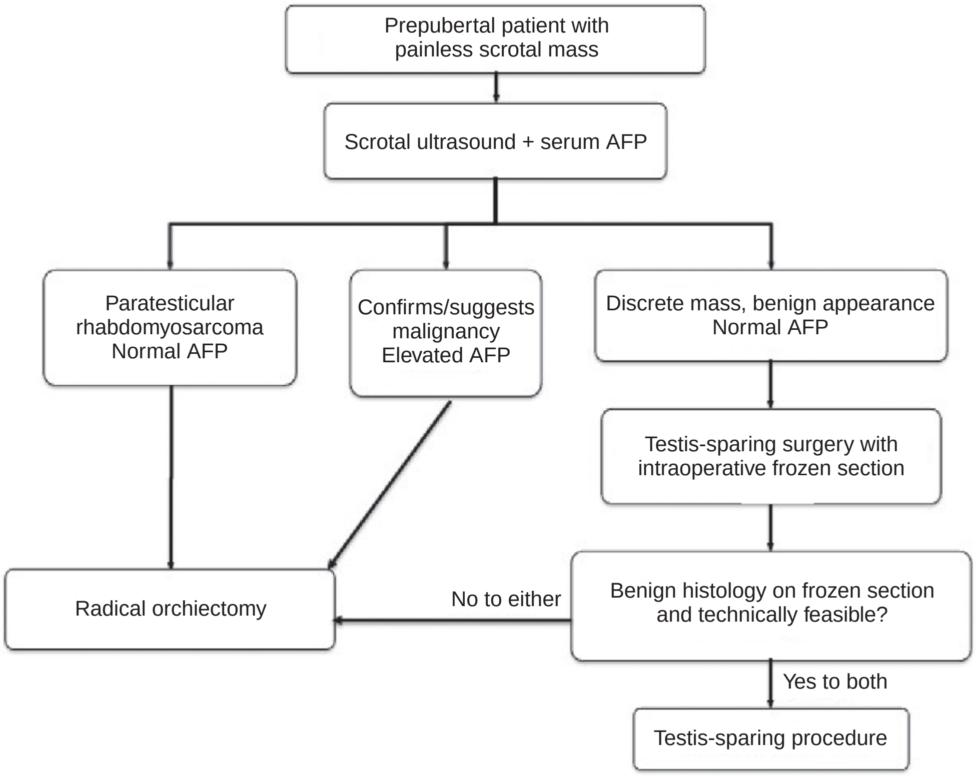

**FIGURE 40-1** Proposed treatment algorithm for prepubertal patients presenting with a painless scrotal mass. AFP, α-fetoprotein. (From Metcalfe PD, Farivar-Mohseni H, Farhat W, et al: Pediatric testicular tumors: Contemporary incidence and efficacy of testicular preserving surgery. J Urol 2003;170:2412-2415; discussion 2415-2416.)

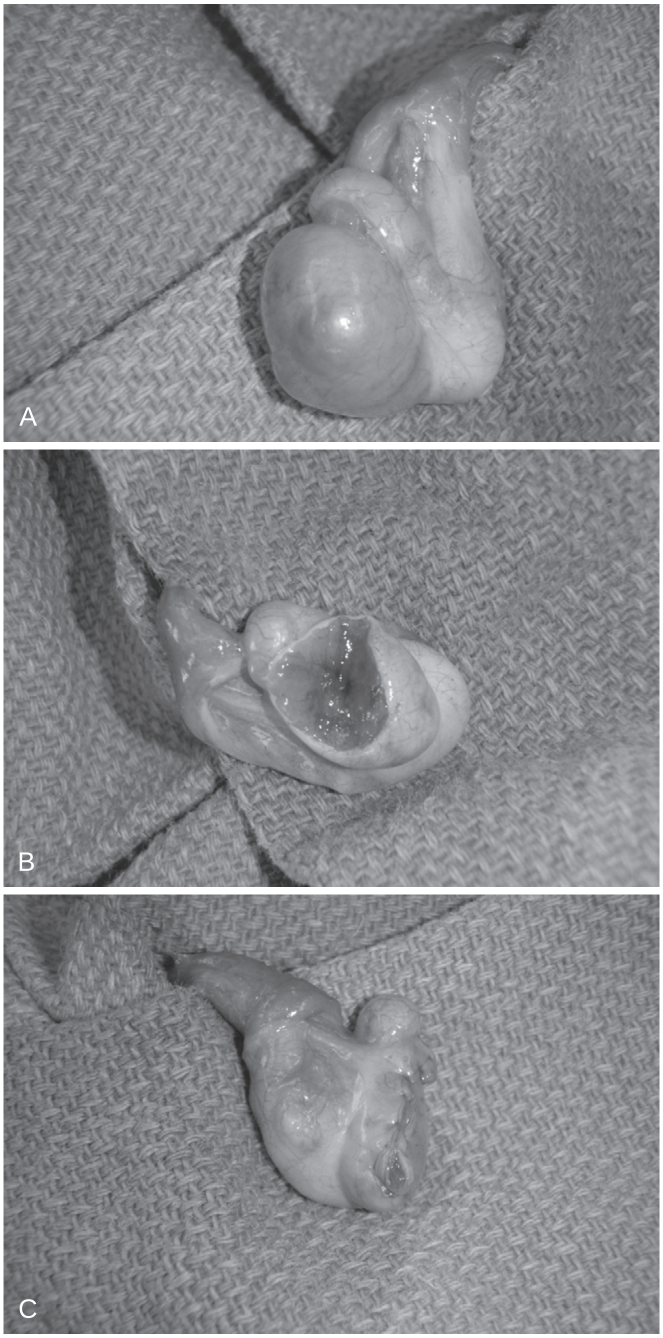

**FIGURE 40-2** **A,** Intraoperative photograph of a child with painless swelling of testicle. **B,** Wedge resection of epidermoid cyst. **C,** Suture closure of testicular capsule. (Courtesy Dr. P. Metcalfe, personal file.)

the mass is performed without violating the tumor capsule. Frozen section evaluation is obtained. Hemostasis is achieved with electrocautery. If a benign testicular tumor is diagnosed, the tunica vaginalis is closed with fine absorbable sutures (see Fig. 40-2), and the testis is replaced in the scrotum. Normal tissue adjacent to the tumor must be assessed by a pathologist to exclude pubertal changes. It is commonly assumed that the postpubertal testis with a tumor will behave in a similar fashion to the adult testis, although specific data are lacking. Adult testicular tumors are associated with intratubular germ cell neoplasia (ITGCN) in the surrounding parenchyma in more than 90% of cases. These cells are the precursors for germ cell tumors and are felt to represent a risk for recurrent neoplasia if the residual testicular parenchyma is left in situ. The progression through puberty evolves over a period of time and sequential histologic changes. The testes go through a maturation process starting from simple tubules without lumen and with interstitial Leydig cells in the neonate. The Leydig cells then regress and the tubules become more tortuous. As puberty begins, the Leydig cells become more prominent, and the basal germ cells begin to divide. There are multiple layers of spermatocytes and the tubule lumens form, followed by the appearance of mature sperm. The appearance of mature sperm or ITGCN would be indicative of completion of pubertal changes.

## RADICAL INGUINAL ORCHIECTOMY AND RETROPERITONEAL LYMPH NODE DISSECTION

A radical inguinal orchiectomy is performed through a standard inguinal incision, with clear demarcation of the external oblique aponeurosis and external ring and opening of the external ring back to the level of the internal ring. The cremasteric fibers are once again dissected from the cord, and the cord is fully mobilized from the inguinal canal, followed by vascular control at the internal ring. The cord is then clamped and divided at the level of the internal ring, after which the stump is suture ligated. After ligation, dissection proceeds distally with mobilization of the testis from the scrotum and division of the gubernaculum. If the tumor is too large to deliver through the scrotal canal, the incision may be carried onto the superior aspect of the scrotum.[42,43] Once the tumor is excised, the wound is closed in standard fashion.

Current pediatric testicular tumor protocols do not include a RPLND. Postchemotherapy masses are treated with local resection. Postpubertal patients will often be managed with adult protocols, although data regarding adolescents is lacking. The indications for and the extent of RPLND are a matter of some controversy even in adults. Prechemotherapy RPLND is no longer employed, and postchemotherapy RPLND is eliminated in some centers if residual disease is less than 1 cm in dimension by imaging.[44] In the event that a RPLND is required, a midline abdominal incision is made and a thorough laparotomy performed to identify retroperitoneal low-volume metastasis not appreciated on preoperative imaging. There is also controversy regarding the extent of dissection. Because of the morbidity of bilateral RPLND (40%), a variety of unilateral templates have been developed in addition to the concept of nerve-sparing dissection.[45,46] In low-stage disease, lymphatic spread is typically unilateral, and therefore a full bilateral RPLND is not used in some centers.[47] For the unilateral template, dissection for patients with right-sided disease involves removal of the lymphatics in the interaortocaval, precaval, and right paracaval distribution (Fig. 40-3, *A*).[43] For left-sided lesions, this includes the left paraortic and preaortic lymphatics (Fig. 40-3, *B*). This dissection strategy is important, because it preserves the contralateral sympathetics important for emission and ejaculation.[48] Preservation of efferent sympathetic fibers maintains emission and ejaculation rates at 99%.[48] The finding of viable tumor outside of the template distribution has led to the recommendation for bilateral dissection

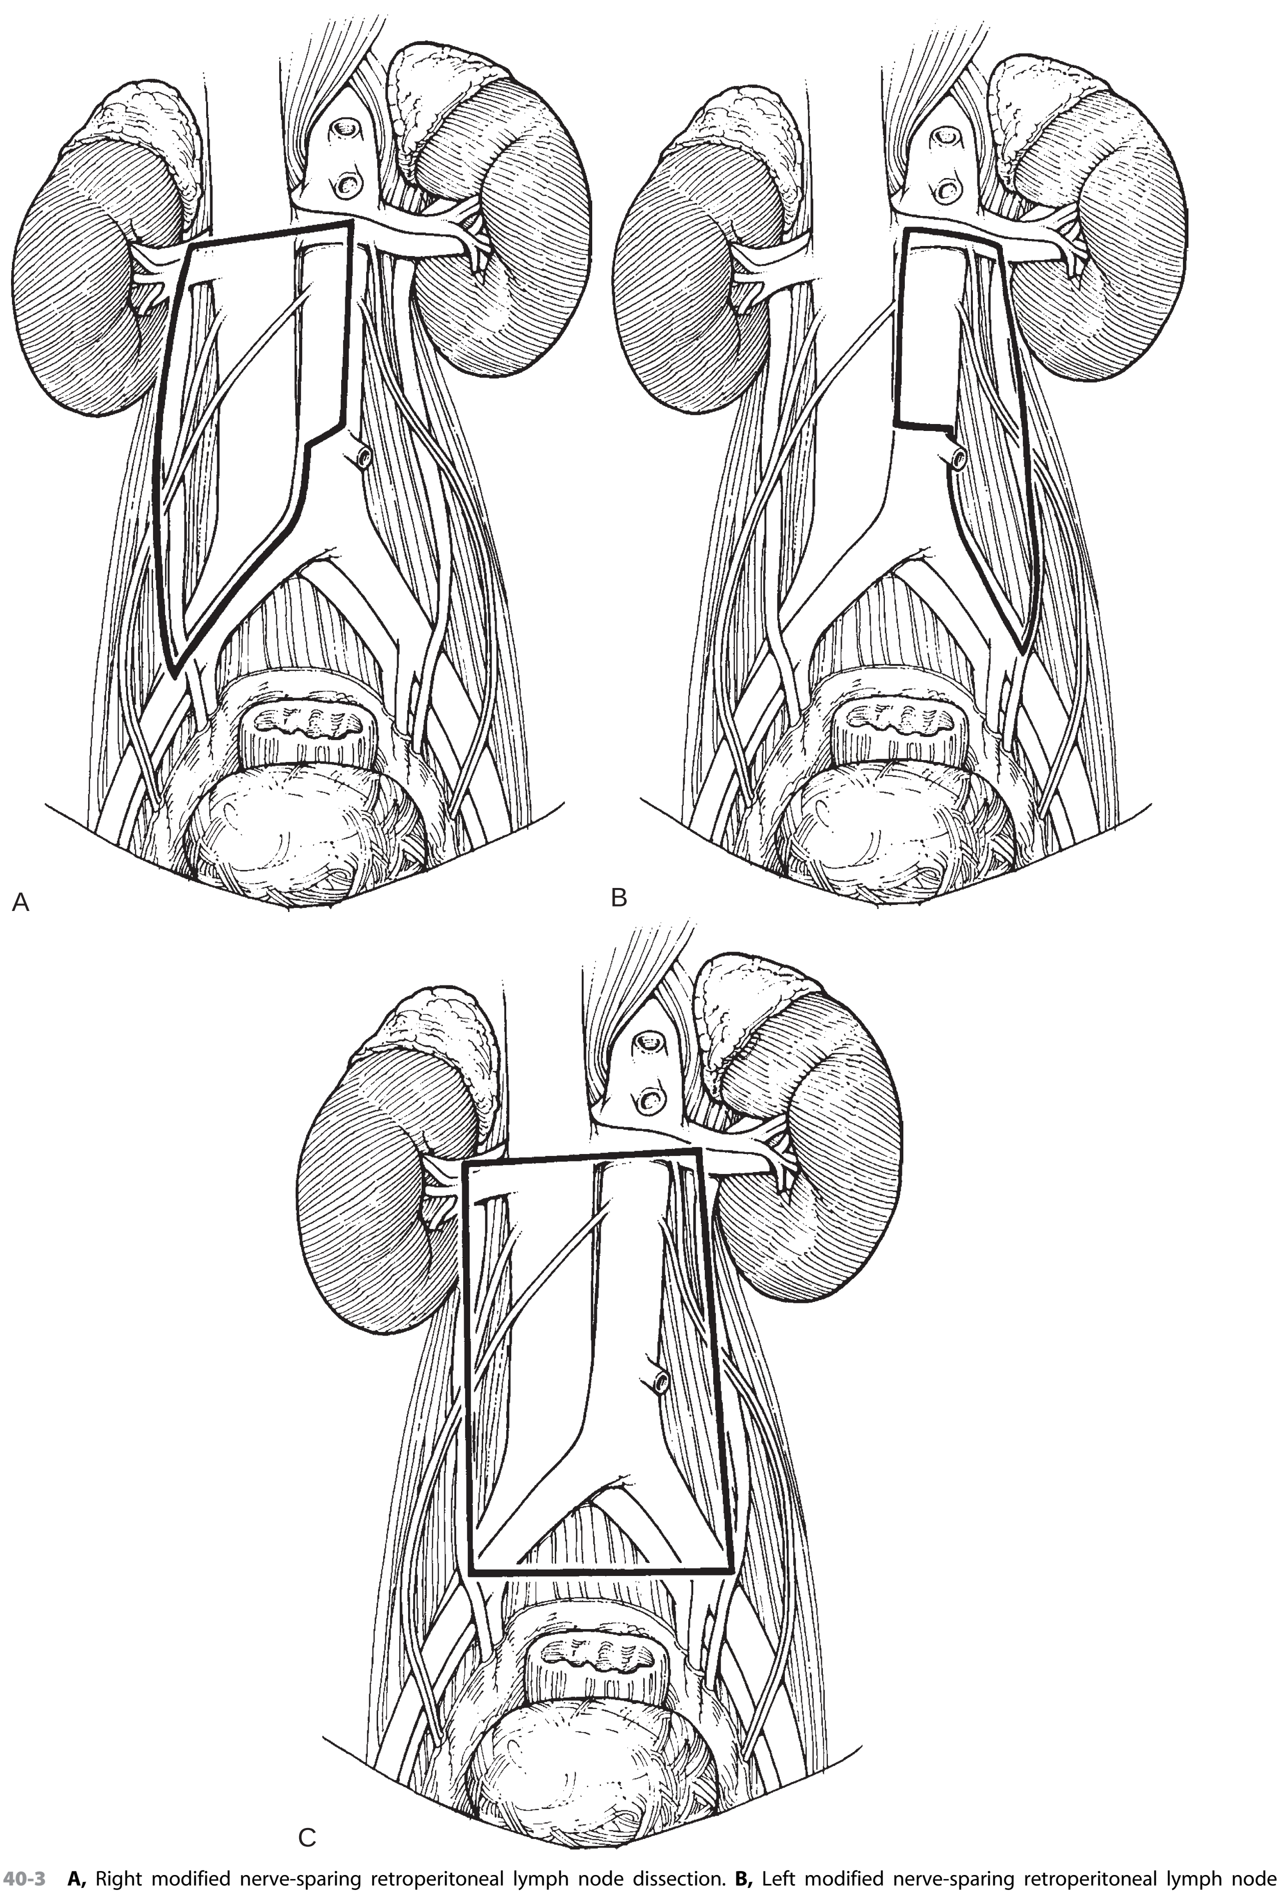

**FIGURE 40-3** **A,** Right modified nerve-sparing retroperitoneal lymph node dissection. **B,** Left modified nerve-sparing retroperitoneal lymph node dissection. **C,** A full retroperitoneal dissection involves left and right combined. (From Marshall FF [ed]: Operative Urology. Philadelphia, WB Saunders, 1996, p 368-369.)

in all patients undergoing RPLND in other centers.[46] In advanced-stage/high-volume disease bilateral RPLND is always used, as shown in Figure 40-3, *C*.[45] With either technique, the nodal packets are split at the 12 o'clock position over the vessels and rolled laterally away. The sympathetic fibers are carefully identified and preserved as they cross the iliac bifurcation.

## CHEMOTHERAPEUTIC STRATEGIES AND SURVIVAL IN CHILDREN WITH MALIGNANT GERM CELL TUMORS

Prior to effective chemotherapy, children with malignant germ cell tumors (MGCT) had 3-year survival rates of 15% to 20% with surgery and radiation.[7,49] The introduction of cisplatin-based regimens has dramatically improved outcomes (Table 40-3).[11] In patients with low- and intermediate-risk (<15 years of age) MGCT, the 6-year overall survival rates for advanced gonadal tumors (stages III and IV) are now greater than 94%.[7] Standard chemotherapy for children with MGCT of the testes includes standard-dose cisplatin, etoposide, and bleomycin (PEB) for 4 to 6 courses.[2] The current protocol under investigation examines stages II to IV with three courses of chemotherapy. Management of patients is based upon risk groups as proposed by the Children's Oncology Group (COG) as follows (see Table 40-3)[11]:

1. **Low risk:** Stage I immature teratoma and MGCT of the testis. Recommend surgery and close follow-up observation to document normalization of tumor markers following resection
2. **Intermediate risk:** Stages II-IV gonadal tumors (excluding patients >15 years with stage IV testicular tumors).

**TABLE 40-3**
**Standard Treatment for Children Younger Than 15 Years with Testicular Germ Cell Tumors by Histology and Stage**

| *Histology* | *Stage* | *Treatment* | *Overall Survival (6-Year)* |
|---|---|---|---|
| Mature teratoma | Localized | Surgery + observation | 100% |
| Immature teratoma | Localized | Surgery + observation | 100% |
| MGCT | Stage I | Surgery + observation | 100% |
| | Stage II-IV* | Surgery + PEB | 94% |

CHAPTER 41

# Adrenal Tumors

Michael G. Caty and Mauricio A. Escobar, Jr.

## Anatomy

The adrenal glands are found anteromedially to the superior pole of the kidneys, are covered by perirenal fat, and enclosed by Gerota fascia. In adults, the glands weigh approximately 5 g each. The right gland abuts the inferior vena cava and liver and lies on the posterior extension of the diaphragm. The left gland lies next to the splenic vessels and the tail of the pancreas.

Although the blood supply to the adrenal glands is variable, it generally comes from three sources: the inferior phrenic artery superiorly, the aorta medially, and the renal arteries inferiorly. The venous drainage does not parallel the arterial supply; instead, a single large adrenal vein provides the majority of the venous drainage for each gland. The right adrenal vein empties into the inferior vena cava, and the left adrenal vein joins the left renal vein.

The adrenal lymphatics arise from one plexus beneath the capsule and from a second plexus in the medulla. The right adrenal lymph vessels drain into the periaortic lymph nodes near the diaphragmatic crus, and the left adrenal lymphatics empty into lymph nodes near the origin of the left renal artery.

The innervation of the adrenal glands arises from the celiac plexus and the greater thoracic splanchnic nerves. The preganglionic sympathetic fibers enter the hilum and end in ganglia within the medulla.

The cortex and medulla form two distinct regions of the adrenal gland. These regions are distinct on gross examination as well as embryologically, structurally, and functionally. The adrenal medulla is derived from ectodermal cells from the neural crest. These precursors form the chromocell system and the neuronal system, accounting for the potential development of two distinct medullary neoplasms: pheochromocytoma and neuroblastoma. Preganglionic sympathetic neural cells innervate the secretory chromaffin cells, which synthesize norepinephrine and epinephrine.

The cortex comprises the outer portion of the adrenal gland and secretes sex hormones, mineralocorticoids, and glucocorticoids. It is divided into three separate zones that have distinct synthetic functions. The zona glomerulosa is the outermost cortical zone and produces aldosterone and related mineralocorticoids. The zona fasciculata lies beneath the zona glomerulosa and secretes cortisol and the adrenal sex hormones. The inner zona reticularis maintains cholesterol stores as a precursor for steroidogenesis and secretes cortisol, androgens, and estrogens.

## Embryology

The primordium of the adrenal cortex becomes visible as early as the fourth week of gestation and is clearly seen by the sixth week. On prenatal ultrasonography (US), the adrenal glands may be visible as early as 20 weeks' gestation and are identifiable in the majority of fetuses by 30 weeks' gestation.[1] During the fourth to sixth weeks of gestation, the mesodermal cells of the posterior abdominal wall at the adrenogenital ridge become more columnar and invade the mesenchyma beneath the epithelial surface, ultimately forming the fetal adrenal cortex. Another proliferation of epithelial cells subsequently forms a cap over these primitive cortical cells, becoming the zona glomerulosa of the definitive cortex. The ectodermal chromaffin cells of the adrenal medulla arise from the neural crest as early as the fifth week, with primitive cells from the thoracic ganglia from the 6th to 12th segments invading the gland and forming the medulla. Differentiation of these primitive medullary cells into chromaffin cells begins at the third month of gestation, ultimately leading to the cells' production of epinephrine and norepinephrine.

The fetal zone of the adrenal cortex begins to appear around the sixth week of gestation. This zone continues to enlarge and occupy the majority of the gland. In fact, because of the large size of the fetal cortical zone, the fetal adrenal gland is 4 times the size of the kidney during the fourth month of gestation. This fetal cortex subsequently decreases in size, disappearing in the first year of life.

During fetal development, ectopic rests of medullary and cortical tissue may remain and persist after birth. Extraadrenal medullary rests are usually found along the aorta and its branches. The organ of Zuckerkandl is an example of a chromaffin mass at the origin of the inferior mesenteric artery. Most extraadrenal chromaffin rests involute after birth; the chromaffin cells in the medulla differentiate.

Extraadrenal cortical rests are common in children and are found in the kidney or liver or along the migratory path of the gonads, in hernia sacs, or in the gonads themselves. Approximately 50% of newborns have adrenocortical rests, but these rests typically atrophy and disappear within a few weeks after birth.[1]

# Physiology

## ADRENAL MEDULLARY FUNCTION

The adrenal medulla synthesizes and releases catecholamines: dopamine, epinephrine, and norepinephrine. Catecholamine synthesis begins with tyrosine, a nonessential amino acid. Tyrosine hydroxylase converts tyrosine into dihydroxyphenylalanine (DOPA) and is the rate-limiting step in the synthetic pathway. DOPA decarboxylase converts DOPA into dopamine. Phenylamine beta-hydroxylase converts dopamine into norepinephrine. Finally, phenylethylamine *N*-methyltransferase converts norepinephrine into epinephrine.

The chromaffin cells within the medulla contain cytoplasmic granules that store the catecholamines. Preganglionic sympathetic nerve endings release acetylcholine, which causes calcium-dependent exocytosis of these cytoplasmic storage granules and release of the catecholamines. Regulation of adrenal medullary catecholamine release is accomplished through inhibitory feedback mechanisms involving norepinephrine. Norepinephrine inhibits acetylcholine release from the presynaptic $alpha_2$ receptors and also inhibits tyrosine hydroxylase activity when present in high concentrations.

## ADRENAL CORTICAL FUNCTION

The adrenal cortex synthesizes three types of hormones: glucocorticoids, mineralocorticoids, and sex hormones. Regulation of these is accomplished by the hypothalamic-pituitary-adrenal axis. The hypothalamus produces corticotropin-releasing hormone (CRH); this is transported to the anterior pituitary gland where it stimulates the release of adrenocorticotropic hormone (ACTH). ACTH then stimulates the production of hormones (glucocorticoids, mineralocorticoids, and sex hormones) from the adrenal cortex.

The physiologic diurnal variation in CRH release leads to a cyclic variation in ACTH and the hormones regulated by it. Serum concentrations peak shortly before or at the time of awakening and decline throughout the remainder of the day. Both cortisol and ACTH inhibit CRH release, creating a negative feedback loop.

Adrenocortical production of glucocorticoids begins with a cholesterol substrate and is regulated by ACTH. The majority of serum cortisol is bound by cortisol-binding protein (90%) and albumin (6%), leaving only a small percentage (4%) free and physiologically active. As with most steroids, the unbound cortisol fraction is lipophilic and therefore readily crosses the plasma membrane of target cells. Specific receptors then bind with cortisol and act in the cell nucleus to regulate messenger RNA synthesis.

Cortisol affects metabolism primarily by opposing insulin. It causes hyperglycemia by increasing the proteolysis necessary for gluconeogenesis and inducing hepatic gluconeogenic enzymes. Cortisol also decreases the use of glucose by peripheral tissues; it inhibits glucose uptake into fat cells and decreases the amount of insulin bound by insulin-sensitive tissues.

Cortisol also decreases inflammation and immune function, affecting wound healing. Cortisol lowers both the lymphocytic and the granulocytic cellular immune response by decreasing the lymphocyte response to antigenic stimulation and impairing chemotaxis and phagocytosis of leukocytes. These two immune functions are an important part of early wound healing; thus wounds have decreased tensile strength and impaired healing in the setting of excess cortisol.

Aldosterone, a mineralocorticoid, is synthesized in the zona glomerulosa and metabolized primarily by the liver. The renin-angiotensin system controls the majority of aldosterone regulation, with ACTH playing only a small role. The macula densa of the renal juxtaglomerular apparatus releases renin in response to a drop in renal perfusion or hyponatremia. Renin converts angiotensinogen, which is produced by the liver, to angiotensin I. Angiotensin-converting enzyme, found in the lung, converts angiotensin I to angiotensin II. Angiotensin II stimulates the synthesis of aldosterone by directly acting on the cells of the adrenal zona glomerulosa; it also acts as a vasoconstrictor. By increasing the renal retention of sodium, aldosterone increases blood pressure and corrects hyponatremia, thus reducing the release of renin.

The serum potassium concentration also provides a small amount of aldosterone regulation. Hyperkalemia leads to increased aldosterone production by directly acting on the zona glomerulosa cells, as well as increasing renin release from the juxtaglomerular cells. Aldosterone promotes an increased renal excretion of potassium, thus lowering aldosterone production and providing another feedback mechanism.

Adrenal androgens are synthesized in the zona reticularis and are regulated primarily by ACTH. These hormones are released in a cyclic manner, correlating with the release of cortisol and ACTH. The adrenal androgens are only weakly active but are converted by peripheral tissues into more active forms such as testosterone and dihydrotestosterone. Metabolism of these hormones occurs in the liver.

# Lesions of the Adrenal Medulla

## PHEOCHROMOCYTOMA

In 1886, Frankel of Freiburg, Germany, published the first description of bilateral pheochromocytomas found during the postmortem examination of an 18-year-old woman who had presented with symptoms of anxiety, palpitations, and headache.[2] In 1912, Pick named the tumor for its predominant cell type, the pheochromocyte, but it was not until 1922 that Labbe and colleagues first described a clear relationship between pheochromocytoma and paroxysmal hypertension. In 1927, Mayo performed the first successful removal of a pheochromocytoma in a patient with paroxysmal hypertension who underwent surgical exploration without a preoperative diagnosis. In 1929, Pincoffs made the first correct preoperative diagnosis, and the successful operation was performed by Shipley.[3] Since that time, the behavior of pheochromocytomas has become better understood, particularly with respect to children.

Pheochromocytoma is an uncommon tumor of childhood, and there are several characteristics that distinguish its presentation between adults and children. The incidence of pheochromocytoma in childhood is 10% of the adult incidence, occurring in approximately 1 in 500,000 children compared with 1 in 50,000 adults.[4] Approximately 10% of childhood pheochromocytomas are familial, which is about 4 times the frequency in adults. Whereas only 7% of pheochromocytomas are bilateral in adults, the reported incidence of

**TABLE 41-1**
**Comparison of Pheochromocytoma in Children and Adults**

| | *Pediatric* | *Adult* |
|---|---|---|
| Incidence | 1:500,000 | 1:50,000 |
| Familial pattern (%) | 10 | 2-3 |
| Bilateral (%) | 24-70 | 10 |
| Extraadrenal site (%) | 30 | 10 |
| Malignant (%) | 3 | 10 |

bilateral pheochromocytomas in children ranges from 24% to as high as 70%. Extraadrenal pheochromocytomas are approximately twice as prevalent in children as in adults (Table 41-1).[5,6]

Pheochromocytomas originate from medullary chromaffin cells, which produce the catecholamines that cause the associated symptoms. These cells migrate along the aorta, usually remaining near the branches of the aorta.

## SYMPTOMS

In children with pheochromocytoma, the average age at presentation is 11 years, although the tumor can occur at any age. Over half the children present with headaches, fever, palpitations, thirst, polyuria, sweating, nausea, and weight loss, but the most common presentation is sustained hypertension.[4,6,7] In children, most causes of hypertension are secondary, with renal abnormalities being most common (78%), followed by renal artery disease (12%), and coarctation of the aorta (2%).[8] Pheochromocytoma accounts for 0.5% of children with hypertension and must be considered once other causes are eliminated. In children with pheochromocytoma, hypertension is sustained in up to 70% to 90% of cases, with only a small minority presenting with paroxysmal hypertension. In contrast, up to 50% of adults with pheochromocytoma have paroxysmal hypertension.[6]

## DIAGNOSIS

The diagnosis of pheochromocytoma relies on the demonstration of elevated levels of blood and urinary catecholamines and their metabolites. A 24-hour urine measurement of catecholamines, metanephrine, and vanillylmandelic acid is the best diagnostic test.[9,10] Urinary metanephrine levels are increased in about 95% of patients, and urinary vanillylmandelic acid and catecholamine levels are increased in approximately 90% of patients.[10] There is also a linear relationship between the amount of vanillylmandelic acid and the size of the pheochromocytoma.[11] The normal 24-hour urinary secretion is less than 100 mg for free catecholamines, less than 7 mg for vanillylmandelic acid, and less than 1.3 mg for metanephrine. Plasma catecholamines can also be measured by radioenzyme assay. However, patients must remain supine and calm during the blood draws, which can be difficult in children. Patients with normal plasma catecholamine levels during a hypertensive episode probably do not have pheochromocytoma, but levels greater than 2000 pg/mL are diagnostic of pheochromocytoma. Plasma catecholamine levels between 500 and 1000 pg/mL are suspicious for a pheochromocytoma, and further testing is indicated.[6] It must be remembered, however, that neuroblastoma can in some cases secrete significant levels of catecholamines.

After establishing the chemical diagnosis of pheochromocytoma, the tumor must be localized. Although large masses such as a neuroblastoma can be seen on plain abdominal films, most adrenal masses cannot be visualized without the use of other imaging methods. Almost all pheochromocytomas occur in the abdomen or pelvis, and although the adrenal gland is the most common site, up to 43% of children may have multifocal disease.[6] The initial study in infants and children is often US, which can be useful in distinguishing between solid and cystic masses while determining their vascularity and avoiding ionizing radiation, but it may not visualize small adrenal lesions. Additionally, it may be difficult to identify the adrenal gland as the organ of origin for large masses, because of compression from adjacent organs such as the kidney. Computed tomography (CT) and magnetic resonance imaging (MRI) offer the advantage of much better resolution and sensitivity (Fig. 41-1). Although CT is an accurate method of diagnosing adrenal lesions, it is less accurate in younger children because of the absence of retroperitoneal fat. Other disadvantages of CT are the need for intravenous contrast material and exposure to ionizing radiation. Simultaneous scanning of the chest to rule out pulmonary metastases in patients suspected of having adrenal carcinoma is a benefit of CT. Currently, both CT and MRI offer multiplanar imaging. Coronal imaging is a useful modality to distinguish

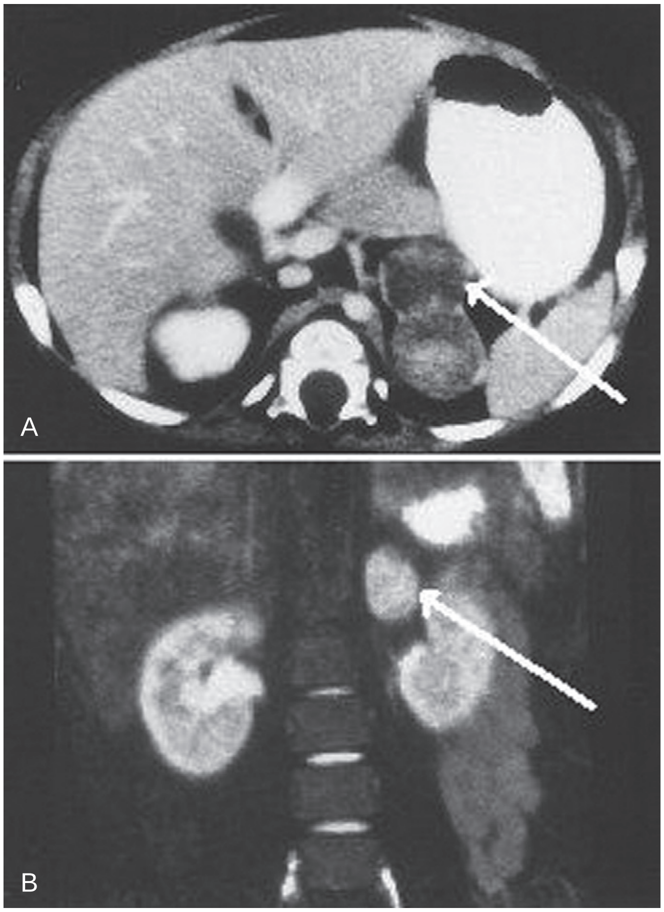

FIGURE 41-1 **A,** Computed tomography of the abdomen in a 10-year-old girl with a left adrenal mass associated with hypertension. **B,** Magnetic resonance image demonstrates a left adrenal pheochromocytoma. No other masses were noted. No contrast agent was required.

adrenal masses from the adjacent kidney and vice versa.[12–14] Pheochromocytomas demonstrate low or intermediate signal intensity on T1-weighted images and enhance with gadolinium-diethylenetriaminepentaacetic acid (DTPA).[15] One significant disadvantage to MRI is that children often require sedation or general anesthesia, given the length of time the study requires, which may be a risk if children have not been treated with blocking agents.

Another useful imaging technique is $^{131}$I-labeled metaiodobenzylguanidine (MIBG) scanning; this radioisotope accumulates where norepinephrine is taken up and allows detection of the tumor. MIBG, which is structurally similar to norepinephrine, is taken up by the norepinephrine transporter system into intracytoplasmic vesicles. Radionuclide imaging is achieved by labeling MIBG with one of two iodine isotopes at the meta position of the benzoic ring. The iodine isotope $^{131}$I has a half-life of 8.2 days and emits high-energy radiation. The iodine isotope $^{123}$I has a shorter half-life and emits lower-energy radiation.[16] Patients undergoing MIBG scanning should be given a saturated solution of potassium iodide to block thyroid uptake of the free iodine isotope. Scintigraphy is performed at 24 and 48 hours. This technique can be particularly useful in localizing extraadrenal tumors or sites of metastasis. It also confirms the adrenal location of a pheochromocytoma in patients with positive urine or serum catecholamine tests. The head and neck may be a more common site of these tumors in children compared with adults, followed by the retroperitoneum.[17]

Positron emission tomography (PET) may be a useful imaging study for pheochromocytoma in the near future. PET scanning uses short-lived positron-emitting agents to identify specific areas of uptake in the body. Because of the increased metabolism of tumors, labeled glucose can be used to identify malignant tissue. The most common form of labeled glucose in use for PET scanning is ($^{18}$F)-fluorodeoxyglucose (FDG). However, resolution of pheochromocytoma and distinction between benign and malignant pheochromocytoma are not optimal with FDG PET. A more useful agent may be 6-($^{18}$F)-fluorodopamine (DA). The similarity between norepinephrine and DA allows selective uptake by sympathoadrenal tissue.[18] One study found that FDG PET demonstrated metastases better than MIBG scanning did in adults (one patient was 16 years old in this cohort of 29 patients).[19] PET scanning results in lower radiation exposure than standard scintigraphy. When specific agents, such as DA, become generally available, PET scanning may prove to be the imaging method of choice.

## TREATMENT

The treatment of pheochromocytoma is surgical excision, although medical management of the hypertension is an essential part of the preoperative preparation. The high levels of catecholamines increase the risk of sudden and severe intraoperative hypertension, as well as profound hypotension once the tumor is removed and catecholamine release has ceased. In fact, these complications accounted for the high mortality rate associated with surgical resection in the past.[6] Improvements in preoperative and intraoperative management have reduced the operative mortality of 24% to 45% in the past to less than 10% today.[20] Preoperative use of alpha-adrenergic blockers, such as oral phenoxybenzamine and phentolamine, reduces the effects of epinephrine and norepinephrine by blocking the alpha-adrenergic receptors. These agents should be started at least 3 to 7 days before the procedure and the dose increased until the pressures are well controlled to minimize the intraoperative risks. Replacement of intravascular volume is often required as alpha blockade is achieved, because patients with pheochromocytomas tend to be hypovolemic at baseline, with an average 15% reduction in plasma volume. This volume re-expansion also helps minimize intraoperative blood pressure fluctuations and cardiac arrhythmias.

Beta-adrenergic blockade with agents such as propranolol and labetalol may be used once an alpha-adrenergic blockade is achieved, particularly if a resting tachycardia develops despite adequate volume replacement. If these agents are used, it is crucial that alpha blockade be established first. Administration of a beta blocker before an alpha blockade can worsen hypertension secondary to unopposed vasoconstriction.

Methyl-para-tyrosine (metyrosine) competitively inhibits tyrosine hydroxylase, the rate-limiting step in catecholamine biosynthesis. Treatment with metyrosine reduces tumor stores of catecholamines, decreases the need for intraoperative antihypertensive drugs, lowers intraoperative fluid requirements, and attenuates blood loss. It has not been tested in children less than 12 years of age. Metyrosine may not be necessary for patients with minimal or no symptoms from a minimally functioning pheochromocytoma.[21]

Despite good preoperative normalization of blood pressure, the anesthesiologist must be prepared for sudden fluctuations. The times of significant intraoperative risk are during anesthetic induction and intubation, during surgical manipulation of the tumor, and immediately following ligation of the tumor's venous drainage.[22] An arterial catheter and a central venous line are crucial for monitoring intraoperative blood pressure and fluid status. The anesthesiologist must also be prepared to use fast-acting agents to raise or lower blood pressure as needed. Sodium nitroprusside and nitroglycerin are useful agents, as are vasopressors and intravenous fluids. Cardiac arrhythmias can be managed with the use of propranolol, esmolol, and lidocaine. Adrenalectomy is described later.

An adrenal pheochromocytoma is typically encapsulated, and although there may be small amounts of normal adrenal tissue, the entire adrenal gland should be removed. It is rarely necessary to perform a nephrectomy, because the tumor is rarely adherent to the kidney.

As previously mentioned, once the adrenal vein is ligated and the tumor is removed, the patient may become hypotensive because of the removal of the catecholamine excess. In fact, it may be several days before the blood pressure normalizes. If hypertension returns postoperatively, one should suspect a second pheochromocytoma. All patients should undergo follow-up to confirm normalization of catecholamine levels. Long-term follow-up is indicated because of the possibility of a metachronous occurrence of a multifocal pheochromocytoma or occult metastasis.[6,22]

## ASSOCIATED DISORDERS

Familial pheochromocytomas may occur in the setting of several syndromes. The most common syndromes are multiple endocrine neoplasia type 2 (MEN-2) and von Hippel-Lindau disease. There is a smaller incidence of familial

pheochromocytomas in patients with neurofibromatosis type 1 and in patients without any other abnormalities.

Traditionally, a 10% incidence of familial cases of pheochromocytoma was expected. However, a germline mutation has been identified in up to 59% of apparently sporadic pheochromocytomas presenting at 18 years of age or younger and in 70% of those presenting before 10 years of age in one series.[21] The inherited predisposition may be attributable to a germline mutation in the von Hippel-Lindau gene, the genes encoding the subunits B and D of succinate dehydrogenase, the *RET* proto-oncogene predisposing to multiple endocrine neoplasia type 2, or the neurofibromatosis type 1 gene. Of these, the von Hippel-Lindau gene is the most commonly mutated gene in children presenting with a pheochromocytoma. A mutation of the von Hippel-Lindau gene on chromosome 3 leads to von Hippel-Lindau disease. This condition is characterized by retinal angiomas, hemangioblastomas of the central nervous system, renal cysts, renal cell carcinoma, pancreatic cysts, and pheochromocytomas. These pheochromocytomas are often multifocal and are frequently extraadrenal.

Multiple endocrine neoplasia type 2 is an autosomal dominant disorder caused by a mutation of the *RET* proto-oncogene on chromosome 10. These patients are at risk for medullary thyroid carcinoma, and up to 50% will develop adrenal pheochromocytoma. These tumors are almost always bilateral and are almost never malignant. Patients with MEN-2A are also at risk for hyperparathyroidism, and patients with MEN-2B may have a marfanoid habitus or mucosal ganglioneuromas.

Malignancy has been reported to occur in up to 10% of children with pheochromocytoma.[7] The diagnosis of malignancy is generally based on the tumor's clinical behavior, because the histologic examination is not an accurate predictor. A malignant pheochromocytoma may have local infiltration or distant metastasis, which most commonly occurs in bone, liver, lymph nodes, lung, and the central nervous system. Synchronous or metachronous pheochromocytomas may present anywhere along the sympathetic chain. Although surgical resection remains the treatment of choice, long-term palliation may be obtained through a multimodal approach, including local excision, radiation, and chemotherapy.[23]

# Lesions of the Adrenal Cortex

Adrenocortical neoplasms are rare in the pediatric population, accounting for less than 0.2% of all pediatric tumors and 6% of all adrenal tumors in children.[24] The incidence of these neoplasms has been reported to be approximately 25 cases per year in the United States, of which about 75% are adrenocortical carcinomas.[25,26] Adrenocortical tumors occur more frequently in girls, with a male to female ratio of approximately 1:2 to 1:3.[27] Like pheochromocytomas, adrenocortical neoplasms behave differently in children than in adults. Approximately 85% to 95% of these tumors are hormonally active in children, compared with less than 50% in adults.[28,29] Further, whereas there are clear pathologic criteria for malignancy in the adult population, these guidelines are not reliable in the pediatric population. Because the clinical behavior of these tumors does not always correlate with the pathologic appearance, the diagnosis of malignancy should be based on clinical behavior. Age less than 3.5 years at the time of diagnosis and symptom duration of less than 6 months before diagnosis are favorable prognostic indicators in adrenocortical carcinoma. Early detection is essential in these children, because a delay in diagnosis adversely affects clinical outcome.[1]

Adrenocortical tumors are associated with several congenital anomalies, including hemihypertrophy; other tumors associated with hemihypertrophy include nephroblastoma and hepatoblastoma. Patients with Beckwith-Wiedemann syndrome (exomphalos, macroglossia, and gigantism) also have a higher than expected incidence of adrenocortical carcinoma.[30] Most adrenocortical tumors, however, occur sporadically.[1]

## CUSHING SYNDROME

In 1932, Cushing first described the syndrome that bears his name in a patient with a pituitary adenoma. Since that time, the understanding of the pathophysiology and cause has expanded considerably. Endogenous Cushing syndrome is a rare condition in the pediatric population. In general, the incidence of spontaneous Cushing syndrome is approximately 5 per million persons; it occurs primarily in young adult women, with a female to male ratio of 9:1. Ten percent of cases occur in children and adolescents.[31]

The typical manifestation of Cushing syndrome in children is generalized obesity and long bone growth retardation.[31] Other symptoms include hypertension, weakness, thin skin with striae and easy bruising, acne, menstrual irregularity, osteoporosis, and glucose intolerance. Unlike in adults with Cushing syndrome, muscle weakness, sleep disturbances, and mental changes, such as emotional lability, irritability, or depression, are rare in children.[31] Cushing syndrome can be divided into ACTH-dependent and ACTH-independent types. In the former condition, the inappropriately high ACTH levels stimulate the adrenal cortex to produce excessive cortisol. In the ACTH-independent type, abnormal adrenal tissue produces excessive cortisol irrespective of ACTH levels.

Cushing disease refers to Cushing syndrome caused by pituitary tumors that lead to excessive ACTH production. Typically, these tumors are microadenomas and are less than 1 cm in diameter; however, large, invasive pituitary adenomas may develop. These tumors lead to bilateral adrenocortical hyperplasia, with a corresponding glucocorticoid excess. As the age of the patient increases, there is a greater likelihood of a pituitary cause of the syndrome. In patients younger than 6 years, the most likely cause of endogenous Cushing syndrome is an adrenal tumor. Although adrenocortical carcinomas represent only 0.2% of all childhood malignancies and 6% of adrenal cancers, approximately 60% to 80% of pediatric Cushing syndrome cases are caused by adrenocortical carcinomas.[28]

The clinical diagnosis of hypercortisolism must be confirmed biochemically to diagnose Cushing syndrome. In addition, the specific source of the syndrome must be localized (Fig. 41-2). Cortisol production is normally suppressed at night, but in Cushing syndrome, this suppression does not occur. The normal circadian rhythm of cortisol secretion is lost in Cushing syndrome. Random serum cortisol levels are of limited value. The three most common tests used to diagnose Cushing syndrome are the 24-hour urinary free cortisol test,

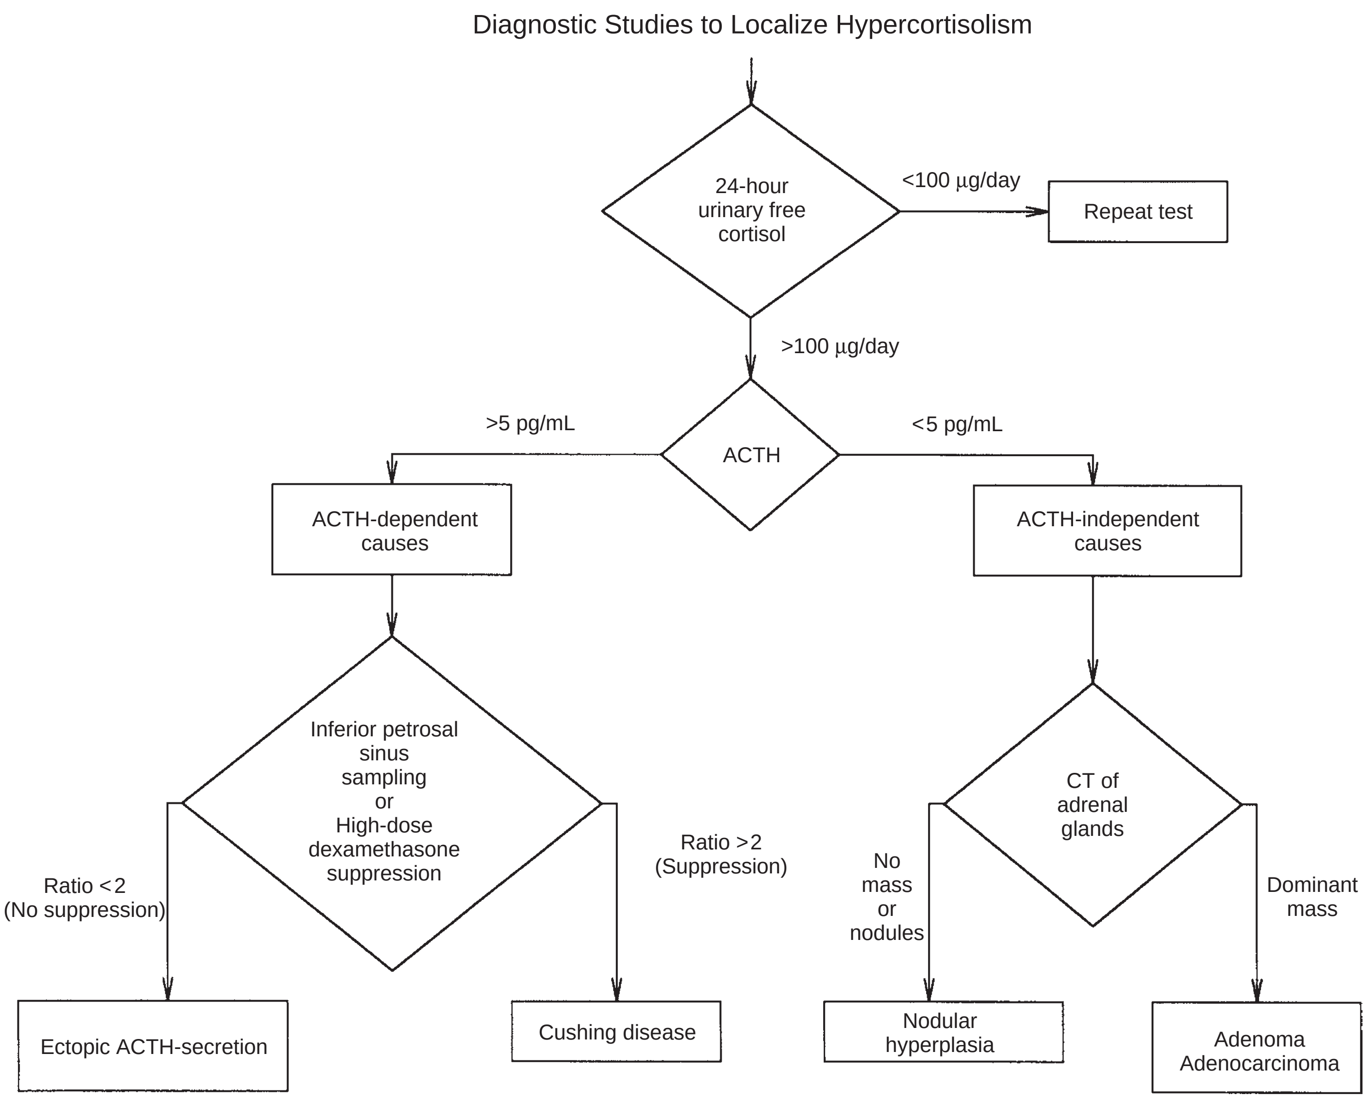

**FIGURE 41-2** Algorithm to localize the cause of hypercortisolism in children with suspected Cushing syndrome. ACTH, adrenocorticotropic hormone; CT, computed tomography.

measurement of midnight plasma cortisol or late-night salivary cortisol, and the low-dose dexamethasone suppression test. The dexamethasone-corticotropin-releasing hormone test may be needed to distinguish Cushing syndrome from other causes of excess cortisol. The 24-hour urinary free cortisol level has a sensitivity of approximately 98%.[32] In children, this value must be corrected for size. A normal value is less than 70 µg/m$^2$ per day; this is elevated with Cushing syndrome. Another useful test is the 24-hour urinary 17-hydroxysteroid excretion; this is an indirect measure of cortisol secretion and is elevated with hypercortisolism. Once it is corrected for creatinine excretion, the normal value is between 2 and 7 mg per gram of creatinine per day. The overnight dexamethasone suppression test is administered as follows: After the administration of 1 mg (or 0.3 mg/m$^2$ in children) of dexamethasone, a morning cortisol level greater than 5 µg/dL indicates unsuppressed cortisol secretion consistent with Cushing syndrome.

Once the diagnosis of Cushing syndrome has been established, the next step is to determine the underlying cause of the hypercortisolism. As shown in Figure 41-2, measurement of the ACTH level can distinguish between ACTH-dependent and ACTH-independent causes. If the ACTH level is greater than 5 pg/mL, the source is ACTH dependent; if the level is less than 5 pg/mL, it is ACTH independent.

ACTH-dependent causes of hypercortisolism include both pituitary and ectopic ACTH-secreting neoplasms. Although ectopic production of ACTH is rare in children, Wilms' tumors and tumors of the thymus, pancreas, or neural tissue can produce ACTH. Most patients with ACTH-secreting tumors have Cushing disease (Cushing syndrome caused by a pituitary tumor). Although a high-dose dexamethasone suppression test or an inferior petrosal sinus sampling can distinguish a pituitary source from an ectopic source, MRI can also show a pituitary tumor. An ectopic tumor producing CRH is another ACTH-dependent source of Cushing syndrome, but this condition has not been reported in a child.[32,33]

In both adults and children, the treatment of choice for Cushing disease is a transsphenoidal resection of the pituitary adenoma. In patients with no postoperative improvement or with recurrence, some response may be obtained with pituitary irradiation using cobalt 60.

If an ectopic ACTH-secreting tumor is indicated by the workup, the patient must undergo screening for medullary carcinoma of the thyroid (serum calcitonin levels) and screening for pheochromocytoma (24-hour urine measurement of catecholamines, metanephrine, and vanillylmandelic acid). Other ectopic locations, such as a bronchial, thymic, or intestinal carcinoid tumor, may be seen on CT of the chest and abdomen. Ectopic ACTH-producing tumors should be resected if possible. If resection is not possible, bilateral adrenalectomy can offer an effective treatment of Cushing syndrome.

ACTH-independent causes of Cushing syndrome include adrenal neoplasms and nodular adrenal hyperplasia. ACTH-independent Cushing syndrome is relatively more frequent in children than in adults.[32] In children, an adrenocortical tumor most frequently occurs in the setting of a virilizing syndrome, and the majority of children present with virilizing symptoms. Approximately 33% of these patients have Cushing syndrome; less than 10% present with isolated Cushing syndrome without any virilizing signs.[29,25]

Nodular adrenal hyperplasia is a rare condition that occurs in children and young adults. This disease usually presents in the first 2 decades of life, predominantly in girls. Although this entity can occur sporadically, many cases are familial and appear in an autosomal dominant fashion.[32] The adrenal glands contain multiple nodules approximately 3 to 5 mm in size. Histologic examination reveals lymphocytic infiltration of the cortex, suggesting an autoimmune cause of the disorder. The treatment of this cause of Cushing syndrome is bilateral adrenalectomy.[32] This procedure is associated with significant morbidity and requires permanent postoperative mineralocorticoid and glucocorticoid replacement.

### SEX HORMONE–PRODUCING TUMORS

An adrenocortical lesion may lead to either a virilizing or a feminizing tumor. As previously mentioned, most adrenocortical tumors in children are hormonally active. Virilization with or without hypercortisolism is the most common presentation.[26,29,34,35] These virilizing tumors may be more difficult to recognize in boys than in girls. Boys may present with precocious puberty, including penile enlargement, acne, and premature development of pubic, axillary, and facial hair. Girls may develop clitoral hypertrophy, hirsutism, and acne. The treatment of choice is adrenalectomy.

Although feminizing adrenocortical tumors are rare in children, they are usually malignant. In the normal adrenal gland, very small amounts of estrogens may be secreted. With adrenocortical tumors, however, overproduction of estrogens, particularly estradiol, may occur. In girls, these tumors present with precocious isosexual development, including early breast enlargement, accelerated growth, and advanced bone age. In boys, these tumors cause bilateral gynecomastia, accelerated growth rate, and delayed pubertal development; there is also an absence of spermatogenesis.

### TREATMENT OF ADRENOCORTICAL TUMORS

Surgical resection is the mainstay of treatment for adrenocortical tumors. The treatment of choice for a benign adrenal adenoma is adrenalectomy. Adrenocortical carcinomas, however, require a wide excision with adequate abdominal exploration for metastatic disease. In either case, postoperative steroid replacement is typically required until the contralateral gland can recover from its suppression.

Computed tomography or magnetic resonance imaging can help distinguish between adrenal hyperplasia and an adrenal tumor. A $^{131}$I-iodomethyl-1-19-norcholesterol (NP-59) scintiscan may aid in the evaluation of an adrenal lesion. This cholesterol analogue is taken up as cholesterol into the steroid pathways of the adrenal cortex. Adrenal adenomas usually have an increased uptake of NP-59, whereas adrenocortical carcinomas typically do not take up the isotope. Bilateral uptake of NP-59 indicates bilateral adrenal hyperplasia, which can be the result of ACTH oversecretion.

The most common sites of metastatic adrenocortical carcinomas are the lung, liver, lymph nodes, contralateral adrenal gland, bones, kidneys, and brain. If complete resection is not possible, tumor debulking may be of some benefit to control symptoms. Medical therapy with mitotane may also play a role in treating patients with unresectable disease. Mitotane acts as an adrenolytic agent by altering mitochondrial function, blocking adrenal steroid hydroxylation, and altering the extra-adrenal metabolism of cortisol and androgens. The success of chemotherapy has not been clearly shown, however, and complete surgical resection is the primary determinant of survival.[36]

## Hyperaldosteronism

Overproduction of aldosterone, or hyperaldosteronism, may be due to either adrenal dysfunction or overproduction of renin. Primary hyperaldosteronism refers to adrenal dysfunction, such as an aldosterone-secreting tumor or bilateral adrenal hyperplasia. Secondary hyperaldosteronism refers to an overproduction of renin, which can be caused by cirrhosis, congestive heart failure, a renin-producing juxtaglomerular cell tumor, or renovascular abnormalities, such as renal artery stenosis.

The symptoms of hyperaldosteronism include headaches, fatigue, weakness, lethargy, poor weight gain, polyuria, polydipsia, and nocturia. Hypertension develops as a result of increased sodium and water reabsorption. Weakness occurs because of hypokalemia, which is the most common laboratory finding, although metabolic alkalosis may be observed from the loss of hydrogen ions in the urine. The biochemical diagnosis of hyperaldosteronism is demonstrated by excessive aldosterone secretion in the setting of suppressed renin secretion. Once the diagnosis of primary hyperaldosteronism has been established, patients with aldosterone-secreting adrenal tumors must be distinguished from those with the more common condition of bilateral adrenocortical hyperplasia. In patients with bilateral adrenocortical hyperplasia, dexamethasone administration normalizes the abnormally high aldosterone level and low renin level.[10]

In the pediatric population, the incidence of aldosteronoma, or an adrenal adenoma causing primary hyperaldosteronism, is extremely low, with only a handful of reported cases in the literature. As previously mentioned, the more common cause of primary hyperaldosteronism is bilateral cortical hyperplasia.[37] An aldosteronoma is best treated by unilateral adrenalectomy. Patients with bilateral adrenocortical hyperplasia do not respond well to surgical treatment and are best

managed with medical therapy using spironolactone and amiloride.[10] Adrenal insufficiency resulting from bilateral adrenalectomy is more difficult to manage than hyperaldosteronism.

## Addison Disease

Insufficient production of steroid hormones (either glucocorticoids or mineralocorticoids) can lead to Addison disease. Children with Addison disease present with a variety of symptoms, including weakness, anorexia, weight loss, fatigue, nausea, vomiting, and diarrhea. If the child has an elevated ACTH level, hyperpigmentation will develop, because melanocytes are stimulated by ACTH. Seizures may also occur in the setting of the hypoglycemia, which occurs with adrenal crisis.

There are many causes of adrenal insufficiency in children. Congenital adrenal hypoplasia can result from either an autosomal recessive disorder or an X-linked disorder that occurs in boys. Errors in steroid metabolism can also lead to adrenal insufficiency. The most common group of inborn errors involves defects in glucocorticoid synthesis and is collectively known as congenital adrenal hyperplasia. Acquired lesions involving the hypothalamus or pituitary can also lead to adrenal insufficiency through a reduction in CRH or ACTH secretion.

Destruction of the adrenal glands can also lead to adrenal insufficiency. Conditions causing adrenal demise include hemorrhage, infection, adrenoleukodystrophy, and autoimmune diseases. In older patients, overwhelming infection can lead to adrenal hemorrhage. Tuberculosis used to be a common cause of infectious destruction of the adrenal; however, the incidence of this condition has fallen in modern times. One of the more common causes of acute adrenal insufficiency is cessation of chronic exogenous glucocorticoid administration.

In newborns, adrenal hemorrhage is not an uncommon event. In fact, the adrenal gland is the second most common source of hemoperitoneum in the newborn period.[38] The pathogenesis of adrenal hemorrhage in newborns is not fully understood. Associated factors include traumatic delivery, asphyxia, maternal hypotension, overwhelming infection, or hemorrhagic disorders.[35,39] The incidence of adrenal hemorrhage is almost 2 cases per 1000 live births,[1] but as the sensitivity of imaging technology improves, this number may increase. Adrenal hemorrhage occurs 3 to 4 times more frequently in the right adrenal gland than the left and is bilateral in 8% to 10% of patients.[39] This bias toward the right side may be due to the direct drainage of the right adrenal gland into the inferior vena cava, making the right gland more susceptible to changes in venous pressure. The left gland remains somewhat protected by its drainage into the left renal vein. The fetal cortex contributes to fetal and neonatal adrenal hemorrhage because of both its size and its later involution. The large size of the fetal cortex makes the adrenal glands relatively large, increasing their vulnerability to trauma. The normal adrenal gland is easily visualized by US during the first week of life. The adrenal soon involutes, and the distinction between the cortex and the medulla is lost. The physiologic involution of the fetal cortex may occur quite rapidly, tearing the unsupported central adrenal gland vessels.[38]

On prenatal US, adrenal hemorrhage appears as an echogenic mass. This mass becomes increasingly hypoechoic and usually involutes on subsequent sonograms.[40] The lesion may completely resolve, leaving only residual calcifications. Adrenal hemorrhage may be confused with neuroblastoma. Patients with normal urinary catecholamine levels and the appropriate risk factors for adrenal hemorrhage can be observed and undergo repeat US. Differentiation of adrenal adenoma and carcinoma by US is difficult; in addition, both resemble an adrenal pheochromocytoma. An ultrasonographic characteristic that suggests malignancy is central necrosis from rapid growth. Biochemical testing and the use of CT, MRI, and nuclear medicine studies narrow the diagnostic possibilities.

The treatment of Addison disease is replacement of the deficient steroid hormone. This may be accomplished with a mineralocorticoid, such as fludrocortisone, or a glucocorticoid, such as hydrocortisone or prednisone. During periods of acute stress, such as infection or operation, increased doses of glucocorticoids are needed.

## Incidental Adrenal Mass

The incidental discovery of adrenal lesions on imaging studies performed for other reasons has been increasing in both children and adults, perhaps because of the increased frequency of imaging studies being performed and the increased sensitivity of those imaging modalities. In adults, the current recommendation is to remove all hormonally active tumors regardless of size. In the case of nonfunctional adrenal masses, it is considered safe to observe a mass less than 4 cm in size.[41–43] In the pediatric population, however, there are no clear guidelines about incidental, nonfunctional adrenal masses. Because of the higher incidence of both functional tumors and malignant tumors in the pediatric adrenal gland, many surgeons recommend adrenalectomy in this setting.[43]

## Adrenalectomy

The objective of adrenal surgery is to attain complete tumor resection, resulting in normalization of endocrine function and cure of malignancy. Perioperative planning includes correction of potential electrolyte abnormalities, establishing alpha and beta blockade in the case of pheochromocytoma, and performing localizing studies to guide the surgical approach. The surgical approach is based on the probable histology of the adrenal mass, the presence of bilaterality, and the surgeon's preference. The introduction of laparoscopic adrenal resection has provided an attractive alternative for the resection of many adrenal masses in children.

Traditional approaches to adrenal resection have included anterior, posterior, and thoracoabdominal approaches. The anterior approach uses a transabdominal incision, usually subcostal, which permits resection of either the left or the right adrenal gland. It also allows bilateral resection through a single incision, as well as visualization of the periaortic sympathetic ganglia, the small bowel mesentery, and the pelvis. More than 95% of pediatric pheochromocytomas are located in the abdomen, and this approach reveals the majority of tumors. The surgeon must make a conscious effort to minimize direct manipulation of the tumor during dissection.

Early control and ligation of the adrenal vein limit the release of catecholamines as the tumor is removed.

During the anterior approach to right adrenalectomy, the duodenum is mobilized by the Kocher maneuver (Fig. 41-3) by reflecting the transverse colon inferiorly and mobilizing the duodenum medially. This exposes the upper portion of the right kidney as well as the right adrenal gland. The Gerota fascia is opened, and the right lobe of the liver is retracted in a cephalad direction. The most important element of the procedure is the dissection between the medial border of the adrenal mass and the lateral wall of the inferior vena cava. This plane is developed in a cephalad direction until the relatively short right adrenal vein is identified entering the vena cava. There is a greater risk of hemorrhage on the right side than on the left, because of the shorter length of the right adrenal vein and the greater risk of tearing this vessel. Multiple veins may be present and should be identified to prevent accidental avulsion. During the anterior approach to the left adrenal gland, the initial maneuver is to mobilize the splenic flexure of the colon. The pancreas and spleen are retracted superiorly, and the Gerota fascia is opened, exposing the left adrenal gland. Alternatively, the surgeon can divide the gastrocolic ligament, mobilizing the stomach superiorly and the transverse colon inferiorly. The posterior peritoneum along the inferior pancreatic border can then be incised, allowing mobilization of the pancreatic tail and exposure of the adrenal vein. The left adrenal vein enters the renal vein superiorly and can be ligated in this plane. Several arteries enter the medial surface of the adrenal gland from the lateral side of the aorta; these arteries need to be divided before adrenal

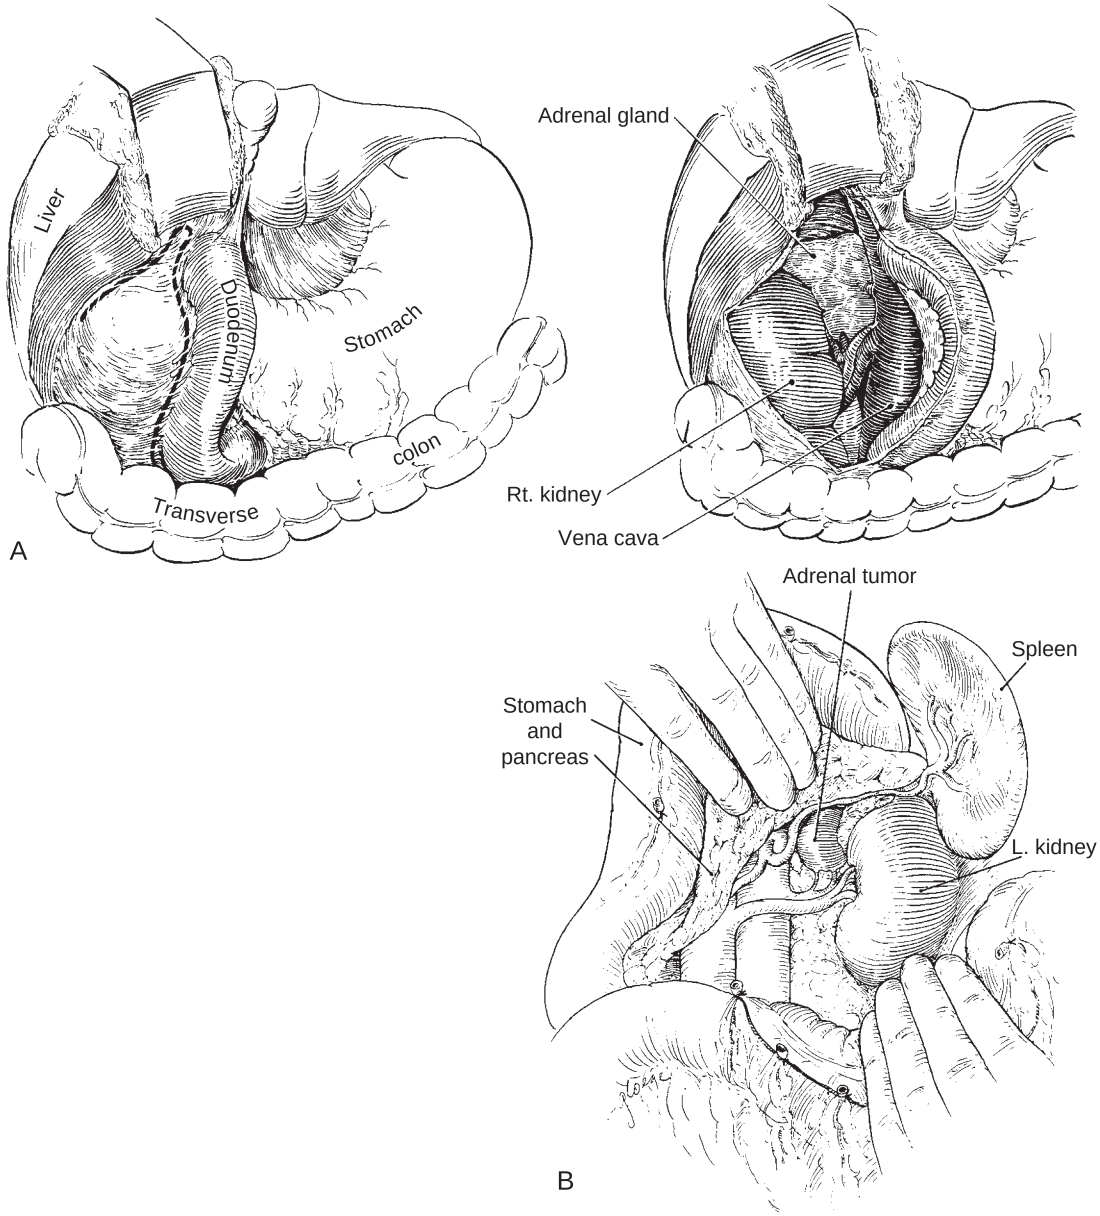

**FIGURE 41-3** Transabdominal approach to tumors of the adrenal glands. **A,** The right adrenal gland is exposed by reflecting the transverse mesocolon inferiorly, mobilizing the duodenum medially with a Kocher maneuver, and incising the posterior fascia to expose the diaphragm, adrenal gland, and superior pole of the right kidney. **B,** The left adrenal gland is exposed by dividing the gastrocolic ligament and elevating the stomach. The colon is retracted inferiorly, and the pancreas is elevated, exposing the adrenal gland and left adrenal vein that enters the renal vein.

removal. The posterior approach to the adrenal gland is accomplished most commonly through the bed of the 11th rib. This strategy avoids intraperitoneal dissection, eliminates postoperative adhesions, and decreases postoperative ileus. The posterior approach is not useful for bilateral adrenal lesions, malignancies, or large vascular tumors. The thoracoabdominal approach to adrenalectomy is best applied to very large unilateral lesions. Although this approach provides optimal exposure of large vascular tumors; postoperative pain and impairment of ventilation limit its application.

The first laparoscopic adrenalectomy was reported in an adult in 1991.[44] Since then, a number of studies involving laparoscopic adrenalectomy in children have been published,[45,46] demonstrating the feasibility and safety of this approach. Most commonly, laparoscopic adrenalectomy is performed with the patient in the lateral position. A kidney rest elevates the flank opposite the adrenal lesion. Four or five trocars are placed in a subcostal position on the side of the adrenal gland to be resected. Exposure is improved on the right side by dividing the right triangular ligament of the liver. Division of the lienocolic ligament on the left improves exposure of the left adrenal gland. When possible, the adrenal vein is ligated with clips at the initial point of dissection. The adrenal specimen should be removed in a specimen bag because of the potential for malignancy. Most adrenal lesions in children are small and benign, making laparoscopic resection an appropriate choice in the majority of cases. Although no absolute contraindications to laparoscopic resection exist, an open approach should be considered in patients with large tumors, malignancies with potential lymph node involvement, and highly vascular pheochromocytomas.

Partial adrenalectomies (termed *cortical-sparing* or *adrenal-sparing*) have been described for bilateral pheochromocytomas, wherein a portion of a single gland or portions of bilateral glands are retained. Preliminary reports indicate few recurrences and maintenance of corticosteroid independence. Children are included in these cohorts but not individually evaluated as a sub-group. Reports are surfacing of successful laparoscopic cortical-sparing adrenalectomies as well.[47] Long-term follow-up and continued surveillance are essential.

CHAPTER 42

# Tumors of the Lung and Chest Wall

Stephen J. Shochat and Christopher B. Weldon

The majority of pulmonary neoplasms in children are due to metastatic disease; however, primary pulmonary tumors of the lung do occur in the pediatric age group. The approximate ratio of primary pulmonary tumors to metastatic neoplasms and non-neoplastic lesions of the lung is 1:5:60.[1] Although primary pulmonary tumors are rare in children, the majority of these tumors are malignant. In a review of 383 primary pulmonary neoplasms in children by Hancock and colleagues,[2] 76% were malignant and 24% were benign. This incidence is similar to that previously reported by Hartman and Shochat.[3] Table 42-1 demonstrates the variety of primary pulmonary neoplasms seen in children. This chapter addresses the more common benign and malignant primary pulmonary tumors in children and discusses the treatment of pulmonary metastatic disease in the pediatric population.

## Benign Tumors of the Lung

### PLASMA CELL GRANULOMA (INFLAMMATORY PSEUDOTUMOR)

Plasma cell granuloma has also been called inflammatory myofibroblastic tumor, fibroxanthoma, histiocytoma, and fibrohistiocytoma.[4] This lesion, which is seen frequently in adults, occurs rarely in children younger than 10 years (approximately 8% of cases). However, plasma cell granuloma is the most common benign tumor in children and accounts for slightly more than 50% of all benign lesions and approximately 20% of all primary lung tumors.[3] These tumors usually present as peripheral pulmonary masses but occasionally present as polypoid endobronchial tumors.[5,6] The pathogenesis of plasma cell granuloma is not well understood, but an antecedent pulmonary infection has been reported in approximately 30% of cases. The mean age at presentation in children is 7 years of age, and 35% of the children are between 1 and 15 years of age.[5–7] Many children are asymptomatic at the time of presentation, but fever, cough, pain, hemoptysis, pneumonitis, and dysphagia may be present. The natural history is that of a slow-growing mass, starting as a focus of organized pneumonia with a tendency for local invasion. However, rare cases of rapid growth have been reported.[8] Extension of the tumor beyond the confines of the lung is common. At least four deaths have been reported resulting from tracheal obstruction or involvement of the mediastinum by massive lesions.

Treatment consists of a conservative pulmonary resection with removal of all gross disease if possible. Primary hilar adenopathy may be present, and local invasion with disregard for tissue planes mimics malignancy. A frequent problem is identifying the benign nature of these masses. However, the diagnosis can usually be confirmed by frozen section. Malignant fibrous histiocytoma of the lung, an extremely rare tumor in children, can mimic plasma cell granuloma and must be considered in the differential diagnosis.[9] Recurrences following resection are rare but have been reported. Nonsteroidal anti-inflammatory drugs have been used to treat large inoperable lesions, with encouraging results.[10]

### HAMARTOMA

Pulmonary hamartoma is the second most frequent benign lesion seen in children. These lesions usually present as parenchymal lesions and can be quite large. Approximately one quarter are calcified, and "popcorn-like" calcification is pathognomonic.[11] Two endobronchial lesions have been reported. Four tumors occurring in the neonatal period were quite large and were associated with significant respiratory distress; all were fatal. An interesting triad is the combination of pulmonary hamartoma, extraadrenal paraganglioma, and gastric smooth muscle tumors; the majority of these patients are young women. Carney triad, in addition to its female predilection, is seen in young patients, is associated with multifocal gastrointestinal stromal tumors (GISTs) and has an unpredictable biological behavior.[12] Conservative pulmonary resection is the treatment of choice; however, lobectomy, or even pneumonectomy, may be required, especially for large lesions and endobronchial lesions when sleeve resection is not possible.

## Malignant Tumors of the Lung

### BRONCHIAL ADENOMA

The most frequently encountered malignant primary pulmonary tumor is bronchial adenoma. These tumors are a heterogeneous group of primary endobronchial lesions. Although adenoma implies a benign process, all varieties of bronchial

adenomas occasionally display malignant behavior. There are three histologic types: carcinoid tumor (most common), mucoepidermoid carcinoma, and adenoid cystic carcinoma. Carcinoid tumors account for 80% to 85% of all bronchial adenomas in children.[13] The presenting symptoms are usually due to incomplete bronchial obstruction, with cough, recurrent pneumonitis, and hemoptysis. Because of diagnostic difficulties, symptoms are often present for months; occasionally, children with wheezing have been treated for asthma, delaying diagnosis for as long as 4 to 5 years. Metastatic lesions are reported in approximately 6% of cases, and recurrences occur in 2%. There is a single report of a child with a carcinoid tumor and metastatic disease who developed the classic carcinoid syndrome.[14] Bronchial adenomas of all histologic types are associated with an excellent prognosis in children, even in the presence of local invasion.[15]

The management of bronchial adenomas is somewhat controversial, because most are visible endoscopically. Biopsy in these lesions may be hazardous because of the risk of hemorrhage, and endoscopic resection is not recommended. Bronchography or computed tomography (CT) may be helpful to determine the degree of bronchiectasis distal to the obstruction, because the degree of pulmonary destruction may influence surgical therapy.[16] However, Tagge and colleagues[17] described a technique for pulmonary salvage despite significant distal atelectasis. Conservative pulmonary resection with removal of the involved lymphatics is the treatment of choice. Sleeve segmental bronchial resection is possible in children and is the treatment of choice when feasible.[18–20] Adenoid cystic carcinomas (cylindroma) have a tendency to spread submucosally, and late local recurrence or dissemination has been reported. In addition to en bloc resection with hilar lymphadenectomy, a frozen section examination of the bronchial margins should be carried out in children with this lesion.

**TABLE 42-1**
**Primary Pulmonary Neoplasms in Children**

| *Type of Tumor* | *No. of Patients (%)** |
|---|---|
| **Benign ($n$ = 92)** | |
| Plasma cell granuloma | 48 (52.2) |
| Hamartoma | 22 (23.9) |
| Neurogenic tumor | 9 (9.8) |
| Leiomyoma | 6 (6.5) |
| Mucous gland adenoma | 3 (3.3) |
| Myoblastoma | 3 (3.3) |
| Benign teratoma | 1 (1.1) |
| **Malignant ($n$ = 291)** | |
| Bronchial "adenoma" | 118 (40.5) |
| Bronchioalveolar carcinoma | 49 (16.8) |
| Pulmonary blastoma | 45 (15.5) |

*Percent of benign or malignant tumors.

## BRONCHOGENIC CARCINOMA

Although bronchogenic carcinoma is rare in children, this tumor was the second most common malignant lesion reported by Hancock and colleagues.[2] Interestingly, squamous cell carcinoma was rare, with the majority of tumors being either undifferentiated carcinoma or adenocarcinomas. The term bronchioalveolar carcinoma has been used in most cases.[21] These tumors are associated with both cystic adenomatoid malformations and intrapulmonary bronchogenic cysts (Table 42-2).[4,11,21–38] Only rare survivors have been reported,

and mortality exceeds 90%. The majority of children present with disseminated disease, and the average survival is only 7 months. Localized lesions can be treated by complete resection, followed by adjuvant therapy. Mucoepidermoid carcinoma of the bronchus has also been described in children as young as 4 years (Fig. 42-1).[39]

## PULMONARY BLASTOMA

Pulmonary blastoma is a rare malignant tumor that occurs primarily in adults and arises from mesenchymal blastema. This tumor is an aggressive lesion, with metastatic disease at presentation in approximately 20% of cases.[40,2] They may arise from the lung, pleura, and mediastinum.[41] These tumors are classified into three types: type I (purely cystic), type II (cystic and solid), and type III (completely solid).[42] Type I tumors may be difficult to distinguish from cystic adenomatoid malformation.[43] Occasionally, these tumors may arise in an extralobar sequestration or in a previous lung cyst (Table 42-3).[22,25,29,36,41,44–73] The majority of cases occur in the right hemithorax (Fig. 42-2). Frequent sites of metastases

are the liver, brain, and spinal cord. Local recurrences are frequent, and the mortality rate is approximately 40%.[2,74–76] The majority of children present before 4 years of age, and symptoms include persistent cough, chest pain, episodes of pneumonia that are refractory to antibiotics, and hemoptysis. Diagnosis is achieved by CT of the chest, bronchoscopy, and biopsy. Because most of these tumors are located peripherally, resection is usually possible by segmental or lobar resection. The use of multimodal neoadjuvant chemotherapy and radiation following surgical resection has shown promising results in a few patients with extensive disease and dissemination.[41,75] Chemotherapeutic agents that have been used include actinomycin D, vincristine, cyclophosphamide alternating with courses of doxorubicin, and cisplatin. Histologic evaluation of the tumor shows an exclusive mesenchymal composition, including primitive tubules, immature blastema, and spindle cell stroma. Some demonstrate elements of embryonal rhabdomyosarcoma (RMS) arising within a multicystic lesion.

## RHABDOMYOSARCOMA

RMSs of the lung are rare and account for only 0.5% of all childhood RMSs (see Chapter 35).[45,77] Many of the lesions are endobronchial in origin (Fig. 42-3); however, several cases apparently originated in congenital cystic anomalies. (see Table 42-3).* This is an important issue because 4% of benign tumors and 8.6% of malignant tumors enumerated in Table 42-1 were associated with previously documented cystic malformations.[2] Tumors that developed in these malformations included 11 sarcomas, 9 pulmonary blastomas, 3 bronchogenic carcinomas, and 2 mesenchymomas.

## COMMENTS

Although children with primary lung tumors represent a heterogeneous group of patients, analysis of the reported cases suggests that evaluation and treatment are similar in the majority of patients. Many children are asymptomatic, especially those with benign tumors; however, cough, recurrent pneumonitis, and symptoms of atypical bronchial asthma may be the initial presentation. Radiographic findings usually indicate a solitary mass lesion or evidence of airway obstruction with resultant atelectasis and pneumonitis. Because many of these tumors can be visualized by bronchoscopy, a bronchoscopic examination should be performed. Flexible bronchoscopic techniques may be helpful for diagnosis, but the use of rigid bronchoscopy with modern magnification, along with general anesthesia, is necessary if endoscopic biopsy is contemplated. Preparation for emergency thoracotomy should be made at the time of bronchoscopy in the event of life-threatening hemorrhage.

Bronchoscopic removal of some isolated lesions may be attempted, but because of the high incidence of recurrence and the possibility of severe hemorrhage, this technique should be used selectively. Conservative surgical resection is the procedure of choice for benign pulmonary tumors to achieve histologic diagnosis and preserve maximum functioning lung tissue. Thoracoscopic resection is an option in these children.[83] CT and magnetic resonance imaging should be performed in children with large space-occupying lesions to determine resectability. Fine-needle aspiration for cytology or core needle biopsy may be performed as the initial procedure for diagnosis in selected cases. Treatment of malignant lesions varies, depending on location and histology. Sleeve resections should be considered for bronchial adenomas. Resection of involved lymphatics should be considered with malignant lesions. Combined-modality therapy with adjuvant chemotherapy and possibly radiation therapy may be helpful in children with large primary malignancies or dissemination.

An important consideration is the association of primary lung tumors with congenital cystic pulmonary malformations. These lesions may be asymptomatic and are often discovered incidentally. In some instances, the natural history of the lung cyst is unknown, and a few may regress.[80] Although some authors recommend simple observation, most pediatric surgeons argue against prolonged observation of cystic lesions because of an increased risk of infection, pneumothorax, sudden cyst enlargement with potential respiratory compromise, and associated malignancy.* As mentioned previously,

there is evidence suggesting a relationship between type IV cystic adenomatoid malformation and type I pulmonary blastoma. Although complete lobectomy with negative margins is adequate treatment for these patients, close observation is recommended.[31,35,84] If patients with asymptomatic cystic malformations are observed without resection, they should be followed closely and evaluated frequently.

# Treatment of Metastatic Disease

Pulmonary metastases occur much more frequently than primary tumors in children, and the surgical approach depends on the histology of the primary tumor and the response of the primary site to combined-modality therapy.[72,85] Pulmonary metastases should not be considered for resection until the primary tumor is eradicated, without evidence of recurrence and other sites of metastatic disease ruled out. Tumors most frequently considered for pulmonary metastasectomy are osteosarcoma (OS), soft tissue sarcoma, and Wilms' tumor.[86]

## OSTEOSARCOMA

Children with OS should be considered for resection of pulmonary metastases once the primary lesion is controlled. The overall disease-free survival is approximately 40% in children who develop metachronous pulmonary metastases. Multiple factors, such as number of pulmonary nodules and time of recurrence, play an important role in children with OS and pulmonary metastases.[87,88] Roth and colleagues[73] showed that patients with fewer than four pulmonary nodules had an improved survival versus those with more than four lesions. According to Goorin and colleagues,[89] a complete resection of all pulmonary lesions is an important determinant of outcome, and penetration through the parietal pleura is associated with an adverse outcome. Although somewhat controversial, the outlook seems to be somewhat improved, even in patients presenting with pulmonary metastases, if complete resection of all metastatic lesions can be accomplished.[90] Harris and colleagues[91] reported a 68% survival rate in 17 patients with fewer than eight pulmonary nodules at presentation following chemotherapy, resection of the primary tumor, and pulmonary metastasectomy. The data in Table 42-4 suggest that an aggressive attempt at surgical resection of pulmonary metastases is indicated in OS, possibly irrespective of the number of lesions or the interval to the development of metastases.*
A number of recent studies have shown a survival advantage in patients with repeated metastasectomy, including patients with as many as five recurrences.[74,78,79]

## SOFT TISSUE SARCOMA

The usefulness of resecting pulmonary metastases in patients with soft tissue sarcoma depends on the histologic subtype. Rarely is pulmonary resection of metastatic lesions required in RMS, and resection of pulmonary metastasis in Ewing

sarcoma has not been found to be efficacious.[71,72] Several European protocols are being developed to better define the role of pulmonary resection in Ewing sarcoma. The remaining sarcomas should be considered for resection if complete excision is possible and the patient's primary tumor is under control. The time to development of pulmonary metastases, number of lesions, and tumor doubling time are all significant prognostic factors in soft tissue sarcomas. Historically, approximately 10% to 20% of these patients can be salvaged by resection of pulmonary metastases.[37]

### WILMS' TUMOR

Rarely is pulmonary resection of metastatic disease required in children with Wilms' tumor. In a review of the National Wilms' Tumor Study by Green and colleagues,[96] no advantage of pulmonary resection was found compared with chemotherapy and radiation therapy alone. In an attempt to avoid pulmonary radiation, de Kraker and colleagues[33] suggested a protocol using primary pulmonary resection after chemotherapy for pulmonary metastases. Only 5 of 36 patients ultimately required resection of pulmonary metastases following chemotherapy, because most patients had a complete response with chemotherapy alone. One encouraging finding was that only 4 of 36 children required whole-lung irradiation. Because the results of chemotherapy and whole-lung irradiation are excellent for children with Wilms' tumor and pulmonary metastases, pulmonary resection of metastases should be reserved for selected cases (see Chapter 30).

### COMMENTS

Operation for pulmonary metastases in children depends on the histology of the primary tumor, the extent of the metastatic disease, and whether the metastatic disease is responsive to chemotherapy. The surgical approach varies, depending on the disease process and the age of the patient. No difference in survival has been demonstrated with sequential lateral thoracotomy versus sternotomy, but the latter is preferable in older patients with OS. Complete resection of all metastatic disease is an important consideration, and the use of automatic stapling devices can be helpful. Wedge resection is usually possible in children with OS. However, formal lobectomy or segmentectomy may be required to remove all of the tumor completely, especially when the primary tumor is not responsive to chemotherapy or radiation.[97] Muscle-sparing techniques are available in those children requiring posterolateral thoracotomies, and thoracoscopy may be appropriate in certain cases.[37] New localization techniques are being developed to aid in the thoracoscopic resection of lung lesions.[81] However, port site recurrences have been reported following thoracoscopic resection of pulmonary metastatic disease.[98,99]

## Tumors of the Chest Wall

### EPIDEMIOLOGY

Tumors of the chest wall are rare entities in the pediatric population with an incidence of no more than 2%,[100,101] and up to two thirds of these lesions are malignant.[102] The majority arise from the bony structures of the chest wall (55%), as opposed to soft tissue (45%).[103] Collectively, a 60% 5-year overall survival rate for all tumors has been reported, with a recurrence rate of 50% (local and distant) and subsequent 5-year survival rate of only 17%.[104]

### PRESENTATION

Masses of the chest wall typically present as lumps bulging underneath the skin, and the majority of malignant lesions have pain as a presenting symptom as well. In young children and infants, they are often found incidentally by caregivers, while older children and young adults may present with larger masses that have been present and growing for some time. Incidental discovery on routine chest imaging has been reported to be as high as 20%.[105] They can be found anywhere on the thorax, and the tissue of origin is generally mesenchymal in nature, regardless of whether the tumors are malignant or benign. Hence, sarcomatous variants are the most common malignant tumors, while carcinomas are almost nonexistent. The minority of patients present with nonspecific symptoms of respiratory compromise or dysfunction (tachypnea, hypoxia, cough, dyspnea on exertion), and these symptoms may have been present for quite a while before seeking medical advice. Symptoms stem from parenchymal compression from the mass intruding into the pleural space and onto the lung or from malignant effusions, both of which interfere with normal respiratory mechanics. Regardless of the presentation, a full history and physical exam, including a family

history, travel history, injury history, and extensive review of systems, is warranted to document other etiologies or associated conditions. Finally, depending on the degree of respiratory embarrassment, pulmonary function tests may be indicated prior to proceeding with any intervention.

## DIAGNOSTIC ADJUNCTS

Once the initial evaluation has been performed in the office, basic laboratory evaluations for complete blood count, coagulation profile, and baseline chemistries are needed. Imaging studies should consist first of erect, posterior-anterior, and lateral chest radiographs to evaluate the location, size, presence of calcifications, osseous involvement, and the presence of pulmonary parenchymal disease. Next, an ultrasound exam to determine the echo features (solid versus cystic, degree of homogeneity) and vascularity of the mass is recommended. Axial imaging (computed tomography or magnetic resonance imaging [MRI]) is performed afterward. The advantages of CT reside in its ability to clearly define the lung parenchyma and pleural space in relation to the osseous, vascular, and soft tissue components of the thorax (and hence mass), and the fact that it is a fast technique requiring minimal to no sedation even in the youngest of patients. The negative aspects of CT are the radiation exposure with subsequent risk of a secondary malignancy.[106] The benefits of MRI include better definition of the soft tissue components versus CT, as well as enhanced evaluation of the osseous and neural structures to determine the extent of central or peripheral nerve involvement and/or the presence of skip lesions or metastases. Unfortunately, this technique is time consuming and generally requires sedation or even general anesthesia to adequately acquire the data. Motion artifact from the heart and lungs can also interfere with this technique, limiting its utility, but this obstacle is being overcome with the use of cardiac-gated, respiratory-triggered protocols.[107,108] Determination of the precise entity from radiology studies alone is impossible, but the accurate construction of a differential diagnosis is readily possible, including the differentiation of malignant versus benign lesions.[107,108] Finally, other imaging studies may also be indicated to determine the presence of metastases (brain and abdominal CT, bone scan, positron emission tomogram [PET] scan) depending on the type of lesion, especially if malignant. Recent reports have suggested that the combination of PET and CT scans yields more accurate data in assessing the primary tumor, local and regional lymph node basins, evidence of recurrence, and for response to ongoing therapies.[109,110] Once initial studies have been performed, retrieval of tissue for histopathologic evaluation and diagnosis is warranted.

## DIAGNOSIS

Biopsy options include small or large specimen approaches. If a mass is small (less than 3 centimeters) or thought to be benign, then an upfront excisional biopsy may be warranted. However, the incision should be oriented so that a future reexcision, if needed, can be performed without compromising oncologic principles. Excising a normal rim of tissue circumferentially around the mass is also something for which the surgeon should opt. If the mass is large (greater than 4 to 5 centimeters), fixed to surrounding structures, involving many structures in the thorax, or if it is considered malignant by imaging, then either an incisional biopsy or core needle biopsy is warranted. Placing the incision in-line with any future resection is of paramount importance, regardless of the technique used, and either approach will yield enough tissue for histopathologic and cytogenetic analyses.[111] Once a diagnosis is confirmed, then disease-specific treatment algorithms may be initiated.

## THERAPEUTIC PRINCIPLES

Though treatment regimens are tumor specific, there are certain general principles that apply. For malignant lesions, multimodality therapy is the accepted paradigm for the majority of lesions, while simple extirpation is the rule with benign entities. With surgery, the most important concept to emphasize is that of the need for negative margins to decrease the risk of recurrence and subsequent therapy. Surgical extirpation also mandates wound reconstruction, which must be considered prior to the initiation of operative therapy. Large defects (greater than 5 centimeters, except for posterior and superior lesions where the defect will be buttressed by the scapula) will require the use of prosthetic materials—rigid (silicone, Teflon [DuPont, Wilmington, Del.], methyl methacrylate) or flexible (Prolene mesh [Ethicon, Cincinnati, Ohio], PTFE mesh, Marlex mesh [Chevron Phillips Chemical, Bartlesville, Okla.], Gore-Tex [WL Gore & Associates, Newark, Del.])—and/or autologous tissues (pedicle or free flaps [latissimus dorsi, rectus abdominis, or pectoralis major]) to reconstruct the chest wall and thus ensure normal chest wall mechanics and prevent respiratory embarrassment.

## TUMOR TYPES

Chest wall tumors are separated into benign and malignant cohorts (Table 42-5), as well as primary and secondary lesions. Specific tumors and their treatment will be outlined in the subsequent sections, but a discussion concerning secondary tumors is beyond the scope of this work.

### Benign Chest Wall Tumors

***Aneurysmal Bone Cyst*** Aneurysmal bone cysts (ABCs) can be found anywhere on the chest wall, and they generally arise in the ribs. They have characteristic patterns of appearance on both chest radiographs and MRI,[107] and they can grow to be quite large, producing local destruction to the adjacent tissues. Surgical extirpation with complete excision is the treatment of choice, and recurrence is rare. Histologically, the lesions are blood-filled cysts composed of fibrous tissue and giant cells.

***Chondroma*** Chondromas are slow growing, painless masses that usually arise in the costal cartilages. On imaging studies, they are lytic lesions with sclerotic margins, and unfortunately, they are difficult to distinguish radiographically from their malignant brethren, chondrosarcomas. Hence, complete resection with a wide margin of normal tissue is advocated.[112]

***Desmoid*** Desmoid tumors are fibrous neoplasms that can be found anywhere in the body. They are thought to be benign, but they have also been reported to undergo malignant degeneration.[112] Desmoid tumors infiltrate adjacent and surrounding tissues, and they are known to travel down fascial planes and to encase neurovascular structures in the mediastinum or

the thoracic inlet. MRI is the radiologic procedure of choice to best define the extent of involvement and the structures involved. Treatment is wide local excision with negative margins, but recurrence rates from 10% (negative margins) to 75% (positive margins) have been described by some authors.[113–115] If a complete resection is not possible, or if vital structures are meant to be sacrificed during operative extirpation, then multimodality therapy consisting of radiation (50 to 60 Gy), and cytotoxic (vinblastine and methotrexate) and cytostatic (tamoxifen and diclofenac) chemotherapy is recommended, though the exact regimen is not well defined.[116–119]

***Fibrous Dysplasia*** Fibrous dysplasia is a benign condition where normal bone is replaced by fibrous tissue. These lesions are generally not large, and patients present with pain, generally from a pathologic fracture. On plain radiographs, these lesions are described as lytic in nature with a characteristic "soap bubble" appearance.[120] Treatment is based on symptoms and concerns for possible fracture secondary to the inherent structural weakness the lesion produces in the bone. Simple excision is the recommended procedure.

***Mesenchymal Hamartoma*** Mesenchymal hamartomas (MH) are masses found in infants or young children that can also be discovered antenatally. The lesions are generally well circumscribed, and though emanating from the chest wall (one or several ribs), they abut or compress, as opposed to invade, thoracic structures (Fig. 42-4). Hence, presenting symptoms are primarily from respiratory embarrassment. These lesions are well defined by radiographic features on cross-sectional imaging, including mineralization and hemorrhagic cystic structures.[121] Histopathologically, these lesions consist of chondroid tissue with blood-filled, endothelial-lined spaces

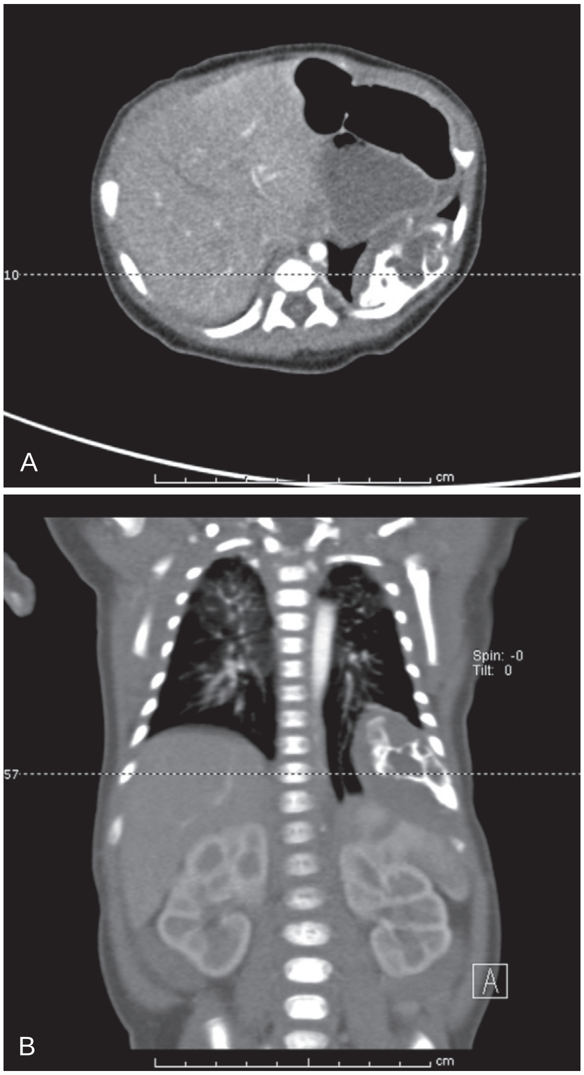

FIGURE 42-4 Axial **(A)** and coronal **(B)** images of a computed tomography scan of the chest in an infant with a mesenchymal hamartoma.

interspersed with osteoclastic giant cells. Treatment strategies have traditionally consisted of complete resection with subsequent chest wall reconstruction, but considering the large size of these lesions and the small volume of the chest cavity in the infants in which they are discovered, concern over the future complications of scoliosis and respiratory compromise from this approach has been considerable. In light of the fact that they are not known to undergo malignant degeneration,[122] observation[123,124] or other less morbid approaches (radiofrequency ablation[125]) have been described and recommended.

***Osteochondroma*** Osteochondromas are tumors composed of bony and cartilaginous elements more commonly found in males (3:1 ratio).[112] The lesion can present with pain from a pathologic fracture or compression of nearby nerves, or it can be asymptomatic if it grows inward into the thoracic cavity. The lesion is well characterized on plain radiographs, and it arises from the cortex of the rib at the metaphysis and has a "cartilage cap."[120] Malignant degeneration has been documented,[107] and resection is warranted in all postpubertal patients, with symptoms, or if the mass is growing.

## Malignant Chest Wall Tumors

The majority of clinically prevalent malignant tumors in the pediatric population are sarcomatous lesions, and a select sampling of these tumors will be addressed individually in the following sections.

***Chondrosarcoma*** Chondrosarcomas (CSs) are derived from cartilaginous elements (costal cartilages) that are the most common primary malignant bone tumor of the chest wall in adults,[126] and they are more common in males.[112] CSs have been associated with a prior history of trauma,[127] as well as being known to form from malignant degeneration of the benign counterpart discussed previously.[126] Some 10% of patients will present with metastatic disease,[103] especially in the lungs and brain. Primary therapeutic intervention is complete surgical extirpation with a margin of normal tissue of at least 4 centimeters[112] secondary to the high risk of local recurrence (up to 75% with positive margins), even with negative margins at the initial operation (10%).[128] These tumors are not chemotherapy responsive, and the role of radiation is only for those lesions that are unresectable or have known positive margins. Five-year survival has been reported to range from 60% to 90%,[128,129] and beneficial prognostic factors are the absence of metastases at presentation and a complete resection.[103,128]

***Ewing Sarcoma Family/Primitive Neuroectodermal Tumors*** Ewing sarcoma family/primitive neuroectodermal tumors (EWS/PNETs) are the most common malignant chest wall lesions in the pediatric population.[123] They are aggressive tumors requiring multimodality therapy, but survival is still poor despite these interventions. The tumors often present as painful masses with frequent metastases (25%) to the lung, bone, or bone marrow.[103] EWS/PNET lesions are characterized by a balanced gene translocation *(EWS/FLI1)* (t11:22 [q24:q12]),[130] and these tumors are defined histologically as sheets of small, round cells with scant cytoplasm. On imaging studies, they have characteristic bony destruction described as lytic or sclerotic lesions.[108] Treatment involves an initial biopsy followed by neoadjuvant chemotherapy (four cycles) with vincristine, actinomycin, cyclophosphamide, and Adriamycin (Adria-VAC) alternating with etoposide and ifosfamide. This regimen has demonstrated a great deal of success in shrinking the tumor to improve survival and facilitate complete resection (Fig. 42-5).[131,132] In fact, with the use of neoadjuvant chemotherapy, complete surgical extirpation with negative margins was possible in 71% of patients versus 37% who underwent primary surgical intervention.[132] The extent of surgery should include all involved structures and a soft tissue or osseous margin. Postoperative adjuvant therapy uses the same preoperative chemotherapy regimens, but not radiotherapy if complete resection is achieved. This should be the goal, despite the known radiosensitivity of this tumor,[133] because of the concern over the late effects (scoliosis, pneumonitis, cardiotoxicity, secondary malignancy, growth retardation, and breast hypoplasia or aplasia) radiotherapy poses.[132] The use of radiotherapy is for residual and unresectable disease and for patients who present with a malignant pleural effusion, where it is an accepted therapeutic intervention. A recent European consensus conference advocated for surgery rather than irradiation in all cases.[134] Five-year survival using the previously mentioned protocol was around 70% for nonmetastatic disease,[135] and the 8-year survival was roughly 30% with metastatic disease.[136] In patients presenting with metastatic disease, the European Intergroup Cooperative Ewing's Sarcoma Studies Group demonstrated improved survival with the use of myeloablative chemotherapy followed by stem cell rescue at the conclusion of conventional treatment protocols.[137]

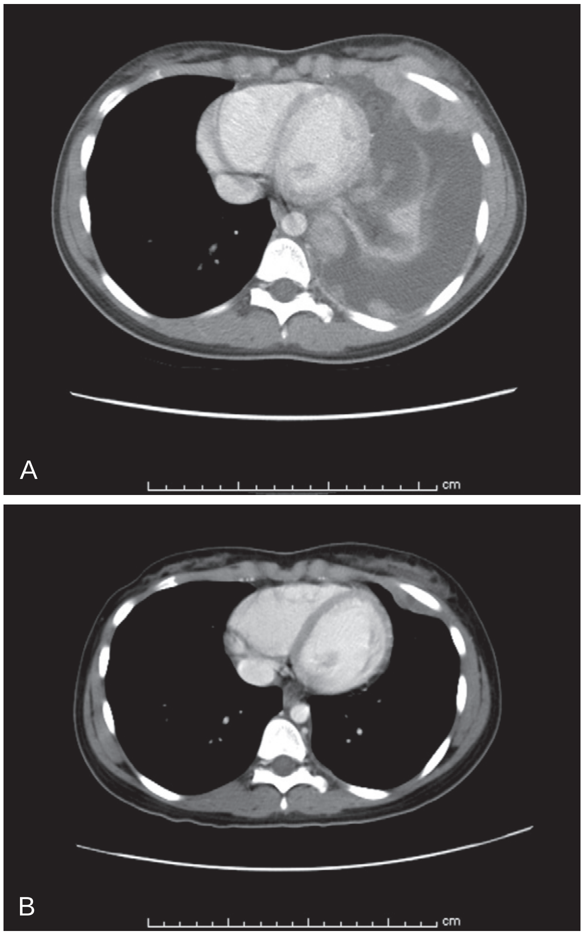

**FIGURE 42-5** Axial images of a computed tomography scan of the chest in a child with a Ewing sarcoma family/primitive neuroectodermal tumor (EWS/PNET) of the chest wall before **(A)** and after **(B)** neoadjuvant chemotherapy.

***Fibrosarcoma*** Fibrosarcoma (FS) (also known as infantile or congenital fibrosarcoma) are malignant tumors found throughout the body in infants who present with large masses that often involve, invade, and surround adjacent structures. FS have been found in the chest wall, and several reports have documented the success of multimodality therapy in combating these tumors.[138,139] FS can be distinguished from other myofibrous and sarcomatous lesions by the presence of a unique gene rearrangement between the *TEL* gene (12q13) and *TRKC* gene (15q25).[138] FSs are chemotherapy sensitive, and reports demonstrating the effectiveness of neoadjuvant chemotherapy with vincristine, actinomycin, cyclophosphamide, and Adriamycin, followed by surgical extirpation, are well accepted.[138,139] A recent report[139] from Europe

demonstrated that 5-year overall and event-free survival rates were 89% and 81%, respectively. The authors reported that in their series complete surgical extirpation was rarely feasible and that conservative surgical approaches should be adopted. Furthermore, 71% of patients responded to alkylating agent-free and anthracycline agent-free regimens, and hence, this regimen should be started first to limit toxicity.

***Osteosarcoma*** OS of the chest wall can be primary or secondary tumors (prior sites of irradiation or from preexisting osseous lesions [Paget disease]).[112] Primary lesions are primarily of the ribs, and on imaging, they can be confused with chondrosarcomas.[140] Chest radiographs will demonstrate a "sunburst pattern," and axial imaging concentrating on regional (bony skip lesions) and distant (lung, liver, brain) metastases must be sought.[112] Pretherapy biopsy is the rule, and neoadjuvant therapy precedes extirpative procedures. Overall survival rates are poor (15% to 20%),[103] but in the presence of nonmetastatic disease, 5-year survival rates can exceed 50%.[103] Prognosis is related to the presence of metastases, the degree of tumor burden, and the response to chemotherapy.[141]

***Rhabdomyosarcoma*** RMS of the chest wall is a rare tumor and encompasses no more than 7% of all RMS in Intergroup Rhabdomyosarcoma Studies (IRS).[142–144] The chest wall site is deemed an unfavorable site, and therefore this is an adverse prognostic factor.[142,143] Other adverse prognostic factors have been reported to be histopathologic findings (alveolar versus embryonal), tumor burden and size, incomplete resection, and presence of metastatic disease (including lymph node metastases).[143,145] Despite advances in the treatment of RMS over the last 40 years, unfavorable sites carry an overall survival of only 55% (versus 90% for favorable sites),[143] and those with truncal RMS have been reported to have a failure-free survival rate of no greater than 67%.[146] These tumors require multimodality therapy, and neoadjuvant chemotherapy followed by surgical extirpation is the norm. Radiation is reserved for lesions with positive margins following surgery, or in unresectable tumors. A report from Saenz and colleagues documented the utility of radiation (median dose of 44 Gy) to salvage some patients with residual disease.[146] However, the necessity for complete surgical resection has been called into question by a recent report from the Children's Oncology Group (COG),[147] where the outcome of patients enrolled in IRS I-IV with chest wall RMS were analyzed. The report documents that regardless of clinical group (I-III) and other tumor-specific factors (histologic subtype, tumor size), the only critical factor to influence failure-free and overall survival was the presence of metastatic disease. In the face of metastases, patients with chest wall RMS had an overall and failure-free survival of 7% and 7% versus 49% and 61%, respectively, in the cohort without metastases ($P < 0.001$). Therefore the authors suggest where gross total surgical resection will produce significant morbidity or physical debilitation, less aggressive operative approaches should be entertained.

CHAPTER 43

# Bone Tumors

Saminathan S. Nathan and John H. Healey

Bone tumors are rare. In the United States, there were 166,487 cases of breast cancer and 164,753 cases[1] of prostate cancer in 2000. By comparison, there were only 2,051 cases of all types of bone sarcomas that year. A large proportion of these tumors, 26.8% in one published database, occur in the pediatric population. There are no population-based benign bone tumor registries; so, it would be impossible to establish their true incidence. Most databases of this nature derive from tertiary referral institutions, and so, benign conditions, which are often asymptomatic, would be grossly underrepresented. Nevertheless, one study has shown that up to 43% of children have a bone lesion that mimics or is a true neoplasm during skeletal development.[2] This implies that the overwhelming majority of lesions are benign.

The pediatric surgeon will often be called into the management of the patient with bone tumors for a number of reasons. The very young child on follow-up for an unrelated condition may manifest with a bone lesion secondary to osteomyelitis or leukemia. The older child with a metastatic osteogenic sarcoma may require the expertise of the pediatric thoracic surgeon for the resection of pulmonary nodules. The teenager with a pathologic fracture through a unicameral bone cyst or nonossifying fibroma may present first to the pediatric surgeon on call in the pediatric emergency department.

The diagnosis of these rare conditions is readily attained through a careful clinical evaluation. In that regard, the utility of plain radiographs can never be overstated. They facilitate the initial workup and allow these patients to be referred to specialized centers with multidisciplinary expertise. Although the subsequent imaging modalities are important, the radiographs form a key part of surgical planning.

It is with the pediatric surgeon in mind that this chapter is written. Lengthy discourse on the pathology is avoided, and several excellent references exist.[3–6] Instead, the format adopted is a practical approach to the management of these conditions. Where prudent, insights and controversies are highlighted to spur interest in specific areas.

## General Considerations

### PATHOPHYSIOLOGY

The main aim of this section is to illustrate the specific issues of the pathophysiology of bone tumors that distinguish them from tumors of soft tissue. Bone tumors should be approached initially from the standpoint of whether they are benign or malignant. Whereas traditional approaches regarding the treatment of most nonskeletal benign lesions have been ones of benign neglect (if these lesions are not perceived to be causing problems), the management of benign bone lesions is complicated by the potential compromise of skeletal structural integrity. Cortical deficiency weakens bones and can mandate treatment to prevent fracture. The prudent, if rare, consideration is one of syndromic presentation and malignant transformation. Many of these principles are applicable to malignant lesions as well. However, malignant lesions have, as the cornerstone of consideration, their implications on survival, which will be elaborated. Metastatic lesions to bone are uncommon in the pediatric age group. Their pathophysiologic implications tend to be structural or diagnostic.

In the pediatric age group, benign lesions far outnumber primary malignant lesions, which in turn outnumber metastatic lesions. Because of the protean manner in which benign lesions behave, some are not evident in the physician's office. Conclusions about their natural history and malignant potential are therefore difficult to ascertain.[4] This is obviously not the situation with malignant and metastatic lesions. In this section, we discuss pathologic conditions of the bone that occur most commonly in the pediatric age group. In the pediatric population, the commonly occurring benign lesions are the unicameral bone cyst, aneurysmal bone cyst, enchondroma, osteochondroma, nonossifying fibroma, and osteoid osteoma. The common malignant bone tumors are osteogenic sarcomas and Ewing family tumors (Table 43-1). Here we highlight specific features of each tumor. For a more thorough understanding of the pathology, the reader is directed to any of a number of fine books on the subject.[3–6]

#### Benign Lesions

The typical benign lesion in the pediatric age group (Table 43-2) is identified incidentally, because they rarely cause symptoms. They are often diagnosed when a parent notices a lump or deformity (e.g., osteochondroma) or a radiograph is obtained for an unrelated condition (e.g., nonossifying fibroma). The two main surgical issues are diagnosis

| 15 to 20 years | Unicameral bone cyst | Osteogenic sarcoma | Fibrous dysplasia |
| | Osteochondroma | Ewing sarcoma | Stress fracture |
| | Osteoid osteoma | | |
| | Aneurysmal bone cyst | | |
| | Nonossifying fibroma | | |
| | Giant cell tumor | | |
| | Enchondroma | | |
| | Chondroblastoma | | |
| | Chondromyxoid fibroma | | |

By considering the factors of age, frequency, and location in the long bones (see Fig. 43-3), a diagnosis can be proposed in the majority of cases. The possibility of trauma should always be borne in mind, and in the noncommunicative child younger than 5 years old, nonaccidental injury may be the cause.

**TABLE 43-2**
**Incidence of the More Commonly Diagnosed Bone Tumors**

| *Bone Tumors* | *All Bone Tumors (%)* | *Bone Tumors in the First Two Decades (%)* |
|---|---|---|
| Benign | | |
| Osteochondroma | 7.86 | 4.69 |
| Aneurysmal bone cyst | 2.60 | 1.96 |
| Osteoid osteoma | 2.99 | 1.94 |
| Nonossifying fibroma | 1.13 | 0.99 |
| Enchondroma | 3.02 | 0.98 |
| Giant cell tumor | 5.10 | 0.80 |
| Chondroblastoma | 1.07 | 0.66 |
| Chondromyxoid fibroma | 0.41 | 0.14 |
| Unicameral bone cyst | Unknown | Unknown |
| Malignant | | |
| Osteogenic sarcoma | 14.9 | 7.53 |
| Ewing sarcoma | 4.6 | 3.50 |

In using this table, a number of caveats need to be remembered. Most benign lesions are often asymptomatic, and only symptomatic ones will present. Of these, most will be managed in the primary care setting. Malignant lesions will, however, usually present at a referral center. Hence, in terms of population incidence, these figures are unreliable. In relative terms, however, they have some utility in indicating their prevalence. Unicameral bone cysts are left in this list as a reminder of their frequency.

through a biopsy and stabilization of bones that have fractured or are at risk to fracture, especially through a precarious location. For example, a bone cyst in the neck of a femur should be seriously considered for surgical stabilization, because a fracture at this site may result in avascular necrosis of the femoral head. The biopsy itself cannot be undertaken lightly, because it can weaken the bone, mandating surgical or external splinting. The challenge is to use a high-yield biopsy with minimal morbidity.

***Size of the Tumor*** Size is an important consideration for surgical approach. For example, cartilaginous rib tumors larger than 4 cm were found to have increased likelihood of malignant behavior.[3] Hence they should be resected widely despite their relatively bland histologic appearance (Fig. 43-1). Large tumors can also grow into neighboring compartments and cause mechanical compromise to joints. Although this is less critical in joints of the upper limb, it is important in the spine and in the lower limbs, where they cause mechanical impingement and pain. The disruption of a tubular bone by growth of a neoplasm weakens the bone. Lesions that involve more than 50% of the cross section of a bone are at risk of fracture and should be treated from a mechanical standpoint.[7–9] Fracture of a malignant lesion may require amputation rather than a limb-sparing operation.

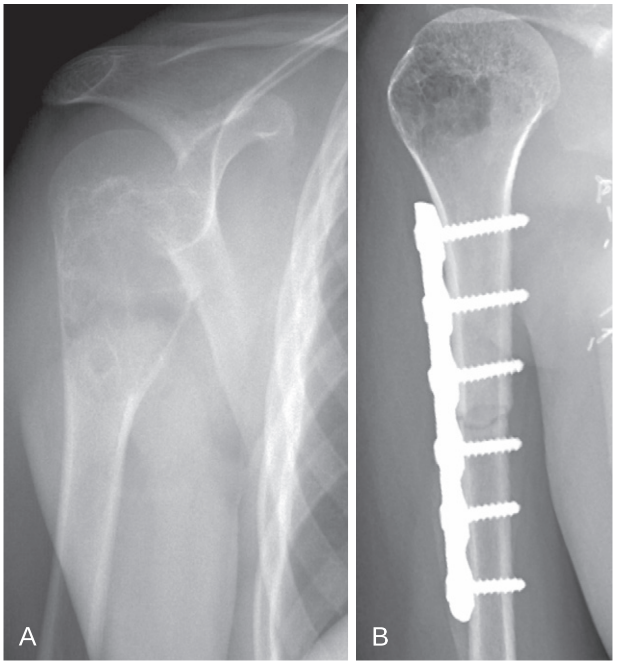

**FIGURE 43-1** **A,** Chondrosarcoma in the proximal humerus of a 13-year-old boy. This is an exceedingly rare diagnosis in this age group. **B,** A proximal humeral resection with allograft reconstruction was performed. In children, the available prostheses may be too large, and hence bulk allografts may be the only choice.

***Fracture Through a Benign Lesion*** The fractured benign lesion is typified by the unicameral bone cyst. These lesions may appear radiographically to be aggressive, but a careful history and physical examination with appropriate imaging modalities will usually establish their benign nature

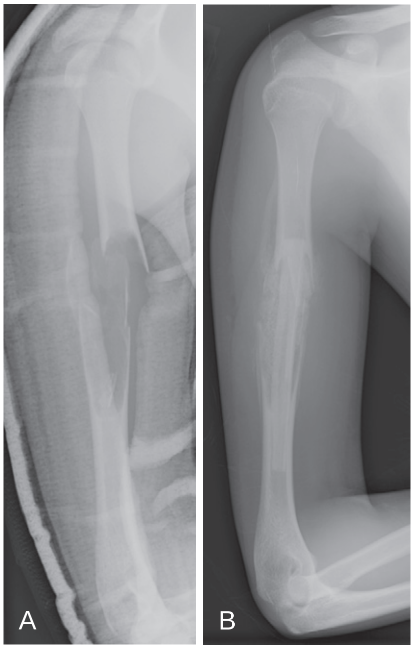

**FIGURE 43-2** **A,** Large unicameral bone cyst of the proximal humerus that had fractured. The aggressive appearance may lead one to suspect a malignant process, but a careful evaluation of the margins of this lesion and absence of periosteal reaction reaffirms the management decision of observation before surgery. **B,** This cyst was curetted and packed with an allograft 1 month after the fracture. Treatment with an intramedullary fibular graft provided stabilization, and supplemental bone graft healed the lesion.

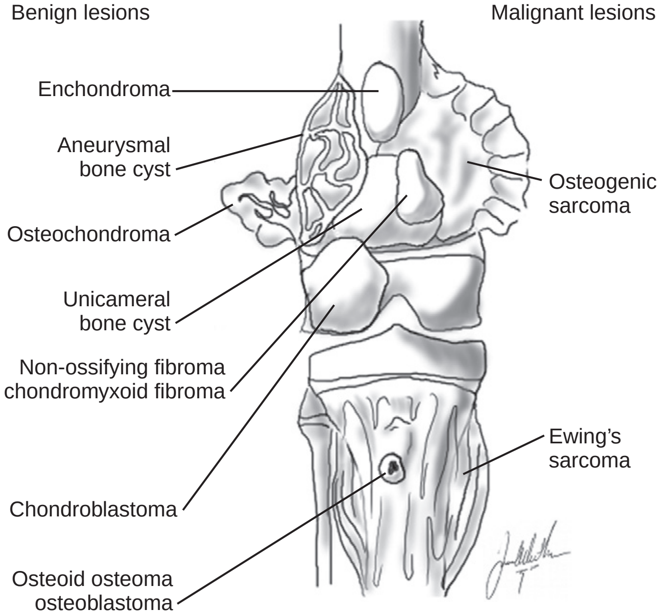

**FIGURE 43-3** The location of lesions in relation to the physis gives a clue to the diagnosis. In most cases, the diagnosis can be made on radiographs, leaving further imaging to plan for surgery.

(Fig. 43-2). Unicameral bone cysts that fracture may resolve spontaneously. However, the vast majority continue to fracture throughout a child's lifetime and prove to be disabling.[10] In general, they should be treated surgically, especially if they are symptomatic.

The timing of surgery is critical. An early biopsy after fracture would show callus formation difficult to distinguish from a malignant process. Therefore these lesions should be observed during healing of the fracture for about a month, after which a biopsy and definitive procedure are performed.

***Location in Relation to the Physis*** Location in relation to the physes is an important consideration distinguishing tumor assessment and management of children versus adults (Fig. 43-3). The term diaphyseal aclasis was coined to highlight a condition in which multiple osteochondromas, a condition primarily of the growth plate, caused disordered linear growth of the long bone.[6] These cases are often familial, and children are rarely compromised by their condition. Joints of the upper limb generally have a high tolerance for the resultant deformity. However, occasionally, degenerative arthritis develops, especially in the lower limb, then requiring early surgery.

***Multiplicity of Bone Tumors*** Multiple bone lesions in an individual are often syndromic and may confer a higher incidence of malignant degeneration than when they occur singly.[4–6] Multiple osteochondromas occur in multiple hereditary exostoses—an autosomal dominant condition caused by abnormalities of the *EXT1, EXT2,* and *EXT3* genes on chromosomes 8, 11, and 19.[11–13] Although each osteochondroma has a low probability of malignant transformation, the cumulative risk is high. Children with this condition have an increased incidence of 10% to 27.6% for malignant degeneration of an osteochondroma into a chondrosarcoma. By comparison, isolated osteochondromas have a malignant degeneration rate of about 1%.[3–5] Because only symptomatic lesions will present to the physician, the true incidence of malignant degeneration in isolated lesions is impossible to ascertain with certainty. Multiple enchondromatoses is a sporadic condition that confers an increased incidence of malignant transformation of up to 50% in the involved bones.[4] Limb-length inequality and malalignment are also common. Ollier disease, as this condition is termed, has another counterpart classically affecting one limb anlage. A variant, Maffucci syndrome, involves widespread enchondromas associated with hemangiomas of the hand. The occurrence of multiple nonossifying fibromas, associated with mental retardation, café-au-lait spots, endocrine disorders, cardiovascular malformations, and ocular abnormalities has been termed Jaffe-Campanacci syndrome, but this entity has no malignant implications.[4,14]

***Site of Involvement*** The site of benign cartilaginous lesions has important implications for malignant potential. Peripheral lesions in the hand rarely turn malignant, while those closer to the axial skeleton have important malignant potential even if they appear benign histologically.[3–6,14,15] Lesions in bones adjacent to weight-bearing joints should be regarded with special concern. In the pediatric group, these lesions are usually chondroblastomas. They grow epiphyseally and in so doing can cause weakening of the subchondral bone and, ultimately, an intraarticular extension or fracture that may even mimic

osteochondral defects. In the case of sarcomas, a relatively conservative resection in this context would have to be deferred to an extraarticular resection.

***Metastatic Potential*** A unique feature of benign bone tumors is that there is a small incidence of metastasis in these lesions. Accordingly, 1.7% of chondroblastomas and 3% of giant cell tumors[5,16–18] do metastasize. There is a controversy about whether some of these lesions were, in fact, malignant from the outset.[19] However, the truly benign lesions that do metastasize are atypical lesions that have had surgical manipulation, which may have embolized tumor cells. When followed, some of these metastatic lesions, primarily in the lung, may remain dormant and not progress. The possibility, therefore, is that they represent a transport phenomenon more akin to a mechanical embolism and not a true metastasis.[3,19]

## MALIGNANT LESIONS

### Epidemiology

The main histologic types of bone tumors are osteogenic sarcoma, Ewing family tumor, chondrosarcoma, and other sarcomas. They affect children at a rate of 6:3:2:1, respectively.[1,5]

Osteogenic sarcomas (also known as osteosarcomas) are malignant bone-forming tumors of the bone. They occur at any age but most frequently present in an extremity in the middle teenage years. There are various subtypes with varying implications for survival. In general, the subtypes behave similarly, except perhaps for telangiectatic osteogenic sarcoma, which bears special mention. In the prechemotherapy era this was regarded as the tumor with the worst prognosis.[20] Presently, however, it has the best prognosis.[21] The lytic nature of these sarcomas weakens bone, resulting in the highest rate of pathologic fracture. Increasingly, rarer forms of osteogenic sarcoma are described. Two variants of note are the small cell sarcoma and giant cell-rich osteogenic sarcoma. The former can be confused with a Ewing family tumor and thus is often treated by similar chemotherapy protocols.[22,23] The latter can be confused, in the appropriate setting, with a giant cell tumor of the bone, which is a benign condition.[24–26]

The Ewing sarcoma occurs at a younger age (see Table 43-1) and may affect any bone, particularly, the femur, pelvis, and humerus. It is the most common cancer in the pelvis, ribs, foot, and fibula. It was once considered to be distinct from peripheral neuroectodermal tumors but has been shown to be genetically identical to this entity. It is presently considered to be in the same family of neoplasms also known as Ewing family tumors.[3,6]

Chondrosarcoma is less prevalent in the pediatric age group. It is more widely distributed in the body compared with its occurrence in adults.

***Genetics*** There have been few consistent genetic or syndromic associations with osteogenic sarcoma. Patients with the Li-Fraumeni syndrome[27] have a *TP53* germline mutation[28,29] on 9p21 and are predisposed to osteogenic sarcoma, breast cancer, and leukemia (Fig. 43-4). Two to 3 percent of patients with osteogenic sarcoma will be the proband for Li-Fraumeni families.[30] Another germline mutation of 13q14, hereditary retinoblastoma (RB), predisposes to osteogenic sarcoma.[31] Children who received radiation therapy for retinoblastoma, Hodgkin and non-Hodgkin lymphoma, Ewing family tumor, and other cancers are at a 5% to 10% risk of developing osteogenic sarcoma. Patients with an *RB* gene deletion and a history of alkylating agent exposure from a prior malignancy are predisposed to this complication as well. About 5% of all osteogenic sarcomas occur as postradiation sarcomas.

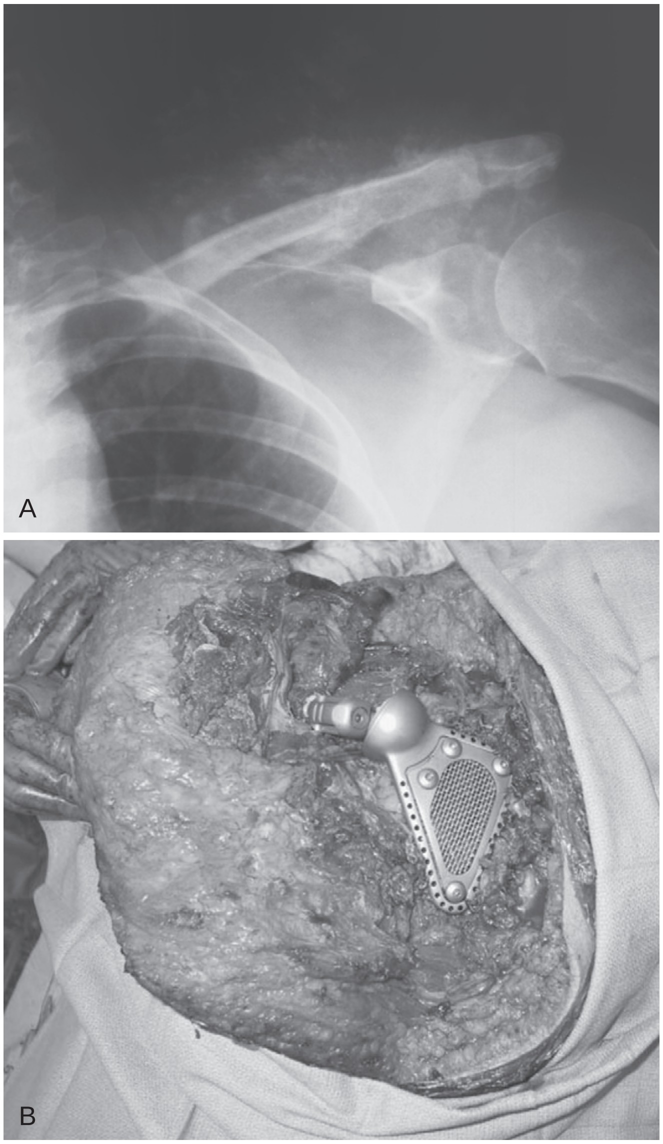

**FIGURE 43-4** **A,** Osteogenic sarcoma in the left scapula of a female patient with Li-Fraumeni syndrome. This patient had a family history of osteogenic sarcoma in a first-degree relative. At the time of staging for the osteogenic sarcoma in the scapula, a lesion in the breast was discovered on computed tomography (CT) of the chest. This was subsequently found to be an adenocarcinoma. **B,** The patient underwent a scapular replacement. A latissimus dorsi flap was used for skin cover.

The Ewing family tumor is a malignancy associated with a number of translocations. The 11 to 22 translocation, resulting in an EWS-FLI1 fusion transcript, is the most common variant, and type 1 is associated with the best prognosis.[32] Other translocations include type 2 EWS-FLI1, EWS-ERG from a 21,22 translocation, and EWS-ETV1 from a 7,22

translocation. These rarer variants have not been as well studied but appear to confer a poorer prognosis.[32] Further additive mutations involving cell-cycle genes reduce the prognosis of these tumors still more. The Ewing family tumor is the most common solid tumor to metastasize to the brain.[33]

## DIAGNOSIS AND STAGING

Bone tumors are diagnosed based on the well-recognized triad of history, physical examination, and investigation. After a clinical diagnosis, it is imperative that imaging and staging procedures are done before biopsy. Preoperative imaging allows for planning of the definitive procedure and hence placement of the biopsy incision. In addition, changes that would occur in the lesion after biopsy would be difficult to distinguish from changes resulting from tumor growth on imaging. Furthermore, changes in the lung after general anesthesia (e.g., atelectasis) are difficult to distinguish from metastatic deposits.

### Clinical Evaluation

Although it is not possible to be comprehensive in this section, the history and physical examination are important parts of the assessment of a patient with a bone tumor. Patient demographics and tumor location narrow the differential diagnosis and focus the workup efficiently.

The patient's age is important (see Table 43-2). Most malignancies occur in the second decade of life.[3–6] Among children, subtle variation occurs in the prevalence of disease with respect to age (see Table 43-1). Demographically, it is exceedingly rare for patients of African descent to have a Ewing family tumor.[6]

Pain at rest is an important sign that occurs in tumors and in other organic conditions, such as infection and bone infarction. It distinguishes these conditions from mechanical pain, which occurs with activity. Most malignant tumors will present with pain. Pain relieved by nonsteroidal antiinflammatory drugs (NSAIDs) is pathognomonic of osteoid osteoma.[34] This lesion can occur at any age and is characterized by painful scoliosis when it occurs in the spine.

A family history of malignancy should be discerned, especially in possible sentinel cases of the Li-Fraumeni syndrome.[27–29] Such patients should have systemic evaluation in the form of radioisotope bone scans or positron emission tomographic scans, to rule out other sites of involvement.

As described earlier, the surgeon should be alert to any dysmorphism that the patient may have. Cutaneous stigmata are evident in patients with neurofibromatosis, fibrous dysplasia, and Jaffe-Campanacci syndrome.[14] Limb length discrepancies are seen in patients with multiple enchondromatoses and multiple hereditary exostoses.[35]

Infection should be considered in the differential diagnosis in almost every case seen. Tumor epidemiology is very telling. For example, childhood leukemia is nearly 10 times as common as Ewing family tumor, and so, rare manifestations of leukemia are more common than routine presentations of Ewing family tumor.

The nature of bony reconstruction also requires that the method chosen be matched with the demands of the patient. As such, an idea of the patient's expectation should be sought at this time.

### Radiology

The minimal radiologic assessment at the first visit should be two orthogonal radiographic views of the area in question. A radiograph remains the most specific diagnostic imaging test and is the only one that gives the "gestalt" of overall assessment of skeletal biology and mechanics. By analyzing the location of the tumor (see Fig. 43-3), as well as whether it is benign or malignant, the diagnosis can be made in the majority of cases.[3–6]

Benign lesions are well circumscribed, with a good sclerotic border, and produce no soft tissue edema. Malignant lesions have lucent or variegated matrices and permeative borders. Edema is often apparent with the presence of fat lines.

The often-quoted eponymous phrases are not specific to distinct malignancies. The Codman triangle refers to the lifting and ossification of periosteum at the periphery of an osteogenic sarcoma. The sunburst appearance is due to the ossification of fibers and vessels subperiosteally, as the tumor expands out of the cortex. Onion skinning refers to the periodic ossification and expansion of periosteum from the cortex. Any of these conditions can be seen in tumors or infections that are sufficiently fast growing.

In Figure 43-3, epiphyseal lesions are typical of chondroblastoma or giant cell tumors; physeal lesions are typical of osteochondromas; metaphyseal lesions are typical of osteogenic sarcomas, unicameral bone cysts, aneurysmal bone cysts, and nonossifying fibromas; and diaphyseal lesions are typical of Ewing family tumor, fibrous dysplasia, or enchondromas.

### Laboratory Evaluation

The main blood parameters of importance are lactate dehydrogenase and alkaline phosphatase.[36–38] Lactate dehydrogenase levels have been used as a surrogate for tumor load and have been correlated with survival in the case of Ewing family tumor.[36] Serum alkaline phosphatase elevation is characteristic of osteogenic sarcoma and is correlated with poor survival in this condition.[37,38] Glucose intolerance is associated with chondrosarcoma of the bone.[39,40] Erythrocyte sedimentation rates, C-reactive protein, and white blood cell and differential counts should be sought to rule out infection.

### Preoperative Planning

Magnetic resonance imaging (MRI) of the lesion offers an assessment of compartmentalization of the tumor. A compartment is an abstract concept and refers to any plane that offers a fascial or cortical bone barrier to contiguous spread. It has implications for the extent of surgery, which by definition must be outside the compartment to be radical (see later).[41] Also, by forming a baseline assessment, one is able to make an assessment of response to chemotherapy in the case of neoadjuvant treatment.[42] It has secondary importance in providing the actual diagnosis. In specific examples it is useful in histologic diagnosis. The aneurysmal bone cyst shows fluid-fluid levels on an MR image. Pigmented villonodular synovitis is hypointense (dark) on T1- and T2-weighted imaging because of hemosiderin deposition. Cartilaginous lesions are hyperintense (light) on T2-weighted imaging. Mineralized and dense fibrous tissues are dark on T1- and T2-weighted imaging.[43,44]

### Staging

Staging studies are meant to assess the degree of spread of the disease. In the case of bone tumors two systems are used: the Enneking system or surgical staging system (SSS),[45] as adopted by the Musculoskeletal Tumor Society and the American Joint Committee on Cancer (AJCC) system, which at the time of writing is in its sixth revision.[46] In the case of Ewing family tumor, a different classification than Enneking is used.[47]

In the SSS, tumors are designated G0, G1, and G2 for benign, low-grade, and high-grade lesions, respectively. Benign lesions (G0) are classified as latent, active, or aggressive—designated by Arabic numerals 1, 2, and 3, respectively. Malignant lesions are designated with the Roman numeral I if low grade and II if high grade. The further designation A or B denotes intracompartmental or extracompartmental disease. Stage III disease is metastatic disease. Therefore in this classification, grade, compartmentalization, and metastases are the fundamental prognostic factors.

In the AJCC system, I and II similarly designate low- and high-grade lesions. The letters A and B designate tumors smaller or larger than 8 cm, respectively. The Roman numeral III denotes multicentric disease, and IV denotes metastatic disease. The designation IVA denotes pulmonary metastases, and IVB denotes extrapulmonary metastases. Therefore this classification considers grade, size, multicentricity, and metastases as prognostic factors.

In the Enneking staging system of Ewing family tumor, stage I tumors are solitary intraosseous lesions, stage II are solitary lesions with extraosseous extension, stage III are multicentric lesions, and stage IV are metastatic. It is unclear how to stage patients who have independent sites of bone marrow involvement versus those who have circulating tumor cells identified by light microscopy (i.e., Enneking stage III or IV). Modern pathology analysis extends these concepts to include immunohistochemistry or reverse transcriptase polymerase chain reaction (RT-PCR) of recombinant gene products.

The modalities used for staging are bone scans and computed tomography (CT) of the chest.[45] Positron emission tomography scans are presently being evaluated, but have fundamental utility in the management of recurrent or metastatic disease.[48] In the case of Ewing family tumor, bone marrow biopsies are obtained to try capturing cases that are multicentric at presentation. The utility of this approach is being evaluated.[49]

## BIOPSY

The biopsy is a critical procedure that can complicate management severely if not performed appropriately. Misplaced incisions continue to be an important cause of resectable tumors being rendered nonamenable to limb salvage surgery.[41,50] A good pathologist who is comfortable handling bony tissue is critical to this process. In the appropriate case, extra tissue may be needed for cytogenetic studies. Ewing family tumors are particularly fragile, and biopsy specimens should be handled carefully to allow for processing.

### Presurgical Considerations

As a general rule, all imaging and staging should be completed before biopsy. The lesion that warrants biopsy should be given consideration for a primary wide excision. This approach is typically applicable to small lesions that are less than 3 cm, lesions in expendable bones (e.g., distal phalanx), distal lesions of the ulna, and proximal lesions of the fibula, where there is a risk of common peroneal nerve contamination (Fig. 43-5).

The lesion should preferably be sampled in the institution where the definitive procedure will be performed and by the same surgeon. It has been shown repeatedly, that when this approach is not used, the results are compromised.[50,51]

Consideration should be given to needle biopsies in the case of lesions in the pelvis or the spine, where the exposure necessary for an open biopsy may be extensive and obliges commitment to a definitive procedure.

A pathologist familiar with processing bone tissue should be on hand to evaluate the biopsy. If tumor tissue can be cut with a knife, then it can be cut with a microtome. Frozen-section analysis is required primarily to ascertain the adequacy and representativeness of the specimen and secondarily for the definitive diagnosis.

Antibiotics should be withheld before the biopsy to improve the yield of cultures. The biopsy may be done with use of a tourniquet, to prevent bleeding and dissemination of the tumor locally. When the tourniquet is applied, simple elevation should be used for exsanguination. Compressive exsanguination should be avoided, because this could rupture the tumor. At all times, the limb should be protected from fracturing, because this would cause extensive local dissemination of disease.

### Surgical Considerations

The planned incision for the definitive surgery should be marked. This should generally follow extensile exposures and be longitudinal along the line of the definitive incision. The incision should be placed directly over the lesion. Flaps and dissection should be avoided.

The incision is developed directly into the tumor. If there is a soft tissue component of the tumor, then this alone needs be sampled. If a bone biopsy is necessary, then the edges of the biopsy specimen should be rounded to minimize a stress riser. Frozen-section analysis will confirm the adequacy of the biopsy. In the meantime, a culture is taken, the tourniquet is released, and antibiotics are given. Absolute hemostasis is needed at the conclusion of the procedure to minimize spread of tumor cells in the hematoma.

The wound is closed in layers. If a drain is necessary, this should be brought out in the line of the incision so that it can be excised at the time of definitive surgery.

### Postsurgical Considerations

The patient should be limited to protected weight bearing, at least until some healing of the biopsy or ossification of the tumor as a response to neoadjuvant chemotherapy occurs. This typically takes up to 6 weeks.

Fractures through osteogenic sarcomas have traditionally precluded limb salvage surgery. Recent studies have shown that limb salvage may still be possible in selected cases.[52–55] Special surgical consideration is needed in these cases.

**FIGURE 43-5** **A** and **B,** An aneurysmal bone cyst of the right proximal fibula in a 17-year-old boy. **C,** In this instance, a primary wide resection was done, because the bone was expendable and it prevented contamination of the common peroneal nerve (*arrow*).

## ADJUVANT THERAPY

This section concentrates on the use of radiation and chemotherapy. In general, these modalities are not used in the treatment of benign conditions. Up to 10% risk of malignant transformation occurs when benign lesions are irradiated.[3–6]

Both chemotherapy and radiation therapy can be used in the neoadjuvant (preoperative) or adjuvant (postoperative) setting in the treatment of malignant conditions. The neoadjuvant approach has the advantage of "shrinking" the tumor and provides a more discernible margin, theoretically improving local control of the disease. In the case of chemotherapy, before the era of modular prostheses, the neoadjuvant route was necessary while the custom prostheses were manufactured. This technique has been shown to be as efficacious as primary surgery. Even so, the one randomized trial of preoperative and postoperative chemotherapy versus only postoperative chemotherapy failed to show any difference in survival. Therefore in selected cases, it is reasonable and may be prudent to perform surgery first.[56]

## SURGERY

In bone tumors, resection and reconstruction are two aspects of management that have largely complementary but occasionally conflicting goals (e.g., cryotherapy is good for extending the margins of resection of a tumor but results in weakening of the bone). Therefore, while the goals of resection are generally quite clear (i.e., cure), the goals of reconstruction are often compromised, especially in malignant conditions. In benign conditions, reconstruction usually restores more function. In this section, we present a general list of considerations that will be elaborated further in the section on specific considerations.

### Minimally Invasive Options

The minimally invasive option is reserved for benign conditions. It is born of two management philosophies—the desire to effect local control and the hesitation to cause more morbidity than the primary lesion. Whichever modality is chosen, it is imperative that a histologic diagnosis be obtained a priori.

***Radiofrequency Ablation*** Radiofrequency ablation uses high-intensity heat in proximity to a lesion, to effect thermal necrosis. It has wide utility in the ablation of various solid tumors. In bone tumors, it has been used principally in the ablation of osteoid osteomas. This condition is a painful one, marked by increased night pain and is promptly relieved by the use of NSAIDs. Otherwise, it is relatively benign. It can be found most commonly in the proximal femur. In these locations, surgical ablation in the form of a resection can incur high morbidity. Hence, an option such as radiofrequency ablation is ideal, although it incurs a 10% to 15% recurrence rate[57,58] compared with surgery, which has a near 0% recurrence rate.[59] It has limited utility in the spine because of the indiscriminate high heat generated.

***Injection*** This technique is principally used in the treatment of unicameral bone cysts. Clinically apparent bone cysts have a tendency to recurrent fracture and need to be treated.[10] However, they have no malignant potential and have been known to regress.[4,10] There is controversy about whether corticosteroid injection is a necessary element of treatment; it has been shown that simple decompression of a cyst is sufficient to induce a regression.[60] Rates of cure up to 50% are reported, with a median injection rate of three and a range of one to nine injections.[61,62] Each of these sessions requires the child to be under anesthesia. Therefore it has not been widely embraced.

As alluded to earlier, various forms of decompression have been advocated in the literature with varying success. One approach involves the injection of bone marrow.[63–67] Rates of cure of up to 50% to 70% may be achieved. However, with this technique, repeated injections may be necessary, incurring multiple episodes of anesthesia and donor-site morbidity.

Curettage, widely regarded to be the gold standard treatment, has a recurrence rate of 5% to 50%.[10] Thus there is no clearly superior modality in the treatment of this condition.

### Resection

Surgical decisions are based on the concept of compartments in relation to a tumor (Fig. 43-6). The compartment is bound by a barrier, which naturally limits the expansion of a tumor. When first described, it was useful in teaching the principles of wide resection or a resection with a margin of healthy tissue: If a resection was performed outside a compartment, it resulted in a margin that was free of malignant involvement.[45] This idea was useful in drawing parallels to conventional cancer surgery of that time. We realize now that this theory is flawed at many levels. For example, most osteogenic sarcomas present with tumors that have breached the cortex, and so, their distinction from a "contained" osteogenic sarcoma is moot. In the lower limb, a tumor that has involved the rectus femoris has involved a compartment extending from the anterior inferior iliac spine of the pelvis to the tibial tubercle. Clearly, it would not be practical, in this setting, to perform a hindquarter amputation. Finally, especially in the region of the linea aspera, there are numerous perforating vessels, which penetrate the lateral intermuscular septum; clearly these do not form a continuous barrier to tumor spread.

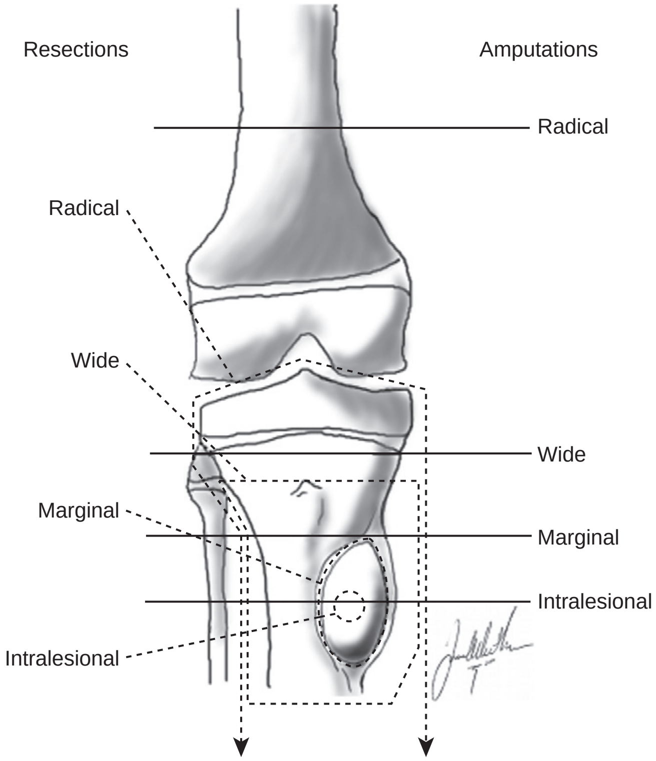

**FIGURE 43-6** Surgical margins in relation to the compartments involved. At left are the resections, and at right are the amputations. These classifications are largely academic, because in the strictest terms, most of the resections, except radical resections and only wide or radical amputations, are performed. Radical resections involve the compartment bearing the tumor, and hence, in this case, would amount to removing the tibia (*arrows*). Marginal amputations may be used in the spine and pelvis, whereupon local adjuvants assume significant roles in disease control (see Fig. 43-7). Intralesional amputations are obviously not therapeutic applications in tumor surgery but are included here for completeness. Of interest, intercalary amputations in the pediatric population can be problematic, when the remnant stump elongates through appositional growth. To avoid this complication, it may be necessary to use a through-joint (e.g., through-knee) amputation.

Still, the concept of compartmentalization is useful when one describes the surgical procedures as intralesional, marginal, wide, and radical.[41] Although not often used in the context of amputations, the concept of compartmentalization applies here as well. Intralesional procedures, as the name implies, are procedures that leave macroscopic residual tissue. A biopsy or injection of a lesion is an intralesional procedure. A marginal procedure stops at the level of the extent of maximal expansion of a tumor. Curettage is a marginal procedure. A wide procedure goes beyond the reactive zone of the tumor. When first described, the "reactive zone" referred to the zone of reaction around the tumor, marked by inflammatory change (i.e., hyperemia and edema).[41,47] This assessment was made predominantly at the time of surgery. With the advent of more sophisticated imaging modalities, it can now be demonstrated that this "zone" may extend further than previously appreciated. Therefore it appears that the description of a reactive zone is rather more abstract than real. As a general rule, resecting a tumor beyond its capsule, where vessel tortuosity and

edema is seen, is a wide resection, and hence this appreciation, while strongly influenced by newer imaging, remains largely surgical. Most malignant tumors are resected widely. A radical resection is an excision of the compartment in which a tumor resides. An above-knee amputation for a tibial lesion is a radical resection.

There are a number of surgical adjuvants that may be used. This can be in the form of heat (e.g., argon beam coagulator) or cold (e.g., liquid nitrogen cryotherapy).[68,69] In addition, chemical measures may be used (e.g., phenol, polymethylmethacrylate cement).[70,71] In the occasional case, specialized forms of radiation (e.g., brachytherapy, intraoperative radiation therapy) may be used, especially in the pelvis (Fig. 43-7). The purpose of these surgical adjuvants is to extend the margins of resection beyond what can be mechanically removed by the surgeon. These improve local control of the tumor.

***Benign Lesions*** It is useful at this juncture to recall the staging system for benign lesions. These are classified as benign, active, and aggressive. It is evident in these entities that, even within this group, specific nuances of the condition warrant special considerations. In benign bony conditions, the procedures available are curettage, high-speed burring of lesion walls, adjuvant procedures, and wide resection.[68,70] It is helpful to describe these procedures from most to least aggressive.

In benign conditions, wide resection may occasionally be used, when the involved bone is expendable (e.g., rib or terminal phalanx of the little toe) or at the end of a bone (e.g., distal ulna or proximal fibula). In these situations, reconstruction provides little value and can, in fact, be the source of considerable morbidity. Additionally, it may be used in the context of a recalcitrant recurrent benign or aggressive lesion. Typical lesions that are resected in this manner are giant cell tumors, aneurysmal bone cysts, or fibrous dysplasia.

Marginal excision is typified conceptually by the technique used to excise a soft tissue lipoma. Such a procedure is not technically feasible in most bony lesions. Osteochondromas and periosteal chondromas may be removed in such a fashion.

Intralesional procedures are more commonly performed in benign tumors. This typically involves curettage of a lesion with high-speed burring of the wall. In general, this is the typical procedure for most latent or active benign bony conditions (e.g., unicameral bone cyst). The use of heat, cold (Fig. 43-8), or chemical modalities serves to extend this margin of clearance further and is typically used in active or aggressive tumors (e.g., giant cell tumor, chondroblastoma).

### Malignant Lesions

The sine qua non of the resection of a malignant bone lesion is that, at minimum, a wide resection must be performed. In certain situations, however, this may not be possible (e.g., a tumor that has expanded into the spinal canal or a tumor that has invaded the pelvic cavity). In these instances, the outcome tends to be suboptimal.

With newer imaging modalities, it is now often possible to perform a physeal-sparing procedure in growing children (Fig. 43-9). Although the physis was thought to be an effective barrier to tumor spread, it has been shown that up to 80% of tumors abutting the physis have, in fact, breached it.[72–75] Physeal-sparing procedures must therefore be carefully balanced with the response to chemotherapy, to determine if this is feasible.

Occasionally, a variation on this theme is to save the epiphysis, and hence the neighboring joint, by performing a distraction procedure through the growth plate. This effectively increases the margin of normal tissue proximal to a tumor. A resection may then be performed through this now-lengthened segment.[76]

Another approach to retaining a joint would be to perform a Van Nes rotationplasty (Fig. 43-10).[77] This procedure, generally undertaken for high-grade tumors near or involving the knee, involves wide extraarticular resections, whereupon the distal leg and foot are joined to the remaining proximal femur. In the process, the sciatic nerve is retained, and a segmental resection of the femoral artery with a true femoral-popliteal arterial anastomosis is performed. The foot is rotated with

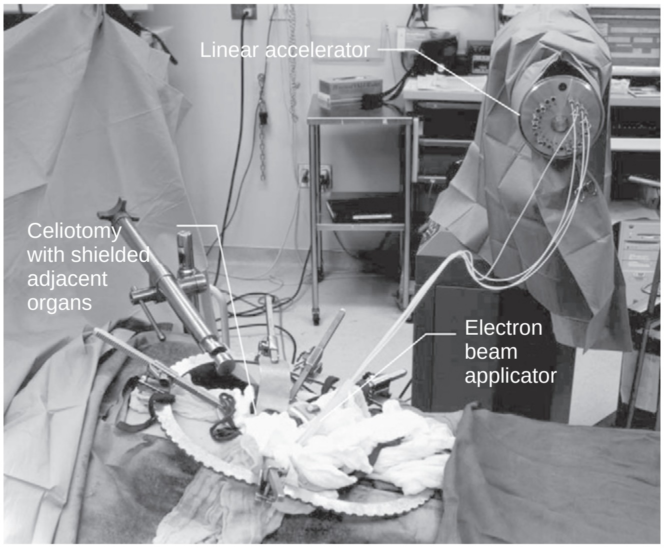

**FIGURE 43-7** Intraoperative radiation therapy in a 19-month-old girl who underwent a wide resection with nodal clearance for a rhabdomyosarcoma of the pelvis.

**FIGURE 43-8** Cryosurgery in a patient with chondrosarcoma. Liquid nitrogen is poured into a funnel that directs the agent into the lesion, while avoiding contact with the surrounding skin. The effect of freezing extends the margins of necrosis beyond that which can be felt by the surgeon, effectively extending the surgical margins from an intralesional or marginal excision to a wide resection.

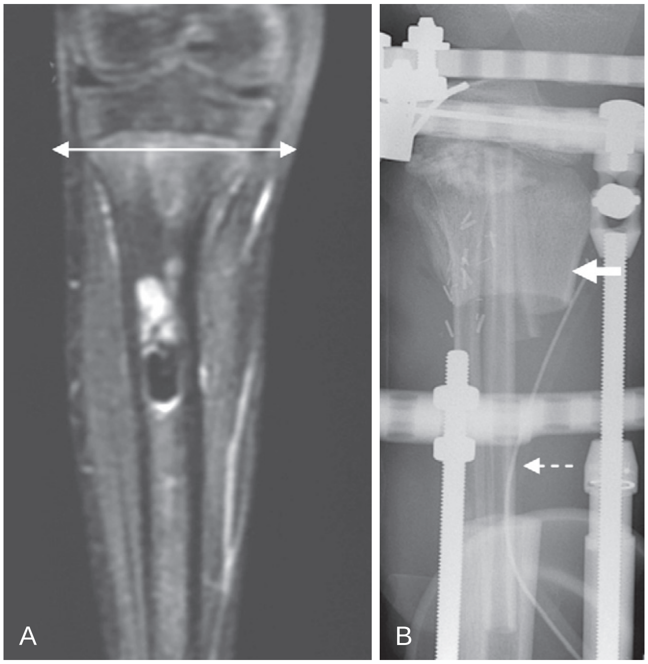

**FIGURE 43-9** **A,** Ewing sarcoma of the tibia in an 11-year-old boy. The lesion extended to 1 cm from the growth plate. It responded well to chemotherapy, with virtually no remaining soft tissue involvement. A physeal-sparing resection was done along a resection plane (*double-headed arrow*), carefully performed under image intensifier guidance. **B,** The use of a pin fixator, in this regard, is extremely advantageous, because it allows stabilization of the small proximal tibial segment that precludes routine pin fixation. The remaining gap was reconstructed with a proximal tibial allograft (*thick arrow*) and vascularized fibular graft (*broken arrow*) harvested with a paddle of skin, which provided skin cover of the construct.

the heel pointing anteriorly. Of practical interest, the distal segment is rotated externally, bringing the sciatic nerve and vessels anteromedial. This should be documented in the surgical note to facilitate further surgical procedures that may be necessary. The ankle, therefore, functions as a knee joint. This procedure has poor acceptance among patients because of their cosmetic abhorrence, but it is highly functional and durable.[78] A similar Winkelmann procedure may be performed, where the proximal tibia is brought to the hip. In children, it is remarkable to note the plasticity and remodeling of these disparate bones, which in time will accommodate each other in a stable fashion.[79,80]

Radical procedures and amputations have received poor support, because they are regarded as being disfiguring. Studies have shown that patients with limb salvage procedures do better in terms of function and cost savings.[81,82] Although this appears true at face value, in-depth analysis shows that these studies are too heterogeneous to allow any firm conclusions. With the aid of modern prostheses, patients with amputations are able to achieve very high levels of activity. Furthermore, complications are 3 to 4 times higher in limb salvage compared with limb ablative surgery. Although most series have not shown a significant survival benefit comparing amputation and limb-sparing surgery, these studies are underpowered or include cases of amputation being used as salvage procedures.[56,83,84] The primary remaining question is whether there is any survival and functional benefit in two-site and stage-controlled groups with respect to amputation or wide resection. This would require a case-controlled study with amputation and wide resection arms, and it is a safe assumption that this will never be performed.

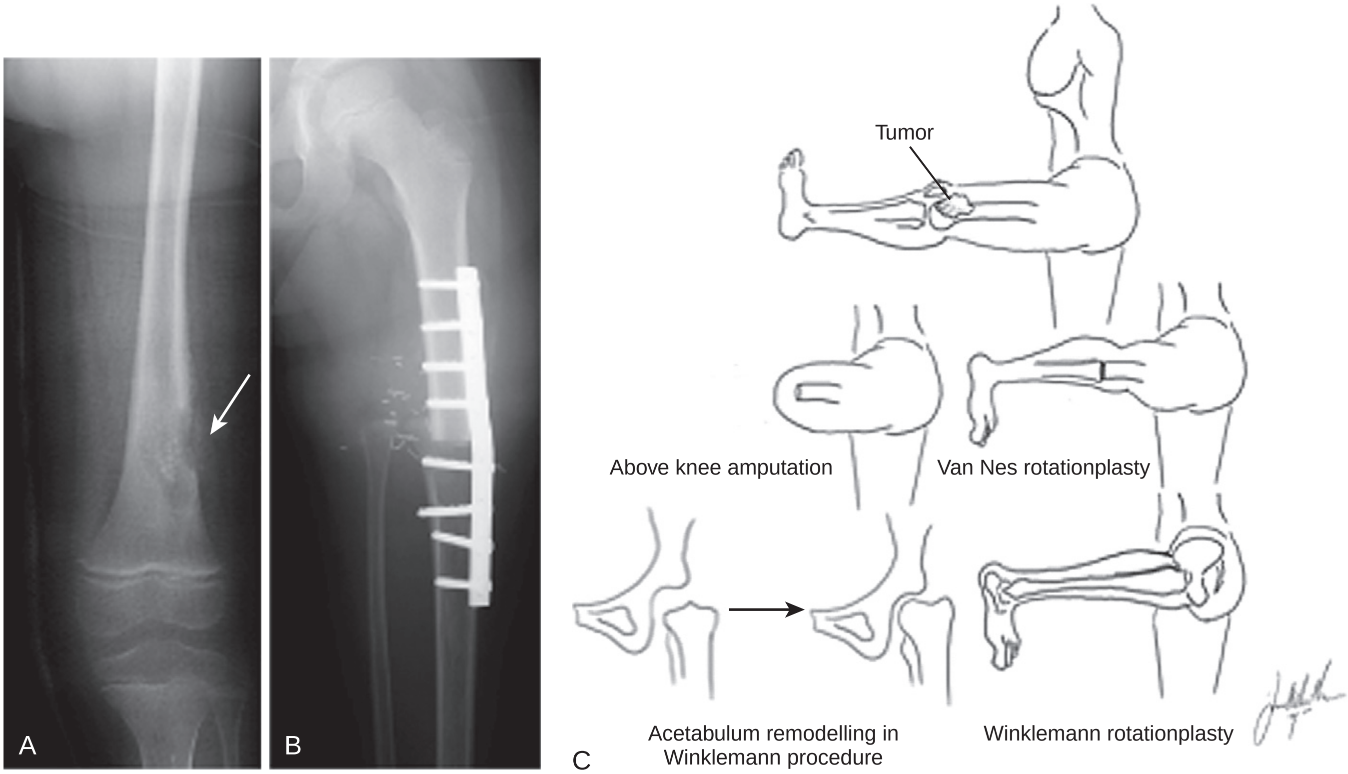

**FIGURE 43-10** **A,** Osteogenic sarcoma (*arrow*) with large soft tissue extension in an 8-year-old child. The small size of the child and high level of activity precluded endoprosthetic reconstruction. **B,** A Van Nes rotationplasty was performed. **C,** Variants of the rotationplasty are compared with the above-knee amputation. The bottom panel illustrates how the proximal tibia remodels and accommodates the acetabulum in the Winkelmann procedure.

There is still a role for amputations, especially when the tumor is in the distal extremity, adjuvant therapies are ineffective, or reconstruction is too problematic because of nerve, vessel, or soft tissue problems.

Local recurrence in malignant lesions is a poor prognostic factor and is associated with a 90% mortality rate. It is generally a reflection of compromised local control, although in one study good chemotherapy response was associated with a low local recurrence rate.[83] Specifically, in this series, when intralesional procedures had been performed for osteogenic sarcoma, standard responders were 3 times as likely to get a local recurrence as good responders. However, even among good responders, local recurrence was 14 times more likely if an intralesional procedure had been done rather than a wide resection. This underscores the need both for good surgical margins and effective chemotherapy.

## Reconstruction

In most instances, after the resection of benign lesions, small defects result. These are easily dealt with through the use of various gap fillers. With malignant lesions, large creative solutions are needed. It becomes difficult to determine which lesions are best treated by which technique because of the relative paucity of cases and the high-risk nature of these procedures. In this section, we will highlight the various modalities available and the pertinent qualifiers for each modality.

***Benign Lesions*** Following resection of benign lesions, a small defect usually remains. Thus the aim becomes reconstitution of bone. The modalities that have been used are bone graft and bone graft substitutes. In general, autografts tend to have better rates of incorporation but incur the risk of donor-site morbidity—or worse, donor-site tumor implantation. Allografts have a low risk of disease transmission and immunologic response.[85,86] Synthetic grafts tend not to incorporate as well as allografts or autografts.[87,88]

In the more aggressive lesions, the risk of recurrence increases. In these situations, bone substitutes could be resorbed by the disease process and would increase the delay before subsequent radiologic imaging is able to distinguish between postoperative change and recurrence. In this setting, bone cement becomes a good alternative.[69,71] Furthermore, radiopaque cement acts as a contrast agent. Recurrence at the margin of the cemented defect can be identified readily and treated.

***Malignant Lesions*** The solutions that have been used to solve the complex bone, joint, and soft tissue defects left after tumor resections form a veritable cornucopia of techniques, spanning all of orthopedic and plastic surgery. It is impossible to reiterate all these solutions here. Instead, we present a list of principal solutions pertinent to the specific reconstructive option.

The paramount requirement of all solutions is to provide a space filler and skin closure. Without meeting these two requirements, chemotherapy cannot resume, and the patient will not survive. Most solutions will provide space-filling ability if there is adequate skin for closure. If skin closure is not possible, a local flap or vascularized pedicular graft may be necessary. In some instances, especially with intercalary resections, the ability to provide intercalary stability with overlying skin closure can be provided by a vascularized fibular graft with a skin paddle. The skin paddle affords the additional advantage of monitoring the viability of the flap. Rotationplasties and their variants are remarkably functional solutions to the problem but have poor acceptance among patients because of their appearance. Similarly, amputations are often an instant solution to the problem, although, even here, the occasional exception exists.[82]

Joint reconstruction is a challenging endeavor. Biologic solutions include the use of bulk allograft (Fig. 43-11). They have the advantage of becoming incorporated by the body. The disadvantages[89] are a high fracture rate of 19%, a nonunion rate of 17%, and an infection rate of 11%. Osteoarticular allografts also become arthritic (16%) with time. Theoretically, however, with good incorporation of the allograft, a conventional, less-constrained joint replacement can be performed (Fig. 43-12). The endoprosthetic solution tends to be easier

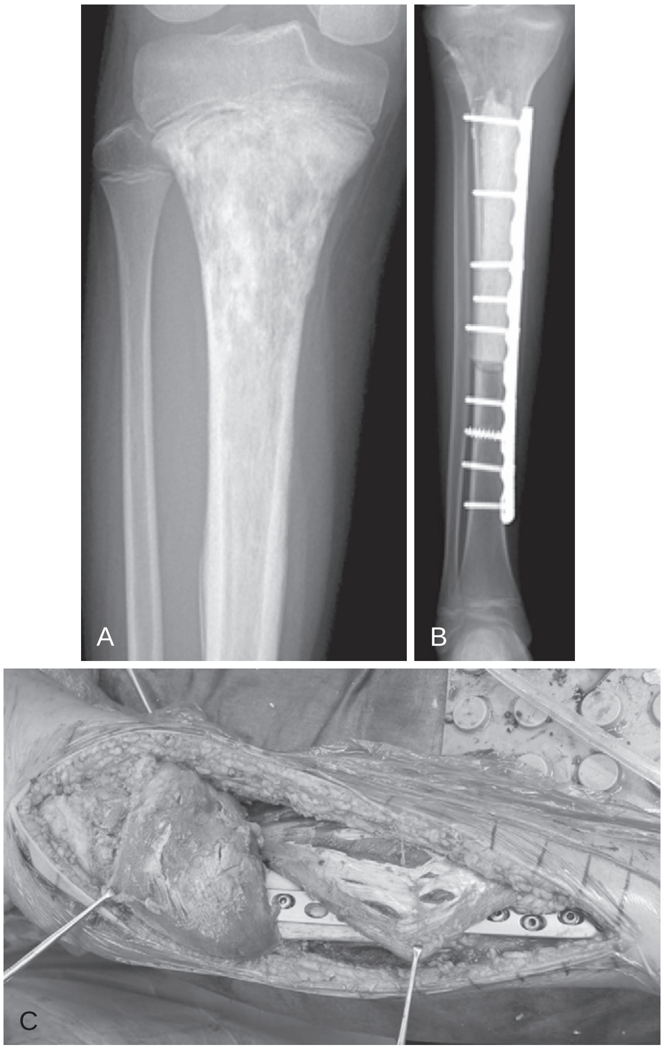

**FIGURE 43-11** **A,** Ewing sarcoma of the proximal tibia in an 11-year-old child. **B** and **C,** This was widely resected and reconstructed with an osteoarticular tibial allograft. A gastrocnemius flap was raised to provide soft tissue cover to the construct.

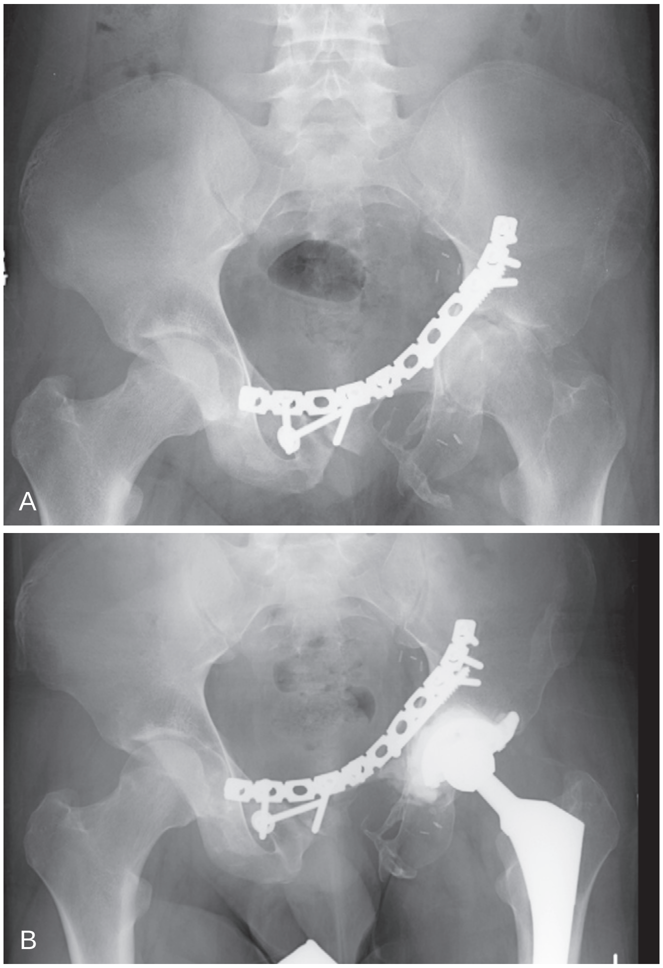

FIGURE 43-12 **A,** Resection and reconstruction of a Ewing sarcoma of the pelvis in a boy. **B,** Two years later, degenerative changes developed in the boy's hip, and he required hip replacement surgery.

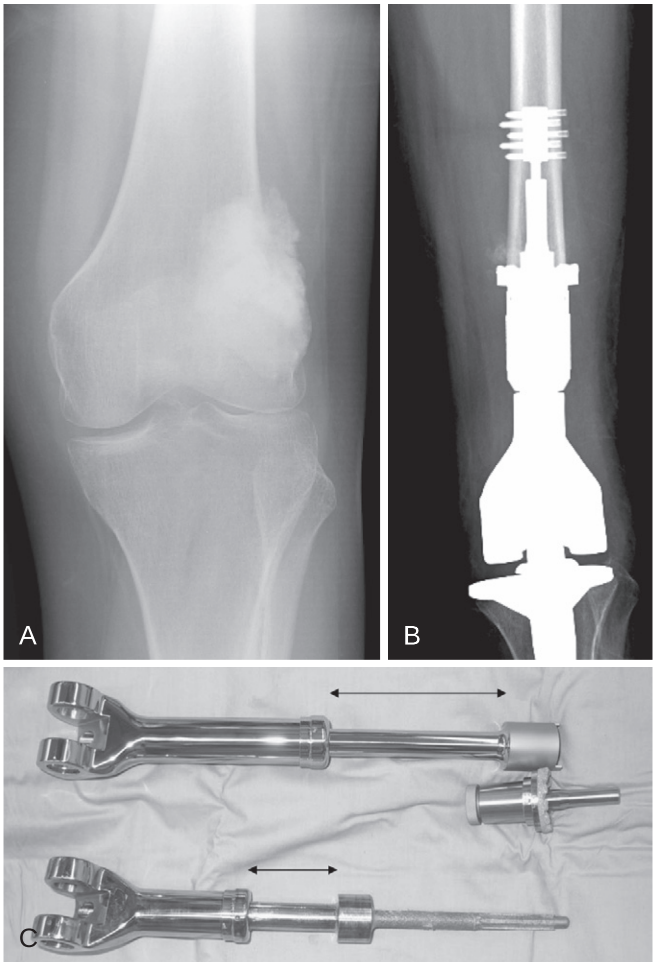

FIGURE 43-13 **A,** Osteogenic sarcoma in a 16-year-old girl. **B,** An endoprosthetic device was placed in the patient after resection of the lesion. **C,** As a child grows, it occasionally becomes necessary to swap implants with devices that can provide further extensibility.

but is less resilient, suffering from wear and loosening with time.[90–92] With advances in technology, better designs will lead to longer-lasting implants (Fig. 43-13). The allograft prosthetic composite is another approach that appears to capitalize on the lasting nature of allografts and their soft tissue capsular attachments and the simplicity of prosthetics (Fig. 43-14). In very young children, the available endoprostheses may be too large, and this may be a relative indication for the use of bulk allografts instead (see Fig. 43-1). Downsized pediatric implants are incapable of holding up in adults and are destined for failure and revision (Fig. 43-15). Prosthetic reconstruction has the distinct advantage of allowing immediate weight bearing, which is very important in patients who may have a reduced life expectancy. In truth, the various modalities are complementary rather than independent.

Growth is a complex issue in the management of patients with bone resection. In the year that patients receive chemotherapy, growth is often stunted. After this, however, the child resumes normal growth. There are various means to predict this growth.[93,94] As a rule of thumb, the distal femur grows 1 cm/year and the proximal tibia grows 7 mm/year. Girls generally stop growing at 14 years of age and boys at 16 years. Therefore a 10-year-old boy who has an extraarticular resection potentially would have 10 cm of growth to accommodate. In general, a 2-cm length discrepancy is considered compensable and does not require treatment. Thus, in this example, an additional 8-cm correction is needed.

The modalities available include contralateral epiphysiodeses. This method ablates the growth plate of the contralateral knee. The procedure needs to be timed accurately and tends to be practical only in the older child approaching the last few centimeters of growth.

Bone transport is another option. This yields good results, but the child must remain in the apparatus for long periods of time. At an elongation rate of 1 mm/day, the child with an 8-cm defect must remain in the apparatus, at minimum, for 3 months for the elongation and a further 3 months for consolidation of the regenerate (Fig. 43-16). This duration is commonly doubled when distraction osteogenesis is done during chemotherapy. Even in healthy individuals, the risk of pin-tract infection during the procedure is greater than

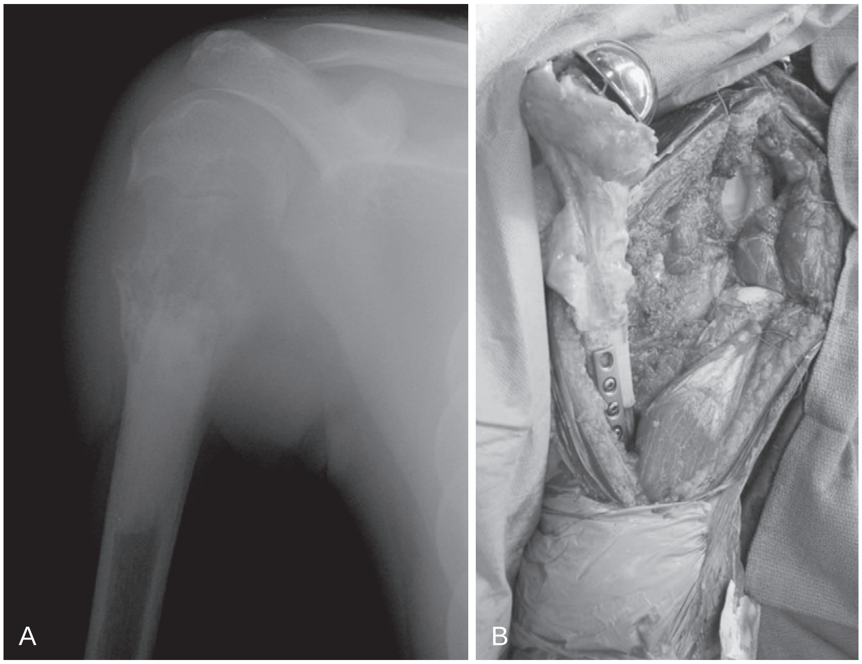

**FIGURE 43-14** **A,** Osteogenic sarcoma in proximal humerus of a 16-year-old boy. **B,** A proximal humeral resection with allograft and prosthetic composite was used to reconstruct the defect.

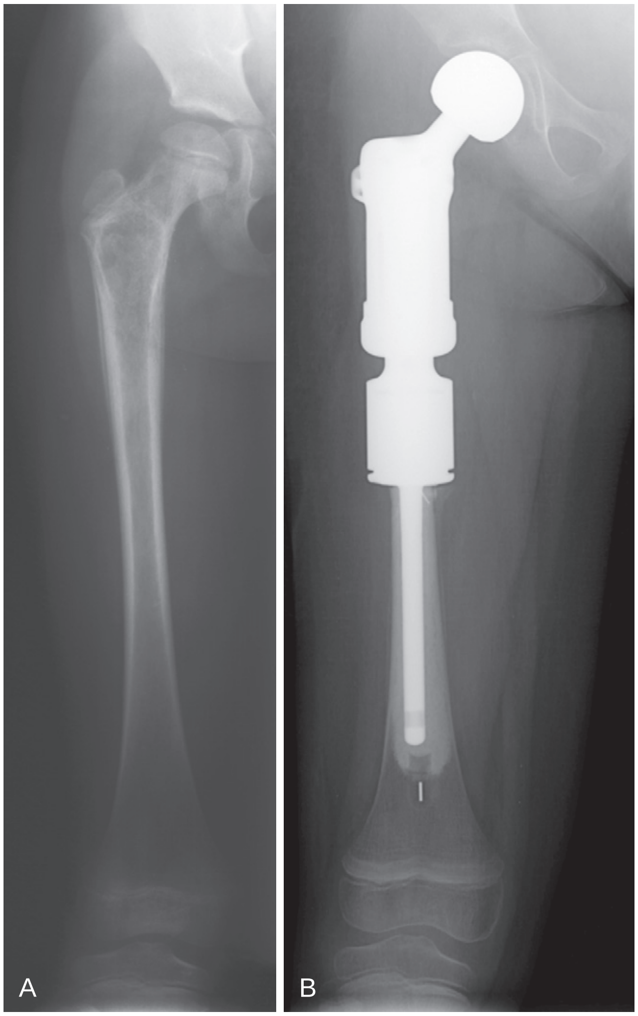

**FIGURE 43-15** **A,** Osteogenic sarcoma of the proximal femur in a 14-year-old girl. **B,** A wide resection and bipolar hemiarthroplasty with proximal femoral replacement was performed. Of note, the femoral head matched the acetabulum; so, an additional bipolar component was not added.

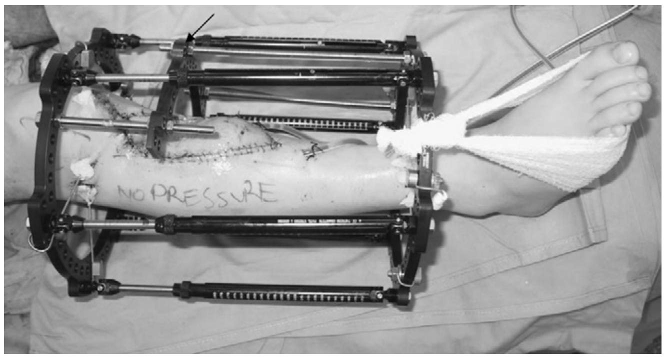

**FIGURE 43-16** Ewing sarcoma of the tibia. The patient underwent wide resection and a planned bone transport procedure. The middle ring (*arrow*) is secured to a segment of bone that has been osteotomized. This segment of bone is allowed 5 days for a provisional callus to form. By progressively advancing the ring distally at a rate of 1 mm/day, the segment of bone is transported to fill the defect, while at the same time remaining connected to the proximal tibia. This regenerate is weak and requires an equivalent amount of time to consolidate. For example, an 80-mm defect would require 5 days to form a provisional callus, 80 days to lengthen, and 80 days to consolidate before removal of the frame. This ungainly device needs to be tolerated by the patient for the duration of the limb-lengthening procedure.

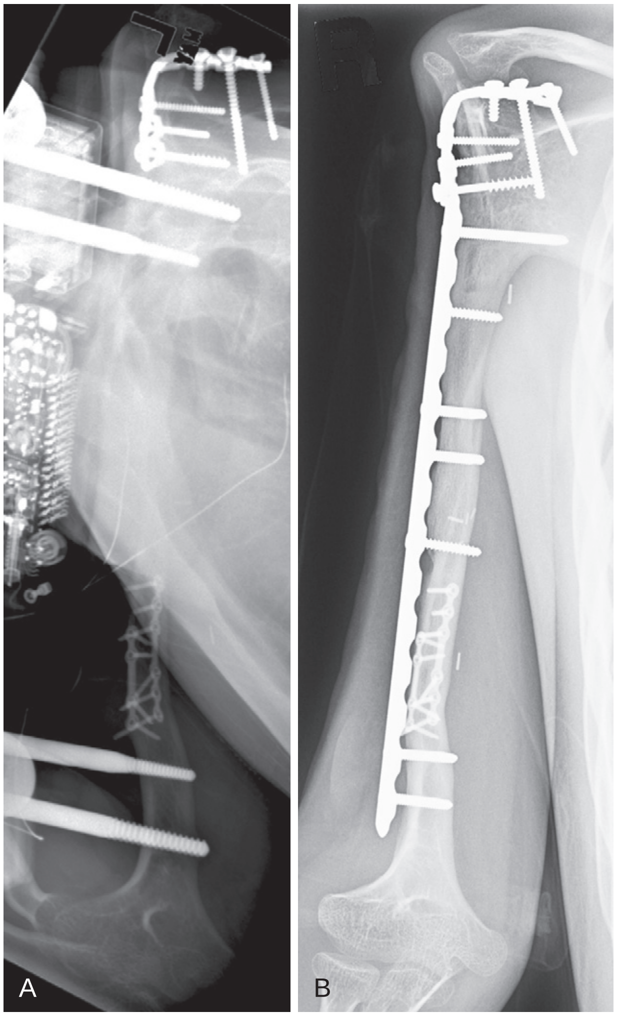

**FIGURE 43-17** **A,** A patient presented with osteogenic sarcoma of the proximal humerus that was resected and reconstructed with a vascularized fibular graft shoulder arthrodesis at 6 years of age. He developed a shortened humerus at maturity, which was lengthened. **B,** After lengthening, the regenerate was protected with a plate and hypertrophied with time.

90%.[95] In the patient with malignant disease who is to receive chemotherapy, this would be an important consideration.[96] In addition, the regenerate tends to be weak and is prone to fracture (Fig. 43-17). Patients on chemotherapy are prone to osteoporosis and are already at risk for fracture.

The extensible prosthesis is a marvel of modern science that is presently undergoing "teething" issues.[97–99] The manual expansion designs require repeated surgical procedures to periodically lengthen the limb to keep pace with normal growth (see Fig. 43-13, *C*). The Stanmore implants (Stanmore Implants Worldwide, Elstree, United Kingdom) have been used for nearly 20 years and have a 23% revision rate.[91] Survivorship analysis, however, shows a near-zero survivorship at 10 years.[100] Self-extending designs work through electromagnetic couplers or heating coils that allow motors or heat-release springs to extend the implant. The Phenix device (Phenix Medical, Paris, France) is presently undergoing evaluation in the United States.[101] Preliminary results show a complication rate of up to 44%, necessitating revision. The Repiphysis system (Wright Medical Technology, Inc., Arlington, TN) uses an external electromagnetic field to provide controlled released of a spring held in place by a locking mechanism. This device is associated with an implant revision rate of 44%.[102] In general, the stems in these devices are too narrow and mechanically insufficient, and fixation techniques remain inadequate. Thus all these designs have poor longevity but reduce immediate surgical complications (e.g., infection). They are well tolerated by patients and families.

There are many solutions to the problem of limb reconstruction in the skeletally immature child, but none is perfect. Therefore it is apparent that the surgeon dealing with potential limb length inequality after tumor resection and subsequent growth must be able to perform, or at least facilitate, the reconstructive procedures previously discussed. Any one of these procedures is applicable to an individual case, and they remain complementary to each other.

CHAPTER 44

# Brain Tumors

Eamon J. McLaughlin, Michael J. Fisher,
Leslie N. Sutton, and Phillip B. Storm

With the exception of trauma, neoplasms are the most common cause of death in children less than 19 years of age. Tumors of the central nervous system are the most common solid neoplasms found in the pediatric population, accounting for 20% of cancer deaths, and are second only to leukemia in overall cancer frequency.[1,2] Approximately 4030 brain tumors are diagnosed each year in the United States, for an overall incidence of 4.71 cases per 100,000 person-years. Of these cases, it is estimated that 2880 will occur in children less than the age 15 years.[1,3]

The important factors in diagnosing brain tumors are location, age, and cell type. Location is probably the most important factor radiographically, followed by the age of the patient. The brain is divided into two compartments by the tentorium. Above the tentorium (supratentorial) are the cerebral hemispheres, basal ganglia, and the thalamus. Below the tentorium (infratentorial) are the pineal gland, the tectum, the pons, the medulla, and the cerebellum. Adult brain tumors tend to be supratentorial; however, pediatric tumors are evenly split between supratentorial and infratentorial. This division of location in the pediatric population is dependent on the age of the patient. In children younger than 2 years of age, the tumors are predominantly supratentorial, whereas children between the ages of 3 and 15 years more often have infratentorial tumors (Table 44-1).[1] The prognosis is usually poor in children with brain tumors younger than the age of 1 year, with choroid plexus papilloma being the main exception.[1,4]

The development of immunohistochemical staining techniques allows pediatric tumors to be classified by histology. Tumors can arise from any of the cell types of the central nervous system. The brain is composed of neurons and glial cells. Glial cells far outnumber the neurons, and provide a nourishing and supportive role. The three main types of glial cells are astrocytes, oligodendrocytes, and ependymal cells, and the neoplasms they give rise to are gliomas. More specifically, they form astrocytomas, oligodendrogliomas, and ependymomas, respectively. Tumors involving both neuronal and glial cells are called ganglion cell tumors and consist of gangliogliomas, desmoplastic infantile gangliogliomas, and gangliocytomas. Another mixed neuronal and glial tumor is a dysembryoplastic neuroepithelial tumor (DNET). Finally, there are embryonal tumors, which include medulloblastoma, primitive neuroectodermal tumors (PNETs), medulloepithelioma, neuroblastomas, melanotic neuroectodermal tumors in infancy, and atypical teratoid/ rhabdoid tumors (ATRTs).[4] Other primary brain tumors include germ cell tumors, choroid plexus tumors, craniopharyngiomas, and meningiomas.

## Clinical Features

The signs and symptoms of brain tumors in children vary considerably based on tumor type, location, and age of the patient. In the absence of a seizure or a focal neurologic deficit (e.g., diplopia caused by sixth nerve paresis), the vast majority of the symptoms are nonspecific and easily attributable to many more common and less serious causes. Common symptoms may include headache, nausea, vomiting, lethargy, subtle changes in personality, and worsening school performance. This constellation of symptoms can often be attributed to gastrointestinal problems, depression, school anxiety, migraines, sinusitis, or the need for prescription eyeglasses. Even a long-standing seizure disorder may ultimately be diagnosed as a supratentorial brain tumor. Infants typically present with failure to thrive, decreased intake, macrocephaly, or lethargy. Because of the nonspecific nature of these symptoms, it is common for a patient to present for neurologic evaluation after having visited numerous other specialists without establishing a diagnosis.

Most pediatric patients with brain tumors are between the ages of 2 and 14 years and typically present with a few days to weeks of headache, nausea/vomiting, gait ataxia, and/or diplopia. This constellation of symptoms is caused by hydrocephalus resulting from obstruction of the ventricles by tumor, commonly located in the midline posterior fossa. Headaches are common in children with viral infections, whereas frequent, daily morning headaches should raise the clinical suspicion of an intracranial mass lesion. This is especially true in the absence of a fever or other viral sequelae. Patients with elevated intracranial pressure often have an exacerbation of their symptoms in the morning. Both lying in the recumbent position overnight and sleep-induced hypoventilation (which leads to an increase in $Pco_2$) cause an increase in intracranial pressure. Elevated intracranial pressure can also cause the cerebellar tonsils to herniate into the foramen magnum and result in occipital headaches and neck pain.

There are two instances in which tumors cause nausea and vomiting. One is the elevation of intracranial pressure, and the other is direct irritation/infiltration of the vomiting center. The

**TABLE 44-1**
**Brain Tumors in Children**

| *Age* | *Tumor Histology* |
|---|---|
| 0 to 2 years | Teratoma |
| | Primitive neuroectodermal tumor |
| | Astrocytoma (high grade) |
| | Choroid plexus papilloma |
| 2 to 15 years | Supratentorial tumors (50%) |
| | Astrocytoma (low grade) |
| | Craniopharyngioma |
| | Hypothalamic glioma |
| | Primitive neuroectodermal tumor |
| | Ependymoma |
| | Choroid plexus papilloma |
| | Infratentorial (50%) |
| | Primitive neuroectodermal tumor: medulloblastoma |
| | Cerebellar astrocytoma |
| | Ependymoma |
| | Brainstem glioma |

vomiting center (area postrema) is located on the floor of the fourth ventricle and is vulnerable to compression from large posterior fossa tumors or from direct invasion of intrinsic brainstem tumors. Given that an intrinsic tumor in the medulla can cause vomiting in the absence of other neurologic symptoms, persistent vomiting should raise the possibility of a posterior fossa tumor, which could be confirmed through a detailed history and neurologic examination. Ataxia is commonly associated with tumors in the cerebellum and is often described by the parents as clumsiness, "walking like he is drunk," walking with the head tilted to one side, or falling to one side.

The visual complaints associated with posterior fossa tumors are frequently diplopia, difficulty looking up (sunsetting eye or Parinaud syndrome), and occasionally decreased visual acuity. As mentioned before, these symptoms are a result of the hydrocephalus. A decrease in visual acuity can result from papilledema. Loss of vision is a more common symptom of supratentorial tumors, because of optic nerve atrophy from direct compression. Patients with posterior fossa tumors are usually diagnosed with magnetic resonance imaging (MRI), because their other symptoms occur long before any visual defects. Therefore lack of visual signs and symptoms does not exclude a brain tumor. However, patients with poor access to health care can present with posterior fossa tumors and accompanying visual deficits.

Supratentorial tumors are especially common in patients younger than 2 years of age. These children often present with a failure to thrive, hemiparesis, seizures, or a full bulging anterior fontanelle and a rapid increase in head circumference.[5,6] At more than 2 years of age, supratentorial tumors present similarly in both children and adults, most commonly with headaches and/or seizures. When a patient presents with sudden onset of severe headaches or a rapid decline in mental status, it usually indicates a hemorrhage into their lesion. Rarely, obstructive hydrocephalus can cause such a rapid decline in mental status, but this is unlikely because of the slow growth rate of most tumors.

Less commonly, brain tumors can present with endocrine abnormalities. These can include weight gain or loss, diabetes insipidus, short stature, truncal obesity, galactorrhea, and precocious or delayed puberty. These symptoms result from tumors affecting the hypothalamic-pituitary axis. Because of the proximity of these tumors to the optic nerves and chiasm, they often cause decreased vision and visual field deficits.

# Radiographic Evaluation

Patients suspected of having a brain tumor should be evaluated with an MRI with and without gadolinium. Although MRI is the gold standard for evaluating tumors, many patients presenting in the emergency department with progressive clinical signs and symptoms of a brain tumor are evaluated with a head computed tomography (CT) without instillation of a contrast medium. CT is the ideal imaging modality to use during emergent situations for a number of reasons. CT is excellent in evaluating hydrocephalus and hemorrhage, the two main causes of rapid neurological decline. Furthermore, CT can be performed in minutes, frequently does not require sedation, gives excellent detail and information, and is considerably less expensive. If the patient's condition is rapidly deteriorating, a contrast agent–enhanced head CT is occasionally performed to better characterize the lesion for the radiologist and neurosurgeon when the patient requires emergent surgical intervention. If the patient's condition is stable, the contrast agent may be omitted, and MRI with and without gadolinium should be performed, the timing of which is dictated by the clinical signs and symptoms.

Magnetic resonance imaging provides much better resolution of the brain and provides images in the sagittal, axial, and coronal planes. Standard MR imaging combined with newer imaging sequences and spectroscopy can even point to a specific histologic diagnosis.[7] Furthermore, it is difficult to evaluate the lower brainstem with CT, because of the bony artifact from the skull base. One limitation of MRI is that it does not show intratumoral calcifications very well, and occasionally, patients require both studies to aid in establishing the proper diagnosis.

Magnetic resonance imaging with and without gadolinium can provide significantly more information about the patient's tumor. The blood–brain barrier is made up of tight junctions in the endothelial cells lining the capillaries in the brain, which prevent most blood contents from entering the brain, including gadolinium. However, certain brain tumors cause breakdown of the blood–brain barrier and permit the gadolinium to enter the tumor and then enhance the tissues (appear bright on T1-weighted images). In general, in the adult population, enhancement in an intra-axial lesion means a more aggressive brain tumor and a poorer prognosis. This is not as consistent in pediatric tumors. There are many enhancing pediatric brain tumors that are not aggressive and are curable with total resection.

When viewing an MRI, the important factors to consider are (1) the location of the tumor (e.g., supratentorial, infratentorial, pineal region, suprasellar), (2) whether the tumor is intra-axial (within the brain tissue) or extra-axial (outside the brain tissue), (3) the age of the patient, (4) whether the tumor enhances, and (5) if there are single or multiple lesions. By systematically assessing the scans and considering these factors, the differential diagnosis can be narrowed considerably, which can be extremely helpful in preoperative planning.

If there are multiple lesions in the brain, or the location and enhancement suggest a tumor type associated with leptomeningeal metastases or "drop mets" to the spine, then a spinal MRI with and without gadolinium is performed. It is preferable to obtain the spinal MRI preoperatively, but this is often dictated by the patient's clinical examination. Postoperatively, brain tumor patients should have an MRI within 36 to 48 hours to evaluate the extent of the resection and rule out hydrocephalus, bleeding, or ischemia. The timing is important, because after 36 to 48 hours, expected postoperative changes can enhance and make it difficult to distinguish scarring from residual tumor. If the patient did not get a preoperative MRI evaluation of the spine and the histologic diagnosis is consistent with tumors that can metastasize to the spine, then the study should be done 2 weeks after surgery, because postoperative debris and blood can be mistaken for metastatic disease

## Surgical Intervention

The goal of a surgical intervention for brain tumors is to safely debulk as much tumor as possible, to obtain a histologic diagnosis, to reestablish normal cerebrospinal fluid (CSF) pathways, or to divert CSF. The location of the tumor is often the determining factor as to how aggressively the tumor is debulked. In fact, some tumors, because of their location and their ability to be diagnosed with MRI, are not biopsied. For example, an intrinsic pontine glioma, which is an astrocytoma of the brainstem, cannot be debulked safely and has a characteristic appearance on MRI. Therefore these patients are referred to a neuro-oncologist for management without a tissue diagnosis. Pineal region tumors are another example of a lesion that may be diagnosed without surgical intervention. Patients with pineal region masses should have serum β-human chorionic gonadotropin (β-HCG) and alpha fetoprotein (AFP) levels obtained. If these are negative, then CSF markers are needed. If the serum or CSF markers are positive, then a diagnosis of a germ cell tumor can be made without the need for a biopsy.

However, most tumors require surgical intervention, consisting of either a stereotactic biopsy or an open craniotomy to obtain tissue for a definitive diagnosis. The most important tool for preoperative planning is MRI. Diffuse intrinsic tumors of the thalamus or basal ganglia typically undergo stereotactic biopsy. This procedure involves rigidly fixing an MRI-compatible frame to the patient's skull. The patient then has an MRI, and the *x, y,* and *z* coordinates are determined. These coordinates are then used to position the frame and the arc so that the tip of the needle is exactly where these three points intersect in the brain. Given the improvements in frameless stereotaxy, all but the smallest lesions can be biopsied without a rigid frame.[8] The advantages of a stereotactic biopsy include a short procedure time, the possibility of diagnosis in areas of the brain that carry an unacceptable morbidity and mortality with an open craniotomy, and the patient is discharged on postoperative day 1. The disadvantages are that only a small amount of tissue is obtained, which may be nondiagnostic or result in the wrong diagnosis, and if bleeding occurs it is difficult to treat, or it may not be recognized until the patient deteriorates neurologically after the procedure. Lastly, if the diagnosis cannot be made with a stereotactic biopsy or the diagnosis requires aggressive debulking, the patient will require a second operative procedure.

Because of the fact that the prognosis of many pediatric tumors is strongly influenced by the amount of postsurgical residual tumor,[9] the majority are approached with a craniotomy/craniectomy for open biopsy, with an attempt at maximal microsurgical tumor resection. Cerebral hemispheric tumors are approached through a craniotomy. Preoperative planning consists of an MRI coupled with a frameless stereotactic navigation study. The navigation study allows the neurosurgeon to view the tumor in the operating room in the sagittal, axial, and coronal planes and can be used to find the tumor and plan the incision and approach. However, the main limitation of this technology is that it is not a real-time study, and actions such as retracting the brain or draining cysts or CSF spaces may cause the brain to shift position, thus compromising the accuracy of the intraoperative navigation system. When this occurs, intraoperative ultrasonography is extremely helpful in localizing lesions.

Intraoperative MRI aims to correct the limitations of the navigation system by providing a real-time image. Previous intraoperative MRIs were limited because of poor resolution; however, newer intraoperative suites have 3-tesla magnets and provide excellent resolution. The drawbacks of the intraoperative MRI suites are that they are prohibitively expensive for many institutions, are helpful in only a small number of procedures, and significantly extend the time of the procedure. Nevertheless, this is exciting technology, and as the expense decreases and the efficiency improves, it will be an invaluable tool to surgeons operating upon brain tumors. Functional MRI (fMRI) techniques can localize speech and motor cortex. When tumors involve these areas of eloquent cortex, fMRI can aid in selecting the safest site to incise the cortex.[10] In the pediatric population, fMRI can prove challenging, because it requires a cooperative non-sedated patient. Electrophysiologic recording and stimulation are sometimes helpful in locating the motor strip. Recently, magnetoencephalography (MEG) is being used to help localize motor, sensory, and language cortex for both tumor surgery and epilepsy surgery.[11]

Such advances undoubtedly aid the neurosurgeon throughout the surgical procedure; however, there is still no substitute for an outstanding understanding of the three-dimensional anatomy of the brain. When choosing an approach, anatomic planes, such as the interhemispheric fissure, the sylvian fissure, and the cranial base are used, if possible, to avoid resecting normal brain. If there is no plane available, the approach is usually through the least amount of tissue, while avoiding areas of eloquent language, motor, and visual cortex.

Tumors of the midline (hypothalamus, thalamus, basal ganglia, and brainstem) were once considered inoperable. However, advances in microsurgical techniques and innovative instrumentation now make these tumors approachable. At the same time, advances in chemotherapy and single-dose and fractionated radiosurgery offer alternatives, and it is currently unclear which strategy or combination of strategies is best for a particular tumor. Advances in surgical techniques now allow for multiple options for the approach to tumors. For example, pineal region tumors may be approached through a posterior fossa route (retracting the cerebellum from the underside of the tentorium), by a supratentorial route between the hemispheres and through the posterior corpus

callosum, or through the tentorium itself. The relationship of the pineal tumor to the tentorium dictates the approach.

Tumors of the cerebellum and the lower brainstem are approached through a posterior fossa craniotomy or craniectomy.[12] Midline tumors of the fourth ventricle usually present with obstructive hydrocephalus. Some neurosurgeons prefer to place a shunt before tumor resection; however, most now favor giving the child corticosteroids and placing a ventriculostomy at the time of the craniectomy. The ventriculostomy is either removed or converted to a shunt if needed in the postoperative period. Between 20% and 40% of children will ultimately require a shunt.[13] Many neurosurgeons are performing an endoscopic third ventriculostomy (ETV) at the time of the resection. This procedure involves inserting an endoscope into the lateral ventricle, passing it through the foramen of Monro and making a small hole in the floor of the third ventricle. This allows the CSF to bypass the distal obstruction and enter directly into the cisternal system.[14] One series of patients with posterior fossa tumors showed a reduction in the postoperative shunt rate of 26.8% to 6% in patients treated with EVT and tumor removal versus tumor removal alone.[15]

To access the fourth ventricle, the patient is placed in the prone position, and the bone overlying the cerebellum is removed, occasionally including the posterior ring of the C1 vertebrae. After opening the dura, the cerebellar vermis is vertically incised, providing access to the tumor and the fourth ventricle. The tumor is removed with bipolar cautery, suction, or an ultrasonic aspirator. Laterally placed tumors of the cerebellopontine angle are reached by retracting the cerebellum medially. Electrophysiologic monitoring of cranial nerves V, VII, VIII, IX, X, XI, and XII is often required throughout this approach. Tumors of the brainstem may be debulked, if they are dorsally exophytic. The dura is closed and covered with DuraGen (Integra LifeSciences, Plainsboro, NJ), a collagen product that augments dura integrity. Replacement of the bone is not required, but we prefer to whenever possible. Postoperative problems include acute hydrocephalus, pseudomeningoceles, aseptic meningitis, mutism, pseudobulbar palsy,[16] cranial nerve or brainstem dysfunction, and gastrointestinal hemorrhage.[17] Patients with swallowing dysfunction and aspiration may require tracheostomy and feeding gastrostomy.

# Tumor Types

## CEREBELLAR ASTROCYTOMAS

These tumors are usually low-grade and curable with total surgical resection. The average age at presentation is 9 years, and the patient normally presents with pernicious vomiting, intermittent morning headaches, and disturbances of balance, usually spanning a period of months. The classical CT appearance of these tumors is a hypodense, cystic cerebellar mass (usually around the vermis) with a brilliantly enhancing "mural nodule."[18] However, about one fourth will be entirely solid tumors. MRI is helpful in defining the surgical anatomy, such as the relationship of the tumor to the brainstem, and the nature of the cyst wall. Cerebellar astrocytomas are typically of low signal intensity on T1-weighted MRI sequences, demonstrate increased intensity on T2-weighted sequences, and show enhancement of the solid component with gadolinium (Fig. 44-1). Because of their location and size, they cause effacement of the fourth ventricle, resulting in obstructive hydrocephalus.

Histologically, they consist of benign-appearing astrocytes.[19] Subtypes are the juvenile pilocytic form (80% to 85%) and the fibrillary form.[4] Detailed examination may reveal cellular pleomorphism and tumor extension to the subarachnoid space, but these tumors rarely disseminate. High-grade astrocytomas in this location are rare and usually follow radiation therapy given for a previous low-grade tumor.[20]

Treatment for cerebellar astrocytomas is complete surgical resection. In tumors with no brainstem involvement, this can be accomplished in a high percentage of cases. If complete surgical excision can be demonstrated radiographically, these tumors rarely recur, and no adjuvant therapy is indicated.[21] Therefore if there is residual tumor on the postoperative scan, reoperation for total excision is recommended. Radiation therapy can be considered for multiple recurrent lesions or in cases in which brainstem involvement precludes complete removal. However, even in these cases, residual tumor may remain indolent for years without additional therapy. Regular postoperative surveillance scanning is appropriate, especially when there is suspicion for residual tumor. Recurrence is treated with reoperation if this is feasible.

## PRIMITIVE NEUROECTODERMAL TUMOR AND MEDULLOBLASTOMA

Primitive neuroectodermal tumor and medulloblastoma are related tumors; and, in fact, the term medulloblastoma and posterior fossa PNET are often used interchangeably. Medulloblastoma is the most common malignant brain tumor of childhood. Histologically, the classical medulloblastoma is composed of densely packed cells with hyperchromatic nuclei and little cytoplasm, giving the histologic slides a blue color when stained with hematoxylin and eosin. Tumors with identical histology can occur in the cerebral hemispheres and are termed supratentorial PNETs. Children with medulloblastoma typically present with headache, vomiting, and lethargy of relatively short duration, and the mean age (3 to 4 years) is typically younger than that seen with cerebellar astrocytomas. Infants typically present with failure to thrive. Supratentorial PNETs present with increased intracranial pressure and focal neurologic deficits, depending on the location of the tumor.

On a CT scan, medulloblastomas typically appear as well-marginated homogeneously dense masses filling the fourth ventricle, causing obstructive hydrocephalus. They usually enhance brilliantly with contrast. However, unlike ependymomas, they lack calcifications. On MRI, they can show variable signal characteristics. The images are often slightly hypointense on T1 weighting, becoming brighter on fluid-attenuated inversion recovery (FLAIR) sequences, and may be bright or dark on T2-weighted studies. They usually enhance on MRI (Fig. 44-2) and show restricted diffusion on diffusion-weighted imaging (DWI). MRI of the spine is indicated 2 weeks postoperatively to evaluate for spinal metastases ("drop mets"; Fig. 44-3).[22]

Treatment begins with biopsy and surgical excision. Medulloblastoma and PNET tumors are not curable with surgery alone; and in cases with metastases at diagnosis or extensive brainstem involvement, the major mass should be debulked,

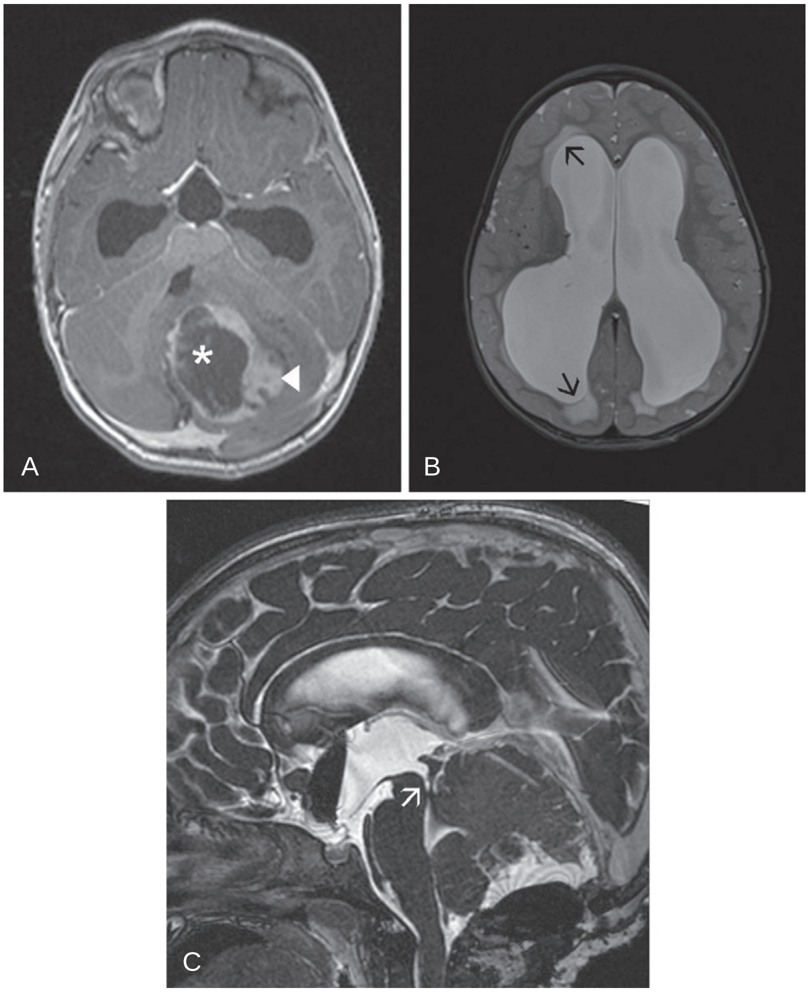

**FIGURE 44-1** **A,** Axial T1WI postgadolinium image of a cerebellar pilocytic astrocytoma, in a 3-year-old boy, showing a large cyst *(white asterisk)* and enhancing mural nodule *(white arrowhead)*. **B,** Axial T2WI image showing markedly dilated lateral ventricles and transependymal flow of cerebral spinal fluid (CSF) out of the ventricles into the surrounding brain parenchyma *(black arrows)*. The obstructive hydrocephalus is a result of the cerebellar astrocytoma. **C,** Sagittal T2WI postoperative image showing resection of tumor and flow through the floor of the third ventricle *(white arrow)* after the endoscopic third ventriculostomy done at the time of tumor resection.

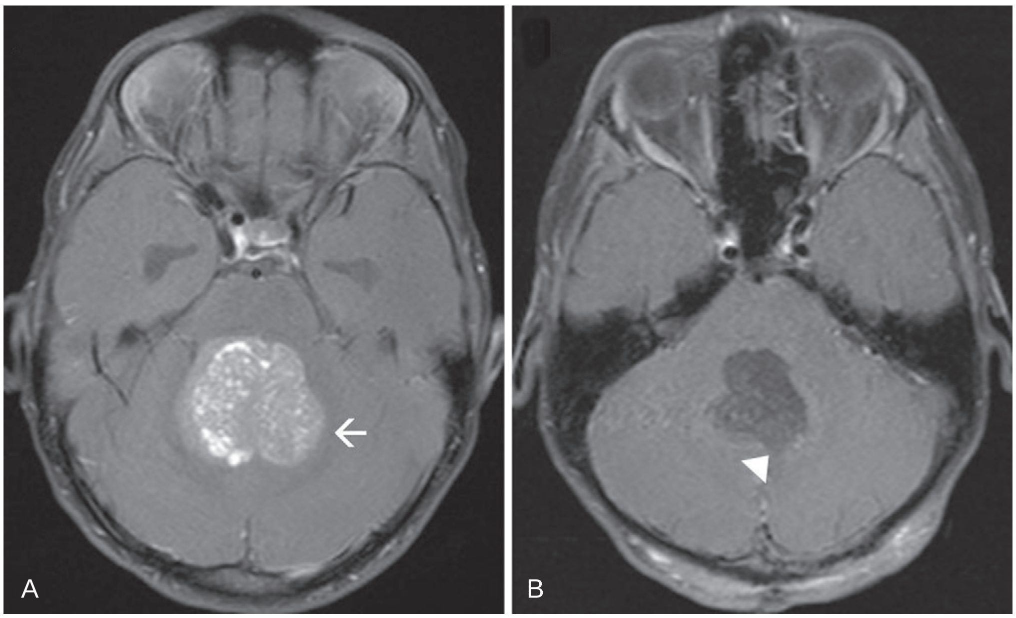

**FIGURE 44-2** **A,** Axial T1WI postgadolinium image, in an 8-year-old boy, showing an enhancing primitive neuroectodermal tumor (PNET) arising from the roof of the fourth ventricle and involving the cerebellar vermis *(white arrow)*. **B,** Axial T1WI postoperative image showing resection of tumor and partial splitting of the vermis *(white arrowhead)*. The patient suffered severe postoperative mutism.

but no attempt should be made to resect tumor in vital areas.[23] After the operation, radiation therapy is usually administered to the entire brain and spinal canal, with a boost to the tumor bed. Younger children (less than 9 years old) suffer significant, global cognitive problems as a result of whole-brain radiation in an age- and dose-dependent fashion.[24] They are chemotherapy sensitive, and various chemotherapy combinations have been used to improve outcomes and allow for a reduction in craniospinal radiation dose.[25–28] Chemotherapy alone has been shown to have some success in treating these tumors and can be used in the treatment of infants (for whom craniospinal radiation is contraindicated); however, the long-term survival of a chemotherapy-only approach is not as good as combined modality treatment.[29–32] In determining the best treatment, staging criteria are important to define risk groups. In the past, the Chang system was used, which incorporated the surgeon's estimate of the tumor size at operation and the extent of metastatic disease based on postoperative imaging.[33] In most centers today, patients are assigned to a high-risk group based on younger age (<3 years old), supratentorial tumor location, postoperative residual disease greater than a volume of 1.5 cubic centimeters, or presence of disseminated disease.[28,34] Molecular markers have been identified that have prognostic significance, but are not yet being used to dictate therapy.[35–39] The rate of progression-free survival at 5 years ranges from more than 80% in groups with standard-risk factors[40,41] to less than 70% in high-risk groups.[28,42–44] Infants treated with chemotherapy alone historically have progression-free survival rates in the range of 20% to 40%,[29–31] although recent studies suggest that intensification of therapy may improve survival rates.[32,45]

Patients require long-term supportive care, preferably in the setting of a multidisciplinary pediatric neuro-oncology clinic. Surveillance scanning is standard practice, and although rates of cure for recurrent tumors are low, high-dose chemotherapy and stem cell rescue can salvage some patients at relapse.[46,47] Late sequelae of therapy include pituitary dysfunction, hearing loss, growth delay, cardiomyopathy,[48] cognitive delay,[49] psychosocial adjustment and family problems, and radiation-induced meningiomas, astrocytomas, and sarcomas.[50]

## EPENDYMOMAS

Ependymomas occur in the region of the fourth ventricle or cerebellopontine angle, spinal cord, or supratentorial compartment. Most are histologically benign, but despite this, they have a tendency to recur in the local tumor bed and disseminate throughout the neuraxis. The median age at diagnosis is between 3 and 5 years, although tumors in infants and adults are not uncommon.[51] Tumors typically arise in the posterior fossa (60% of cases), and symptoms are similar to those of other tumors in this region. Cranial nerve and brainstem involvement can occur. Vomiting may arise without hydrocephalus, which suggests infiltration of the region of obex, which is characteristic of ependymomas. When the tumors do arise in the supratentorial compartment in children, they are often extremely large, and despite their presumed ependymal origin, may demonstrate no connection with the ventricle.

Computed tomography typically shows an isodense mass with flecks of calcification and an inhomogeneous pattern of enhancement. Posterior fossa lesions may extend through the foramina of Luschka into the cerebellopontine angle (Fig. 44-4). On MRI, ependymomas are usually isointense to hypointense on T1-weighted images, hyperintense on T2/FLAIR images, do NOT show restricted diffusion on DWI, and often enhance inhomogeneously with gadolinium.[52]

FIGURE 44-4 Axial T2WI image of a fourth ventricular ependymoma, in a 5-year-old boy, growing out of the foramen of Luschka into the cerebellopontine angle *(white arrows)*.

Treatment for ependymomas primarily consists of surgery and radiation. Prognosis is highly dependent on the extent of surgical resection as determined by postoperative imaging. The 5-year progression-free survival after complete resection is 60% to 80%, compared with less than 30% after incomplete resection.[53] However, radical surgical resection may result in permanent neurologic damage and may not be possible in some cases. Unless the tumor has disseminated at diagnosis, postoperative radiation is confined to the operative bed. Trials of radiosurgery for unresectable tumors are ongoing at several centers. Ependymomas are now being treated with proton beam therapy because of the decreased radiation exposure to the adjacent, normal uninvolved structures. Adjuvant chemotherapy has minimal impact on survival[54]; however, several chemotherapy agents have activity in this tumor,[30,55] and chemotherapy is being evaluated in a neoadjuvant setting to see whether giving chemotherapy after a subtotal resection may shrink the tumor in such a way that a complete resection can be achieved at a second surgery.

## BRAINSTEM GLIOMAS

It is now recognized that there are several types of brainstem gliomas, each associated with very different outcomes.[56] The most common variety is the diffuse intrinsic brainstem glioma, which is not amenable to surgical resection. These tumors are often centered in the pons and typically present with cranial neuropathies rather than hydrocephalus. Patients tend to be less than the age of 4 years, with sixth nerve palsies, facial weakness, and ataxia. The diagnosis is established by MRI, which shows a swollen pons with diffuse signal abnormalities (Fig. 44-5). Surgery is not indicated. Radiation therapy can provide symptomatic relief and prolong survival, but most children die within a year.[57] Chemotherapy has not been shown to be effective.

Cervicomedullary astrocytomas are considered to be rostral extensions of intrinsic spinal cord tumors and carry a better prognosis. Signs and symptoms may include vomiting, torticollis, and slowly evolving motor weakness. MRI shows an enlarged upper cervical spinal cord, with a rostral extension presenting in the cisterna magna. They are often amenable to aggressive surgical resection, and if the histology is benign, adjuvant radiation therapy is usually deferred.

Dorsally exophytic brainstem tumors arise from the floor of the fourth ventricle and present with symptoms of hydrocephalus. These tend to be pilocytic astrocytomas.[58] Treatment is primarily surgical. Gross total resection is difficult to achieve without unacceptable neurologic risk; however, most patients remain progression-free after resection because of the indolent nature of the tumor. Radiotherapy is reserved for recurrence or progression.[59]

Tectal gliomas are now recognized to be a not infrequent cause of hydrocephalus.[60] They typically present with symptoms referable to ventricular obstruction and are usually treated with either a ventriculoperitoneal shunt or endoscopic third ventriculostomy. Biopsy is not required. They are usually extremely indolent, and treatment of the tumor itself is required only if it progressively enlarges.

## HYPOTHALAMIC/CHIASMATIC ASTROCYTOMAS

Suprasellar astrocytomas are usually low-grade neoplasms, which may occur in association with neurofibromatosis type 1 or as isolated tumors. The etiology of these tumors is not well described, but the association with neurofibromatosis type 1, which is localized to chromosome 17q, suggests a molecular genetic basis. They may present primarily with vision abnormalities (visual field cuts, asymmetric loss of visual acuity in association with optic atrophy, or nystagmus) or as hypothalamic dysfunction (precocious puberty, diabetes insipidus, other endocrine dysfunction, growth failure, obesity, or diencephalic syndrome, which consists of failure to thrive and vomiting). Often both visual and hypothalamic complaints coexist.[61]

Imaging studies usually cannot distinguish hypothalamic tumors from those arising from the visual apparatus. The tumors typically do not calcify, which helps distinguish them from craniopharyngiomas, and appear as solid hypodense lesions on CT or T1-weighted MRI sequences and enhance

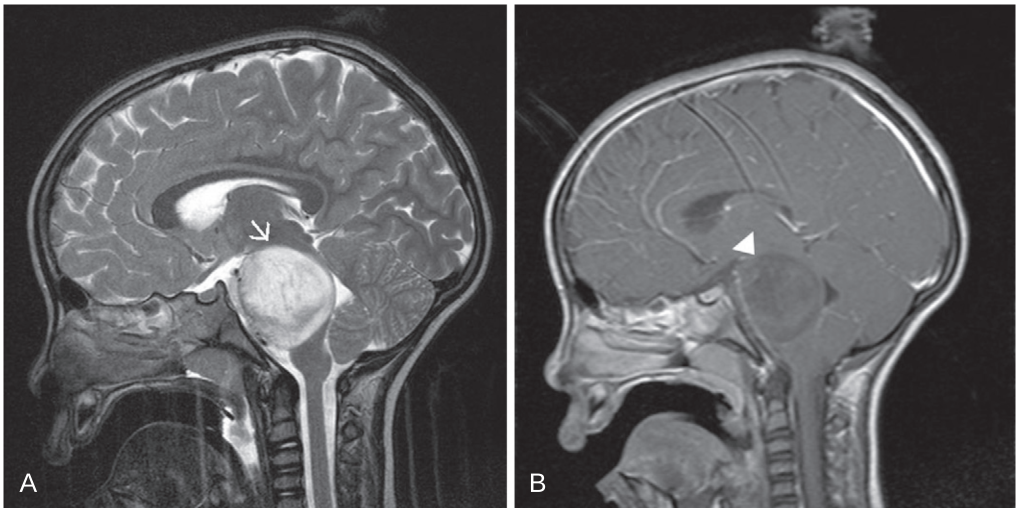

**FIGURE 44-5** **A,** Sagittal T2WI image in a 4-year-old girl showing an infiltrative, hyperintense tumor in the pons *(white arrow)*. **B,** Sagittal T1WI postgadolinium image showing that the tumor does not enhance *(white arrowhead)*. This tumor is an intrinsic pontine glioma, and the diagnosis is made by MRI alone, a biopsy is not required.

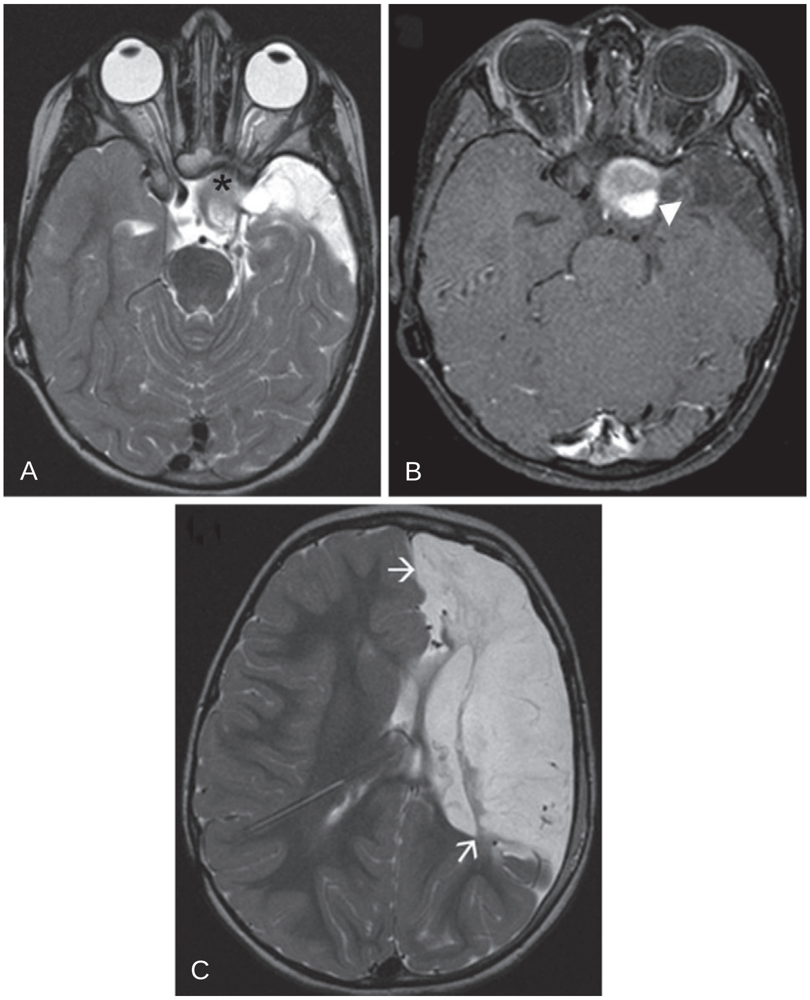

**FIGURE 44-6** **A,** Axial T2WI image in a 3-month-old girl who has a hyperintense lesion *(black asterisk)* in the left optic nerve and into the optic chiasm. **B,** Axial T1WI postgadolinium image showing an enhancing tumor *(white arrowhead)*. The tumor causes stretch on the internal carotid artery and middle cerebral artery, putting the patient at risk of a postoperative stroke when this chiasmatic/hypothalamic glioma is resected. **C,** Axial T2WI postoperative image showing a large left internal carotid stroke *(white arrows)* that occurred on postoperative day 4 and was a result of vasospasm in the stretched arteries.

after administering contrast. Extension to the intraorbital optic nerves or along the optic radiations is diagnostic and rules out craniopharyngiomas, germinomas, or other tumors in this location (Fig. 44-6).

Because most of these tumors will not progress significantly (especially in the setting of neurofibromatosis type 1), initial management is usually observation with serial imaging and ophthalmologic screening. Tumors that progress significantly and/or cause worsening vision are treated with chemotherapy. The most common regimen used is vincristine and carboplatin[62,63]; however, thioguanine, procarbazine, lomustine (CCNU), and vincristine (TPCV) are also effective.[64] Radiotherapy is avoided if possible because of the high risk of secondary effects, such as endocrine dysfunction, stroke, secondary malignant neoplasms, and neurocognitive deficits. Although radical surgical resection results in prolonged disease stability in the majority of patients, it carries a higher risk of stroke and injury to the optic pathways and the hypothalamic/pituitary axis.[65,66] Surgery is reserved for cases when the diagnosis is unclear, there is a unilateral optic nerve tumor with severe visual impairment or painful proptosis, and tumors are causing obstruction of the third ventricle or exerting mass effect on surrounding areas of the brain.

## CRANIOPHARYNGIOMA

Craniopharyngiomas are histologically benign masses believed to arise from embryonic rests derived from the hypophyseal-pharyngeal duct. Symptoms result from optic chiasm or nerve compression, hypopituitarism, hypothalamic dysfunction, or increased intracranial pressure in association with hydrocephalus.[67] They also occur in adults, but the childhood form represents a distinct entity characterized by large size and extensive calcification. There are two varieties of craniopharyngiomas, the papillary and adamantinomatous types, the latter being the most common in the pediatric population. Histologically, they typically are composed of a squamous epithelial cyst wall, with cystic fluid composed of cholesterol crystals, and calcifications. They tend to be inseparable from the pituitary stalk and may have an interdigitating gliotic interface with the hypothalamus above. This makes complete surgical removal challenging, because small rests of tumor may reside in the brain. This is also the reason for hypothalamic dysfunction that may be seen after surgical excision.[68]

Computed tomography can reveal either a cystic mass with basal calcifications or an entirely solid tumor. MRI shows

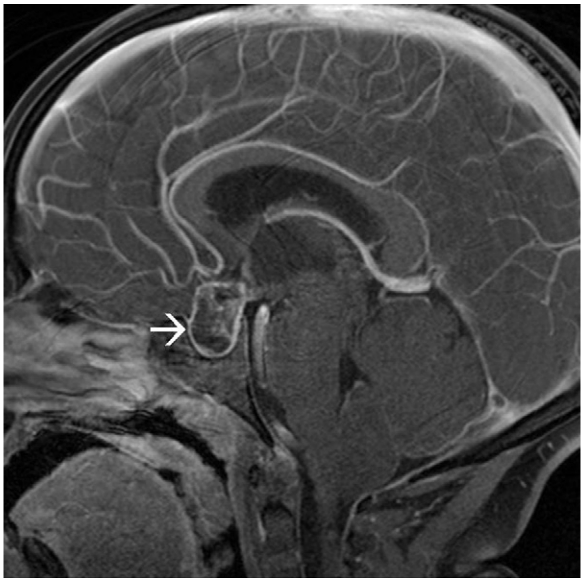

**FIGURE 44-7** Sagittal T1WI postgadolinium image, in a 6-year-old boy, showing a sellar/suprasellar craniopharyngioma growing down into the sella turcica and up into the third ventricle *(white arrow)*.

the sagittal anatomy well, but may miss the calcifications[69] (Fig. 44-7). In some instances, imaging cannot distinguish a craniopharyngioma from a hypothalamic glioma.

Controversy persists regarding the best treatment approach for patients with this tumor. Gross total resection and subtotal resection with adjuvant radiation have similar local control rates.[70–72] Both are associated with potential post-treatment problems, including panhypopituitarism, diabetes insipidus, obesity, visual problems, stroke, behavioral difficulties, poor school performance, and pseudoaneurysms of the carotid artery.[73–75] Although aggressive resection of very large craniopharyngiomas is often associated with more significant post-treatment complications, gross total resection of smaller tumors in high-volume centers are more likely to be achieved safely. Long-term survival is in the range of 90% at 10 years, but local recurrences are not uncommon.[76] Recurrences are treated by reoperation,[77] instillation of colloidal $^{32}$P into cysts, or radiosurgery.

## LOW-GRADE SUPRATENTORIAL ASTROCYTOMAS

Low-grade astrocytomas and gangliogliomas involving the cortical regions and temporal lobes can often present with intractable seizures. CT may show masses of low density. MRI usually shows a mass of decreased signal on T1-weighted images and increased signal on T2-weighted images that may or may not enhance with gadolinium.

Complete resection is the goal of surgery, but this may prove difficult because of problems in defining the tumor margins and its proximity to eloquent areas. Adjuncts to aid in this include language and motor mapping using implantable grids or intraoperative electrophysiologic monitoring techniques,[78] functional MRI techniques, and image-directed tumor resection.[79] Tumors of the temporal lobe are often treated by formal temporal lobectomy to decrease the incidence of seizures. Seizure mapping techniques have also been employed with cortical tumors, but simple removal of the tumor usually provides good seizure control, and the value of these strategies is uncertain.[9,80]

The outcome of low-grade astrocytomas,[9] gangliogliomas,[81](Fig. 44-8), and DNETs (Fig. 44-9) that are completely resected is favorable, although surveillance scanning is

**FIGURE 44-8** Axial T2WI image, in a 15-year-old girl, showing a small hyperintense right temporal tumor *(white arrow)*. The patient presented with seizures and the tumor was a ganglioglioma.

**FIGURE 44-9** Axial T2WI image showing a hyperintense lesion involving the white matter and overlying grey matter *(white arrow)*. This 5-year-old boy presented with a seizure, and the tumor was a dysembryoplastic neuroepithelial tumor (DNET).

warranted. About 70% of children will remain recurrence free. Recurrent tumors can be treated by reoperation alone or reoperation followed by radiation therapy.[82]

## PINEAL REGION TUMORS

Tumors of the pineal region encompass a wide range of histologic types. They can be divided into germ cell tumors (teratoma, germinoma, choriocarcinoma, embryonal carcinoma, yolk sac tumor), pineal parenchymal tumors (pineocytoma, pineoblastoma), tumors of surrounding structures (astrocytomas, meningiomas), and other benign conditions (cysts, vascular malformations). The older term pinealoma is no longer used.

Patients typically present with signs and symptoms of hydrocephalus and Parinaud syndrome (upgaze paresis, convergence nystagmus, and light-near dissociation). MRI confirms the presence of a tumor, but is nonspecific regarding histologic type. Specific germ cell tumors may secrete "tumor markers," which may be measured in CSF (obtained from a lumbar puncture or ventriculostomy) or blood. Elevated β-HCG is seen in choriocarcinomas, and elevated AFP is seen in yolk sac tumors and embryonal cell carcinomas.

In the past, surgery in the pineal region was considered prohibitively dangerous, and tumors were often treated without histologic confirmation. Today, this region is now readily approachable using supracerebellar/infratentorial or interhemispheric-transcallosal routes with minimal morbidity, and in most centers, biopsy is performed if germ cell markers are negative. As in the suprasellar region, pure germinomas of the pineal gland carry an excellent prognosis after radiation therapy. For focal disease, the radiation field usually includes the whole ventricular volume with a boost to the tumor bed. For disseminated disease, craniospinal radiation is required.[83] Initial treatment with chemotherapy, followed by response-based radiation field and dose, is advocated in some centers. The nongerminomatous germ cell tumors have a worse prognosis and require more intensive chemotherapy along with radiotherapy.[84] Pineoblastomas are treated like PNETs in other regions of the brain. Pineocytomas may be simply observed if totally resected or given focal radiation for residual tumor.

## ATYPICAL TERATOID/RHABDOID TUMORS

Atypical teratoid/rhabdoid tumors (AT/RTs) were previously misclassified as PNET tumors, but have been shown to be a distinct entity. They are highly malignant tumors with histologic resemblance to rhabdoid tumors of the kidney. Histologically, they can be distinguished from PNETs by larger cells with pink cytoplasm that show immunohistochemical staining for smooth muscle actin, vimentin, and epithelial membrane antigen. AT/RTs typically occur in young children and most commonly occur in the posterior fossa, but they may be located in the spine or supratentorial space. Fluorescence in situ hybridization (FISH) shows a deletion of the tumor suppressor gene *INI-1* in most cases.[85] The prognosis of these tumors is historically poor; however, treatment consisting of surgical excision, intensive chemotherapy, and radiation in older children has resulted in long-term survival in some patients with localized disease.

## MALIGNANT SUPRATENTORIAL ASTROCYTOMAS

Anaplastic astrocytomas and glioblastoma multiforme account for roughly 9% of pediatric tumors, which is a smaller incidence than in the adult population. Clinical signs and symptoms are reflective of their location. Imaging features are similar to those seen in adults, and the masses are often large, with enhancing rings and necrotic centers (Fig. 44-10). Dissemination occurs in about 10% of cases.[86]

Treatment includes maximal resection followed by radiation therapy. Unfortunately, the prognosis is still poor. Although more extensive resection confers better outcome, this may be due to the fact that more favorable tumors are more amenable to aggressive surgery. Chemotherapy has a modest impact on survival.[87,88]

## CHOROID PLEXUS TUMORS

Tumors of the choroids plexus are divided into the benign choroid plexus papilloma (CPP) and the malignant choroid plexus carcinoma (CPC). In children, they tend to arise in the trigone of the left lateral ventricle, and the patients often present with hydrocephalus during infancy. On imaging, the appearance is an intraventricular, homogenously enhancing, lobulated mass (Fig. 44-11). Carcinomas are typically larger and may disseminate. The vascular supply is from the choroidal arteries, which may be seen on high-resolution MRI.

Treatment is surgical excision, which is curative for papillomas. The procedure is hazardous, because of the highly vascular tumors and the small size of the patients. Carcinomas are particularly difficult to remove, because of extreme vascularity. This has led some surgeons to biopsy CPCs, followed by chemotherapy and then second-look surgery.[89] Otherwise,

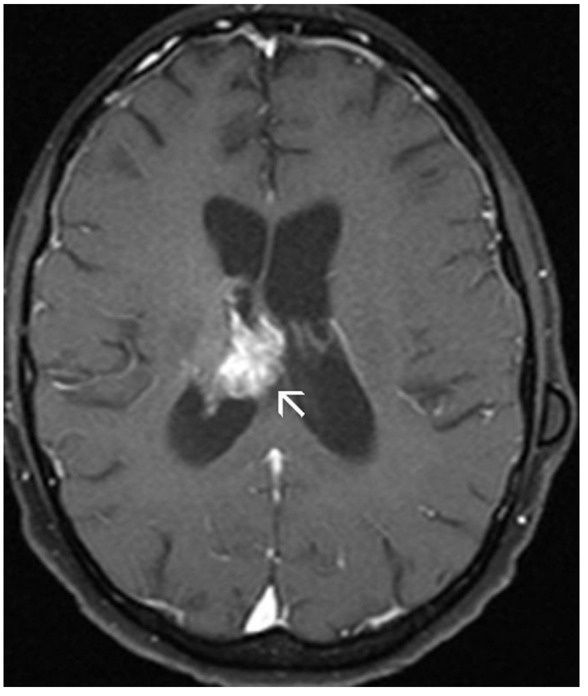

FIGURE 44-10 Axial T1WI postgadolinium image showing a thalamic enhancing tumor in a 14-year-old girl with headaches *(white arrow)*. The tumor was a glioblastoma multiforme (GBM).

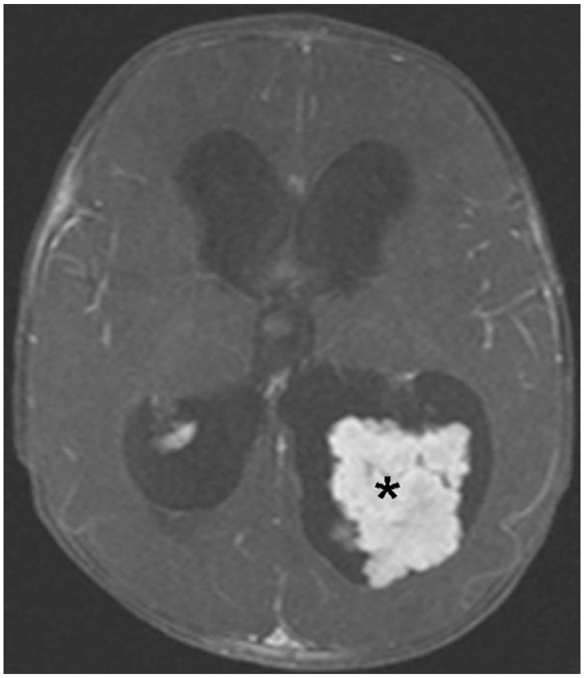

**FIGURE 44-11** Axial T1WI postgadolinium image showing an avidly enhancing tumor in the atrium of the left ventricle in a 6-month-old girl with a rapidly growing head circumference *(black asterisk)*. The tumor was a choroid plexus papilloma.

the benefit of chemotherapy and radiotherapy is unproven. With complete tumor removal, prolonged survival and even cure are possible even in the case of CPCs.

### MENINGIOMAS

Meningeal tumors are uncommon in childhood, accounting for about 2% of intracranial tumors. Meningiomas can occur in the orbit, sphenoid wing, or virtually any portion of the intracranial compartment, and do not necessarily need a dural attachment. Radiographically, they typically enhance and may be extremely large. Treatment is surgical resection. In adults, a gross total resection is curative; however, in the pediatric population, it is less common to have a meningioma with the typical benign histology seen in adults. Meningiomas in pediatric patients are usually much more aggressive and carry a worse prognosis than in adults.[90]

### METASTASES AND DURAL-BASED MASSES

Sarcomas, particularly rhabdomyosarcoma and Ewing sarcoma, are the most common, primary, dural-based non-CNS tumors in children. Metastatic brain tumors are extremely uncommon in the pediatric population and have been reported with most tumor types, including neuroblastoma, Wilms' tumor, osteogenic sarcoma, and hepatoblastoma. Presentation is often abrupt, with potential catastrophic neurologic symptoms resulting from hemorrhage.

## Tumor Genetics

In the past 2 decades, there has been a rapid development in imaging, navigational systems, and surgical instruments and techniques. However, despite this rapid increase in surgical technologies, many tumors, especially high-grade lesions, are still incurable with either surgery alone or in conjunction with chemotherapy and radiation therapy. Like much of medicine, the future in treating brain tumors lies in better biological, molecular, and genetic understanding. For example, such techniques have given physicians a better understanding of neurofibromatosis type 2, which is associated with the development of meningiomas and acoustic neuromas in the pediatric population. The gene locus was identified on chromosome 22,[91] the same chromosome that has been identified in pediatric meningiomas in patients without neurofibromatosis type 2.[92] These tumors have been shown to arise from a loss of a tumor suppressor gene.

In contrast, neurofibromatosis type 1 is associated with childhood gliomas, particularly of the optic pathway, hypothalamus, and brainstem. The affected gene locus, located at 17q11.2, encodes for the protein neurofibromin. This protein acts as a negative regulator of the RAS signaling pathway; therefore, a mutation in neurofibromin results in dysregulated RAS signaling, leading to cell growth and differentiation.[93]

Although molecular markers with prognostic significance have previously been identified for medulloblastoma, only recently have pathways been identified that may be implicated in the pathogenesis of certain medulloblastoma subtypes.[35–37,94] Approximately one third of medulloblastoma samples show increased signaling of the Sonic Hedgehog (SHH) pathway, and constitutive activation of SHH pathway promotes medulloblastoma formation in mice. Based on the work implicating this pathway and the preclinical efficacy of inhibition of this pathway on medulloblastoma formation in mice, clinical trials of SHH pathway inhibitors are underway.[84,85]

It has also recently been demonstrated that DNA from sporadic (non–NF1-associated) pediatric low-grade astrocytomas contain a novel duplication at chromosome band 7q34.[95] This duplication was identified in both juvenile pilocytic astrocytomas and fibrillary astrocytomas. This area of duplication contained approximately 20 genes, one of which was shown to be *BRAF*, which plays a regulatory role in the mitogen-activated protein kinase (MAPK) pathway. Reverse transcription polymerase chain reaction–based sequencing reveals that this duplication results in a fusion product between *KIAA1549* and *BRAF*. It is predicted that this fusion gene would lack the N-terminal regulatory domains and could result in constitutive BRAF kinase activity and subsequent unregulated activation of the MAPK pathway. Western blot analysis revealed phosphorylated MAPK protein in tumor cells with this duplication.[95] Further studies are required to determine the actual expression and function of this KIAA1549-BRAF fusion protein. However, neuroscientists are already exploring *BRAF* as a potential tumor marker or even a potential therapeutic target.

This discovery of a novel tumor pathway represents the ongoing trend in how the medical community is approaching the treatment of brain tumors. The future will require continued collaboration between neurosurgeons, oncologists, radiologists, and molecular neuroscientists to continue improving outcomes and diagnosis of patients with pediatric brain tumors.

CHAPTER 45

# Principles of Transplantation

Jorge Reyes, Noriko Murase, and Thomas E. Starzl

The replacement of failing body parts with the transplantation of organs, cells, and tissues has been a centuries-old dream, fulfilled in the last 50 years. This success with both solid organ and bone marrow cell transplantation has been established on the following principles: histocompatibility matching, immunosuppression, tissue preservation, and techniques of implantation. However, neither kind of transplantation could have emerged as a clinical service if not for the induction by the graft itself of various degrees of donor-specific nonreactivity (tolerance). Without this fifth factor, no transplant recipient could survive for long, if the amount of immunosuppression given to obtain initial engraftment had to be continued.

## Enigma of Acquired Tolerance

The variable acquired tolerance on which transplantation depends has been one of the most enigmatic and controversial issues in all of biology. This was caused, in part, by the unexpected achievement of organ engraftment (the kidney) at an early time (a decade before successful bone marrow transplantation) and in ostensible violation of the very principles that would shape the impending revolution in general immunology. As a consequence, clinical organ transplantation was developed empirically rather than as a branch of classic immunology. This occurred in four distinct phases, each lasting more than a decade. Only at the end was it possible to explain organ engraftment and thereby eliminate the mystique of transplantation.

### PHASE 1: 1953 TO 1968

The modern era of transplantation began between 1953 and 1956 with the demonstration that neonatal mice[1,2] (with an immature immune system) and irradiated adult mice[3] (with an immune system weakened by total-body irradiation) develop donor-specific tolerance after successful engraftment of donor hematolymphopoietic cells. The key observation was that the mice bearing donor cells (donor leukocyte chimerism) could now accept skin grafts from the original donor strain but from no other strain (Fig. 45-1). The chimeric neonatal mice and the irradiated adult mice were analogues of today's bone marrow transplantation into immune-deficient and cytoablated humans, respectively. But because a good histocompatibility match was required for avoidance of graft-versus-host disease (GVHD) and of rejection,[4] clinical application of bone marrow transplantation had to await discovery of the human leukocyte antigens (HLAs). When this was accomplished,[5–7] the successfully treated human bone marrow recipients of 1968 were oversized versions of the tolerant chimeric mice.

By the time of the clinical bone marrow transplant breakthrough of 1968, kidney transplantation[8–14] already was an established clinical service, albeit a flawed one.[15] In addition, the first long-term survivals had been recorded after liver[16] and heart transplantation[17]; these were followed between 1968 to 1969 by the first prolonged survival of a lung[18] and a pancreas recipient[19] (Table 45-1). All of the organ transplant successes had been accomplished in the ostensible absence of leukocyte chimerism, without HLA matching, and with no evidence of GVHD. By going beyond the leukocyte chimerism boundaries established by the mouse tolerance models, organ transplantation had entered unmapped territory.

#### "Pseudotolerant" Organ Recipients

Two unexplained features of the alloimmune response had made it feasible to forge ahead precociously with organ transplantation.[14] The first was that organ rejection is highly reversible. The second was that an organ allograft, if protected by nonspecific immunosuppression, could induce its own acceptance. "Self-induced engraftment" was observed for the first time in 1959 in two fraternal twin kidney recipients, first in Boston by Joseph Murray[12] and then in Paris by Jean Hamburger.[8] These were the first successful transplantations in the world of an organ allograft, in any species. Both patients had been conditioned with 450-rad sublethal total-body irradiation before transplantation. The renal allografts functioned for more than 2 decades without a need for maintenance drug therapy, which was, in fact, not yet available.

A similar drug-free state was next occasionally observed after kidney transplantation (and more frequently after liver replacement) in mongrel dogs who were treated with a single immunosuppressive agent: 6-mercaptopurine (6-MP),[20,21] azathioprine,[22,23] prednisone,[24] or antilymphocyte globulin (ALG).[25] After treatment was stopped, rejection in some

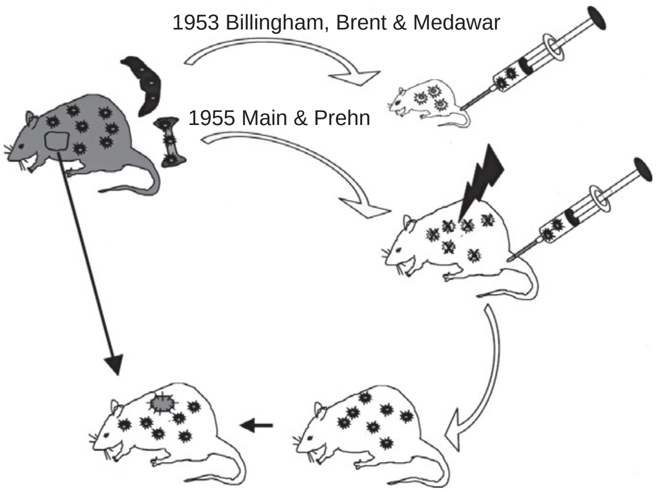

FIGURE 45-1 The mouse models of acquired tolerance described between 1953 and 1956. White cells (leukocytes) were isolated from the spleen or bone marrow of adult donor mice *(upper left)* and injected into the bloodstream of newborn mice *(upper right)* or of irradiated adult mice *(middle right)*. Under both circumstances, the recipient immune system was too weak to reject the foreign cells *(dark shaded)*. With engraftment of the injected cells (i.e., donor leukocyte chimerism), the recipient mice now could freely accept tissues and organs from the leukocyte donor but from no other donor *(bottom left)*.

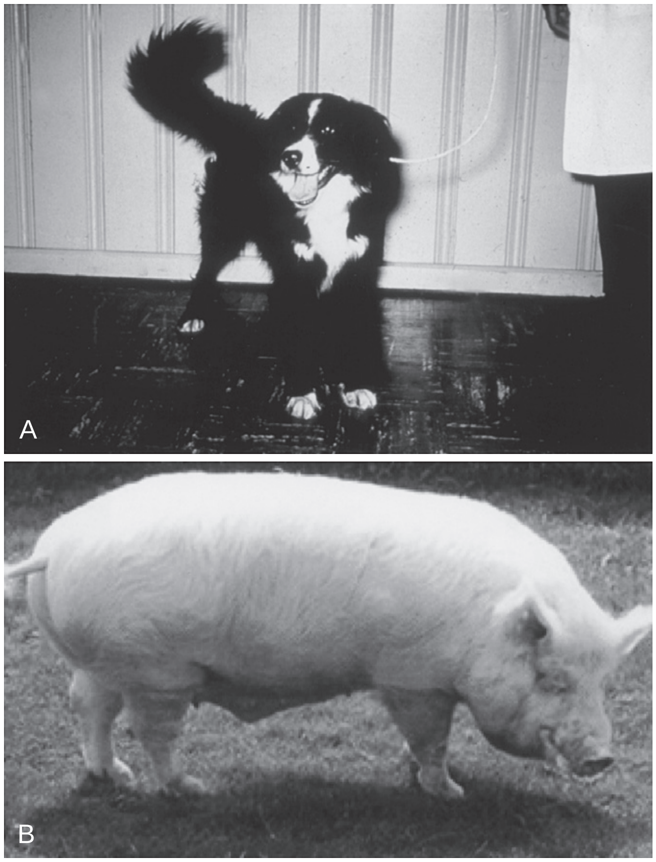

FIGURE 45-2 **A,** Canine recipient of an orthotopic liver homograft, 5 years later. The operation was on March 23, 1964. The dog was treated for only 120 days with azathioprine and died of old age after 13 years. **B,** A spontaneously tolerant pig recipient described by Calne.[29]

animals never developed (Fig. 45-2, *A*). Such results were exceedingly rare, less than 1% of the canine kidney experiments done under 6-MP and azathioprine up to the summer of 1962. However, the possibility that an organ could be inherently tolerogenic was crystallized by the human experience summarized in the title of a report in 1963 of a series of live-donor kidney recipients treated in Denver, "The Reversal of Rejection in Human Renal Homografts with Subsequent Development of Homograft Tolerance."[14] The recipients had been given azathioprine before as well as after renal transplantation, adding large doses of prednisone to treat rejections that were monitored by serial testing of serum creatinine (Fig. 45-3, *A*). Rejection occurred in almost every case, and 25% of the grafts were lost to uncontrolled acute rejection. However, the 1-year survival of 46 allografts, obtained from familial donors during a 16-month period from 1962 to 1963, was an unprecedented 75%.

The development of partial tolerance in many of the survivors was inferred from the rapidly declining need for treatment after rejection reversal (see Fig. 45-3, *A*). Nine (19%) of the 46 allografts functioned for the next 4 decades, each depicted in Figure 45-4 as a horizontal bar. Moreover, all immunosuppression eventually was stopped in seven of the nine patients without rejection for periods ranging from 6 to 40 years (the solid portion of the bars). Eight of the nine patients are still alive and bear the longest surviving organ allografts in the world.[26]

What was the connection between the tolerant mouse models, the irradiated fraternal twin kidney recipients in Boston and Paris, the ultimate drug-free canine organ recipients (see Fig. 45-2, *A*), and the unique cluster of "pseudotolerant" human kidney recipients in Denver (Fig. 45-4)? What were the mechanisms of engraftment and what was the relationship of engraftment to tolerance? The mystery deepened with the demonstration in 1966 in France,[27] England,[28–31] and the United States[32] that the liver can be transplanted in about 20% of outbred pigs without any treatment at all (see Fig. 45-2, *B*). Because graft-versus-host disease had yet to be seen (despite the use of organs from HLA-mismatched donors) none of the animal or human organ recipients, whether off or on maintenance immunosuppression, was thought to have donor leukocyte chimerism to explain organ engraftment.

## False Premises of Phase 1

Organ transplantation became disconnected at a very early time from the scientific anchor of leukocyte chimerism that had been established by the mouse models and was soon to

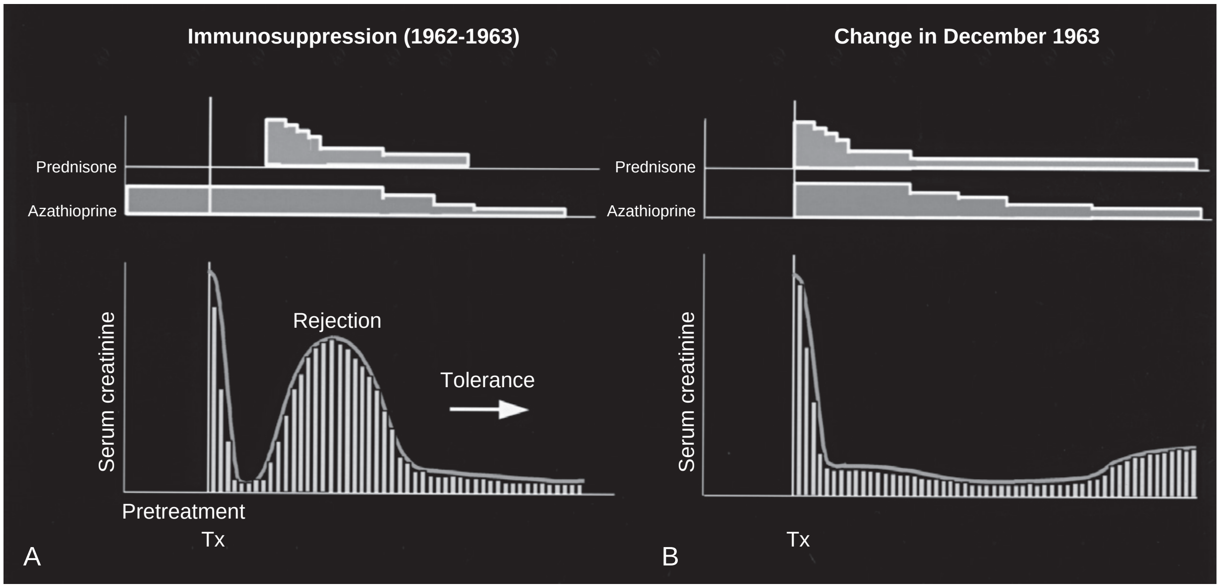

**FIGURE 45-3** **A,** Empirically developed immunosuppression used for kidney transplant recipients from 1962 to 1963. Note the reversal of rejection with the addition of prednisone to azathioprine. More than a third of a century later, it was realized that the timing of drug administration had been in accord with the tolerogenic principles of immunosuppression (see text). **B,** Treatment revisions in immunosuppression made at the University of Colorado in December 1963, which unwittingly violated principles of tolerogenic immunosuppression. Pretreatment was de-emphasized or eliminated, and high doses of prednisone were given prophylactically instead of as needed. Although the frequency of acute rejection was reduced, the drug-free tolerance shown in Figure 45-4 was no longer seen. Tx, treatment.

be exemplified by human bone marrow transplantation. The resulting intellectual separation of the two kinds of transplantation (Fig. 45-5) was an unchallenged legacy of phase 1, passed from generation to generation.

There was another dark legacy of phase 1 that began in 1964. This was a modified version of the treatment strategy that had been developed with azathioprine and prednisone (see Fig. 45-3, *B*). The principal change was the use of large prophylactic doses of prednisone from the time of operation, instead of the administration of corticosteroids only when needed. In a second modification, the pretreatment was de-emphasized (see Fig. 45-3, *B*). The incidence of acute rejection was greatly reduced after these changes. However, no cluster of drug-free kidney recipients, such as shown in Figure 45-4, was ever seen again, anywhere in the world. More than 35 years passed before the long-term immunologic consequences of the modifications were realized.

## PHASE 2: 1969 TO 1979

Throughout the succeeding phase 2 that began in 1969, immunosuppression for organ transplantation was based on azathioprine and prophylactic high-dose prednisone to which ALG was added after 1966[25,33] in about 15% of centers. Phase 2 was a bleak period. In the view of critics, the heavy mortality, and particularly the devastating morbidity caused by corticosteroid dependence, made organ transplantation (even of kidneys) as much a disease as a treatment. Most of the liver and heart transplant programs that had been established in an initial burst of optimism after the first successful cases closed down.

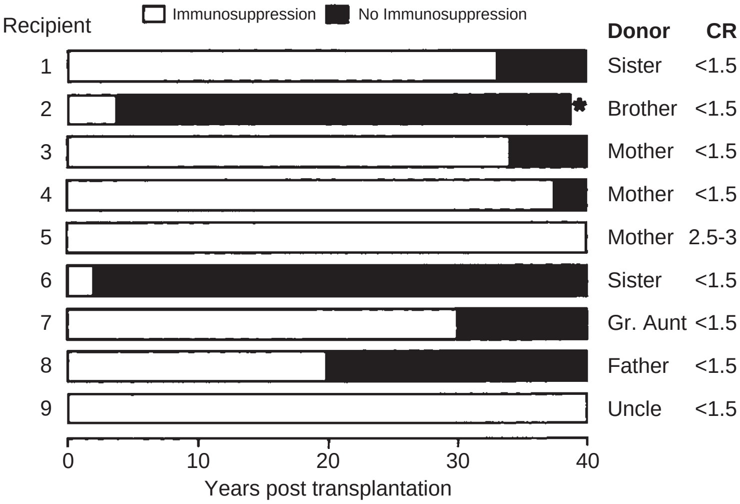

**FIGURE 45-4** Nine (19%) of the 46 live-donor kidney recipients treated at the University of Colorado during an 18-month period beginning in the autumn of 1962. The solid portion of the horizontal bars depicts the time off immunosuppression. Note that the current serum creatinine concentration (CR) is normal in all but one patient. *Murdered: kidney allograft normal at autopsy.

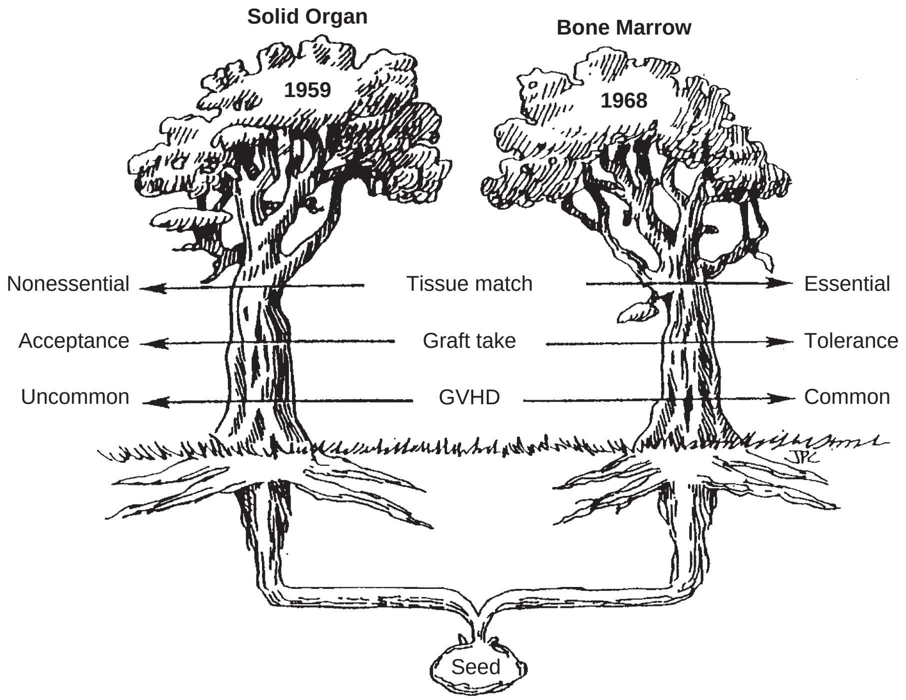

**FIGURE 45-5** The developmental tree of bone marrow *(right)* and organ transplantation *(left)* after it was demonstrated that rejection is an immunologic response. GVHD, graft-versus-host disease.

But in the few remaining centers, patients, such as the one shown in Figure 45-6, bore witness to what some day would be accomplished on a grand scale. Four years old at the time of her liver replacement for biliary atresia and a hepatoma in 1969, the patient depicted is the longest surviving recipient of an extrarenal organ.

## PHASE 3: 1980 TO 1991

In fact, what had appeared to be the sunset of extrarenal organ transplantation was only the dawn of phase 3, which began with the clinical introduction of cyclosporine,[34–37] followed a decade later by that of tacrolimus.[38–41] The use of these drugs was associated with stepwise improvements with all organs, but their impact was most conclusively demonstrated with liver and heart transplantation. The results with liver transplantation shown in Figure 45-7 using azathioprine-, cyclosporine-, and tacrolimus-based immunosuppression were presented at the meeting of the American Surgical Association in April 1994.[42] By then, intestinal transplantation under tacrolimus-based immunosuppression had become a service.[43,44]

As the new agents became available, they were simply incorporated into the modified formula of heavy prophylactic immunosuppression that had been inherited from phases 1 and 2. Used in a variety of multiple-agent combinations from

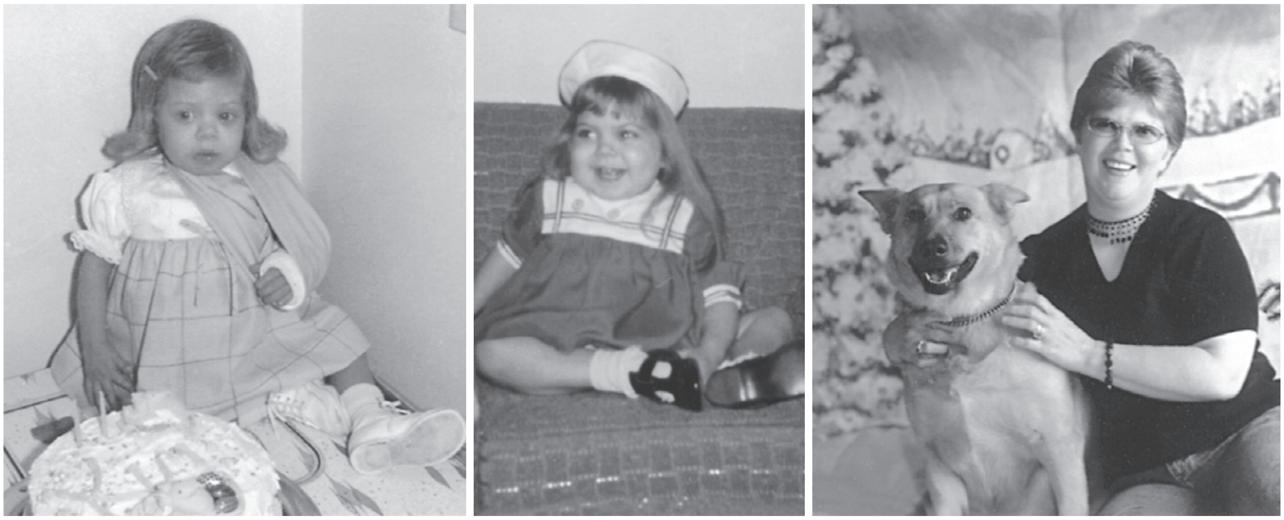

**FIGURE 45-6** Four years old at the time of liver replacement for biliary atresia and a hepatoma, but now in her 40th post-transplant year (shown here at 35 years post-transplant), the (former) patient is the longest-surviving recipient of an extrarenal organ.

the time of surgery, the better drugs fueled the golden age of transplantation of the 1980s and early 1990s. Acute rejection had become almost a "nonproblem." However, the unresolved issues now were chronic rejection, risks of long-term immunosuppression (e.g., infections and de novo malignancies), and drug toxicity (e.g., the nephrotoxicity of cyclosporine and tacrolimus).

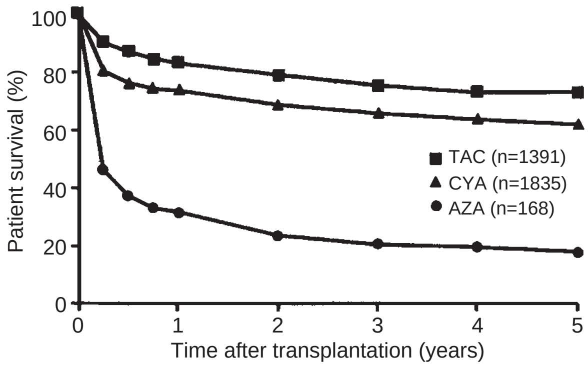

**FIGURE 45-7** Patient survival: results with orthotopic liver transplantation at the Universities of Colorado (1963 to 1980) and Pittsburgh (1981 to 1993), in periods defined by azathioprine (AZA)-, cyclosporine (CYA)-, and tacrolimus (TAC)-based immune suppression. Stepwise improvements associated with the advent of these drugs also were made with other organs.

## PHASE 4: 1992 TO PRESENT

It was clear that relief from the burden of lifetime immunosuppression would require elucidation of the mechanisms of alloengraftment and of acquired tolerance. An intensified search for the engraftment mechanisms has dominated the current phase 4, which began in the early 1990s. There was a growing realization (particularly with recipients of liver allografts), that immunosuppression could be withdrawn successfully in selected cases, which sparked various prospective trials of immunosuppression withdrawal.[45]

### Historical Dogma

Until this time, organ engraftment had been attributed to mechanisms that did not involve either the presence or a role of leukocyte chimerism. Although it was known that organs contain large numbers of passenger leukocytes, these donor cells were largely replaced in the successfully transplanted allograft by recipient leukocytes as shown in Figure 45-8, *A*. The missing donor cells were thought to have undergone

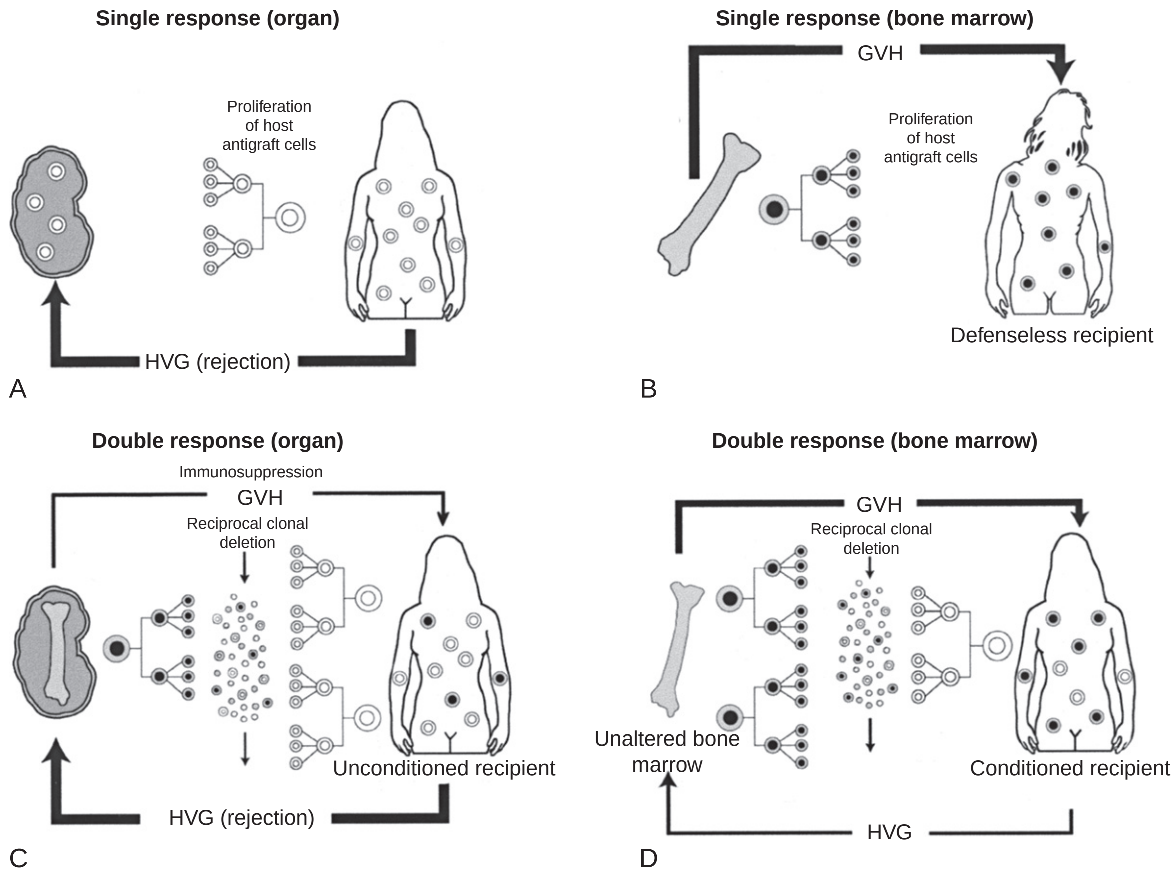

**FIGURE 45-8** Old (**A** and **B**) and new views (**C** and **D**) of transplantation recipients. **A,** The early conceptualization of immune mechanisms in organ transplantation in terms of a unidirectional host-versus-graft (HVG) response. Although this readily explained organ rejection, it limited possible explanations of organ engraftment. **B,** Mirror image of **A** depicting the early understanding of successful bone marrow transplantation as a complete replacement of the recipient immune system by that of the donor, with the potential complication of an unopposed lethal unidirectional graft-versus-host (GVH) response, that is, rejection of the recipient by the graft. **C,** Our current view of bidirectional and reciprocally modulating immune responses of coexisting immune-competent cell populations. Because of variable reciprocal induction of deletional tolerance, organ engraftment was feasible despite a usually dominant HVG reaction. The bone silhouette in the graft represents passenger leukocytes of bone marrow origin. **D,** Our currently conceived mirror image of **C** after successful bone marrow transplantation. Recipient's cytoablation has caused a reversal of the size proportions of the donor and recipient populations of immune cells.

immune destruction with selective sparing of the specialized parenchymal cells. As for bone marrow transplantation (see Fig. 45-8, *B*), the ideal result had been perceived as complete replacement of recipient immune cells (i.e., total hematolymphopoietic chimerism).

### Discovery of Microchimerism

A flaw in this historical dogma began to be exposed in the early 1990s. The first puzzling observation in Seattle[46] and Helsinki[47] was the invariable presence of a small residual population of recipient hematolymphopoietic cells in patients previously thought to have complete bone marrow replacement (see Fig. 45-8, *D*). This was followed in 1992 by the discovery of donor leukocyte microchimerism in long-surviving human organ recipients. Now it was evident that organ engraftment (see Figure 45-8, *C*) and bone marrow cell engraftment (see Fig. 45-8, *D*) were mirror-image versions of leukocyte chimerism, differing in the reversed proportion of donor and recipient cells.

The discovery of microchimerism in organ recipients was made with a very simple clinical study.[48–52] With the use of sensitive detection techniques, donor hematolymphopoietic cells of different lineages (including dendritic cells) were found in the blood, lymph nodes, skin, or other tissues of 30 of 30 liver or kidney recipients who had borne functioning allografts for up to 30 years. The donor leukocytes obviously were progeny of donor precursor or pluripotent hematolymphopoietic stem cells that had migrated from the graft into the recipient after surviving a double immune reaction that presumably had occurred just after transplantation, years or decades earlier.[53–56]

It was concluded that organ engraftment had been the result of "responses of coexisting donor and recipient cells, each to the other, causing reciprocal clonal exhaustion, followed by peripheral clonal deletion."[48,50] The host response (the upright curve in Fig. 45-9) was the dominant one in most cases of organ transplantation but with the occasional exception of GVHD. In the conventionally treated bone marrow recipient, host cytoablation simply transferred immune dominance from the host to the graft (the inverted curve in Fig. 45-9), explaining the high risk of GVHD. All of the major differences between the two kinds of transplantation were caused by the recipient cytoablation. After an estrangement of more than a third of a century, the intellectual separation of bone marrow and organ transplantation was ended (Fig. 45-10).

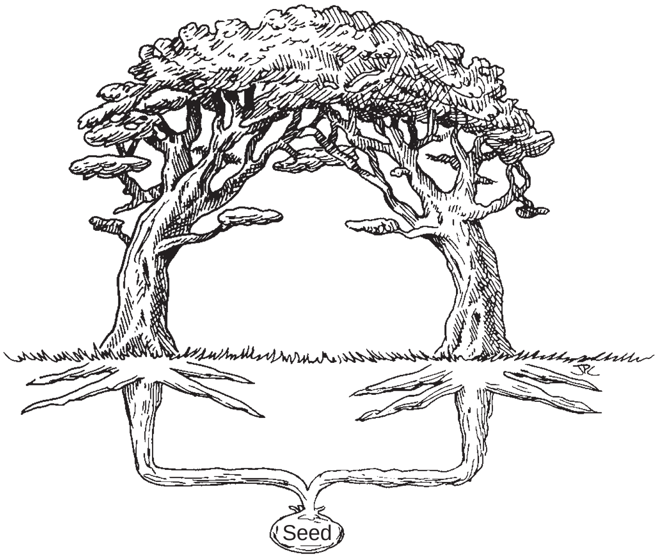

FIGURE 45-10 Unification of organ and bone marrow transplantation (see text).

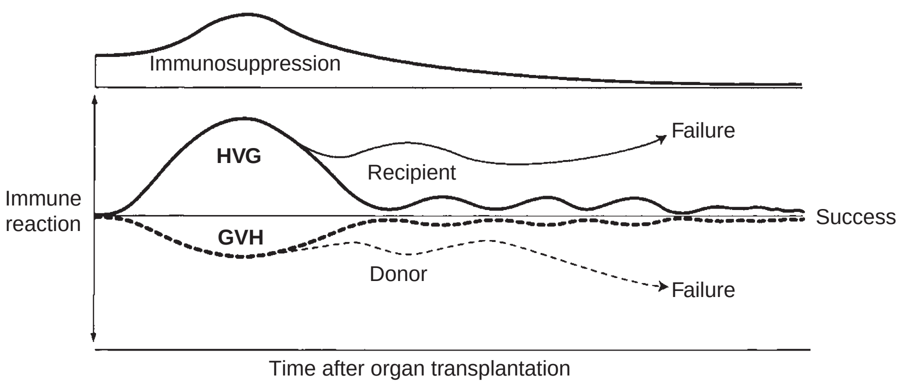
### Immune Regulation by Antigen Migration and Localization

But how was the exhaustion-deletion of the double immune reaction shown in Figure 45-9 maintained after its acute induction by the first wave of migratory leukocytes? Rolf Zinkernagel, in Zurich (Fig. 45-11), had addressed this question during the 1990s in experimental studies of the nonresponsiveness that may develop to intracellular microorganisms, such as tubercle bacillus and noncytopathic viruses.[57–60] The analogies between the syndromes caused by such infectious agents and the events following transplantation were described in 1998 in a joint review with Zinkernagel in the *New England Journal of Medicine*.[61]

The analogies between transplantation and infection had been obscured by the characteristic double immune reaction of transplantation and by the complicating factor of immunosuppression. Now, these analogies were obvious. The antidonor response induced by the initially selective migration of the graft's leukocytes to host lymphoid organs (Fig. 45-12, *left*)[62–65] is comparable to the response induced by a spreading intracellular pathogen. The migration patterns of the donor leukocytes were the same whether these cells emigrated from an organ or were delivered as a bone marrow

FIGURE 45-9 Contemporaneous HVG *(upright curves)* and GVH *(inverted curves)* responses after transplantation. In contrast to the usually dominant HVG reaction of organ transplantation, the GVH reaction usually is dominant after bone marrow cell transplantation to the irradiated or otherwise immunodepressed recipient. Therapeutic failure with either type of transplantation implies the inability to control one, the other, or both of the contemporaneous responses with a protective umbrella of immunosuppression.[61]



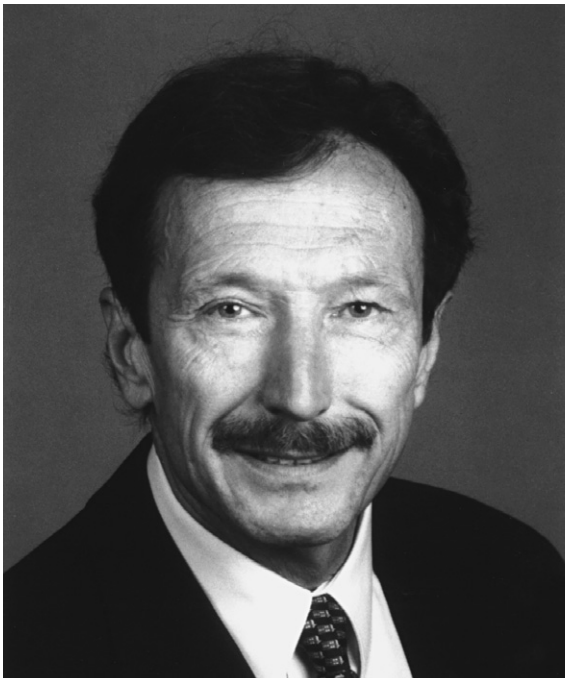


**FIGURE 45-11** Rolf Zinkernagel. Swiss physician-immunologist whose discovery, with Peter Doherty, of the mechanisms of the adaptive immune response to noncytopathic microorganisms earned them the Nobel prize in 1996.

cell infusion. Cells that survived the antidonor response that they had induced begin within a few days to move on (see Fig. 45-12, *right*) to protected nonlymphoid niches, where their presence no longer may be detected by the immune system (immune ignorance[61,66–69]). This was a survival tactic of noncytopathic microorganisms.

The migration of donor leukocytes is shown schematically in Figure 45-13, *left* by centrifugal arrows: first by hematogenous routes to lymphoid organs and, after a few weeks, on to nonlymphoid sites *(outer circle)*. A subsequent reverse migration of donor cells from protected nonlymphoid niches back to host lymphoid organs is depicted by the inwardly directed *dashed arrows* in Figure 45-13, *right*. The retrograde migration is a two-edged sword. On the one hand, these cells may sustain the clonal exhaustion-deletion induced at the outset, usually requiring an umbrella of maintenance immunosuppression. But on the other hand, these cells can perpetuate alloimmunity in the same way as surviving residual microorganisms perpetuate protective immunity. Not surprisingly, therefore, an alternative consequence of microchimerism may be the high-panel reactive antibody (connoting sensitization to HLA antigens) that commonly develops after unsuccessful transplantation.[70,71]

## Therapeutic Implications

How could the new insight be exploited clinically? The window of opportunity for the donor leukocyte-induced clonal deletion that corresponds with collapse of the antigraft response (Fig. 45-14, *left*) is open only for the first few

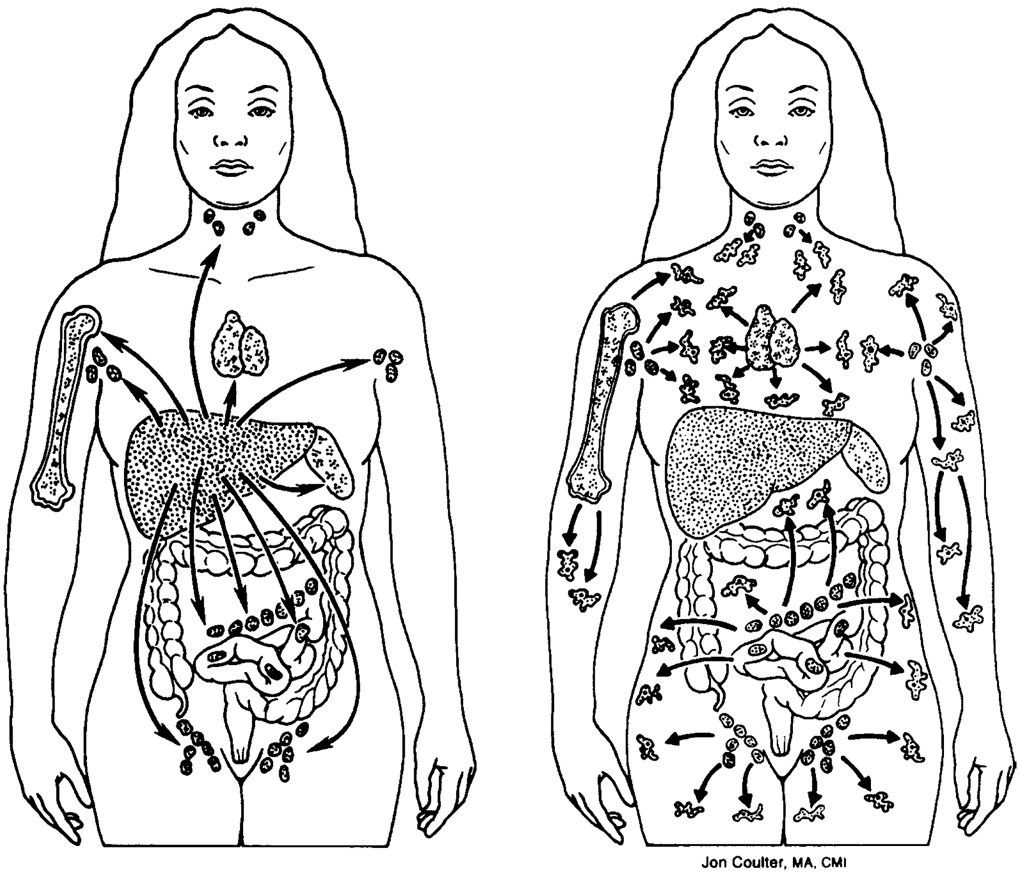

**FIGURE 45-12** Initial preferential migration of passenger leukocytes from organ allografts (here a liver) to host lymphoid organs *(left)*, where they induce a donor-specific immune response. After about 30 days, many of the surviving cells move on to nonlymphoid sites *(right)*.

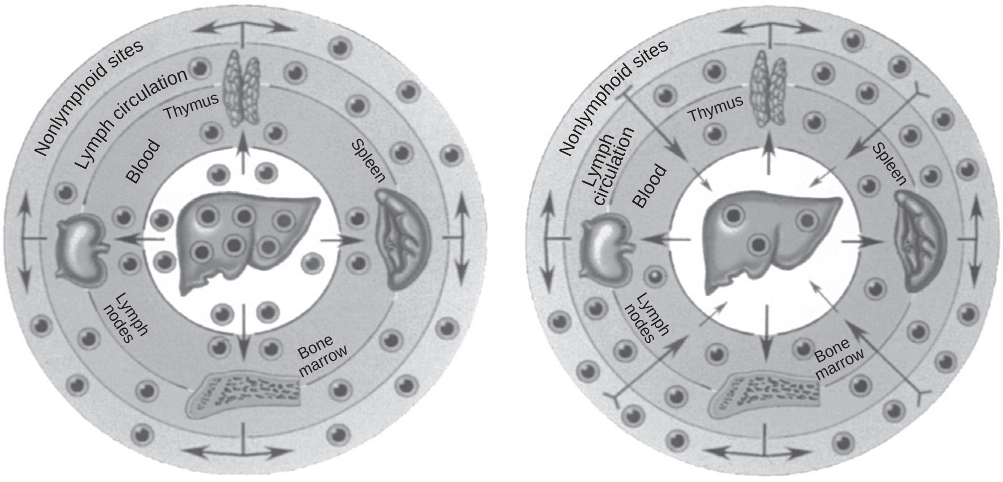

**FIGURE 45-13** The migration routes of passenger leukocytes of transplanted organs are similar to those of infused bone marrow cells. *Left,* Selective migration at first to host lymphoid organs. After 15 to 30 days, surviving leukocytes begin to secondarily move to nonlymphoid sites. *Right,* Establishment of reverse traffic by which the exhaustion-deletion induced at the outset can be maintained.

post-transplant weeks.[55,72–74] It was apparent that the window could be closed by excessive postoperative immunosuppression (Fig. 45-14, *middle*). With later reduction of the initial overimmunosuppression, recovery of the inefficiently deleted clone would be expected, leading to the delayed acute rejection, or the chronic rejection, that was being seen in the transplant clinics. Even in the best-case scenario, the patients would be predestined to lifetime dependence on immunosuppression. However, too little immunosuppression would result in uncontrolled rejection (Fig. 45-14, *right*).

The problem faced by clinicians was how to find just the right amount of post-transplant immunosuppression. In 2001, it was suggested that this dilemma could be addressed by successively applying two historically rooted therapeutic principles: recipient pretreatment, followed by minimalistic post-transplant immunosuppression.[75] With pretreatment, the recipient's immune responsiveness would be reduced before exposure to donor antigen, thereby lowering the anticipated donor-specific response to a more readily deletable range (Fig. 45-15). Clonal deletion by the kidneys' passenger leukocytes undoubtedly is what had been accomplished after sublethal irradiation alone in the ground-breaking fraternal twin (i.e., sublethal total-body irradiation or myelotoxic drugs) cases of 1959.[8,12] In fact, radical pretreatment by recipient cytoablation ultimately became the essential therapeutic step for conventional bone marrow transplantation. Because of the high risk of GVHD, this approach was too dangerous and too restrictive to be practical for organ transplantation.

However, less drastic lymphoid depletion by ALG or other measures (so-called nonmyeloablative conditioning) had been repeatedly shown since the 1960s to be effective without causing GVHD[33] (see Fig. 45-15).

After pretreatment with one of today's potent antilymphoid antibody preparations, the preemptively weakened clonal activation could proceed efficiently to clonal deletion under minimalistic short- and long-term maintenance therapy (Fig. 45-16). In July 2001, we instituted the double-principle strategy in adult organ recipients. The pretreatment was with a single infusion of 5 mg/kg of Thymoglobulin. Beginning in 2002, a single Campath dose of 30 mg was substituted for Thymoglobulin in most adult cases. After either kind of lymphoid depletion, treatment after transplantation was given with a conservative daily dose of a single drug (usually tacrolimus), adding other agents only in the event of breakthrough rejection and for as brief a period as

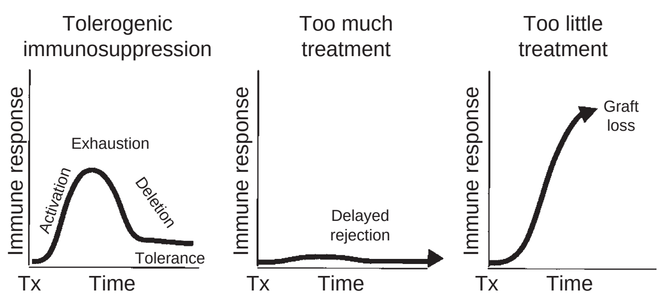

**FIGURE 45-14** The effect of post-transplant immunosuppression on the seminal mechanism of clonal exhaustion-deletion. *Left,* Just the right amount. *Middle,* Too much. *Right,* Too little (see text). Tx, treatment.

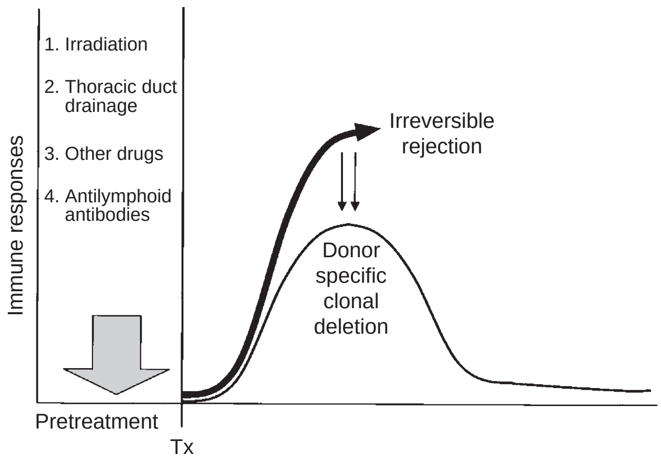

**FIGURE 45-15** Rather than producing rejection *(thick dark arrow),* the donor-specific immune response to allografts may be exhausted and deleted, as depicted by the fall of the initially ascending continuous thin line, when recipient immune responsiveness is weakened in advance of transplantation (the pretreatment principle). Tx, treatment.

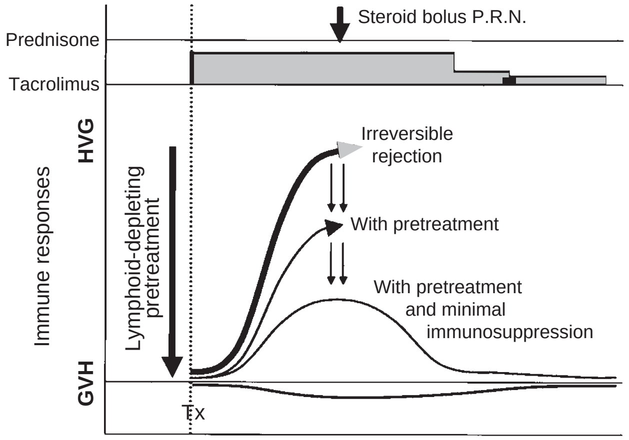

**FIGURE 45-16** Conversion of rejection *(thick dark arrow)* to an immune response that can be exhausted and deleted by combination of pretreatment and minimalistic post-transplant immunosuppression. Tx, treatment.

possible. The strategy was extended to infants and children for intestinal transplantation in 2002 and for all kidney transplantations after April 2003.[76]

After 4 to 8 months, weaning from monotherapy to less-than-daily doses was begun in adults whose graft function was stable: every other day, then three times per week, twice a week, and in many cases to once a week by 1 year (Fig. 45-17). The strategy has been used for the treatment of more than 1000 adult kidney, liver, intestine, pancreas, and lung recipients.[77–79] This experience has demonstrated that the quality of life of transplant recipients can be improved. For the first time, children are being considered for spaced weaning.

These and other clinical trials have spawned definitions of clinical or operational tolerance (normal graft function without features of graft rejection and without the need for immunosuppressive drugs), and "prope," or "near" tolerance (the state of normal graft function in the presence of minimal or undetectable levels of immunosuppression).[80,81] However, achieving this on a consistent basis may hinge on the development of standardized clinically applicable markers of immune tolerance that can assess the appropriateness of this clinical strategy on the individual patient. Prospective weaning trials sponsored by the Immune Tolerance Network are currently underway in stable adult and pediatric recipients of liver allografts, incorporating the aforementioned strategies and mechanistic studies.[82]

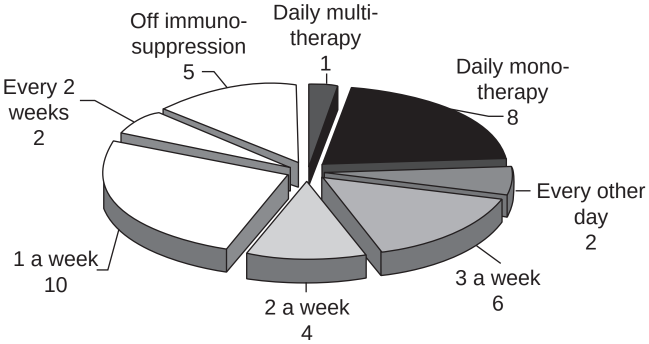

**FIGURE 45-17** Diagram of 2.5-year follow-up.

# Organ Preservation

## PROCUREMENT

The breakthroughs of the early 1960s that made transplantation clinically practical were so unexpected that almost no formal preparation had been made to preserve the transplanted organs. Cardiac surgeons had used hypothermia for open-heart operations from 1950 onward and knew that ischemic damage below the level of aortic cross-clamping could be reduced by cooling the subdiaphragmatic organs.[83] In an early report, Lillehei and colleagues[84] immersed intestines in iced saline before autotransplantation. In Boston, Sicular and Moore[85] reported greatly slowed enzyme degradation in cold slices of liver.

Despite this awareness, kidneys were routinely transplanted until 1963 with no protection from warm ischemia during organ transfer. The only attempt to cool kidney allografts until then was by the potentially dangerous practice (used by thoracic surgeons for open-heart surgery) of immersing the live donor in a bathtub of ice water (total-body hypothermia).[86] This cumbersome method of cooling was quickly replaced by infusion of chilled solutions into the renal artery after donor nephrectomy,[87] exploiting a principle of core (transvascular) cooling that had been standardized several years earlier for experimental liver transplantation.[88]

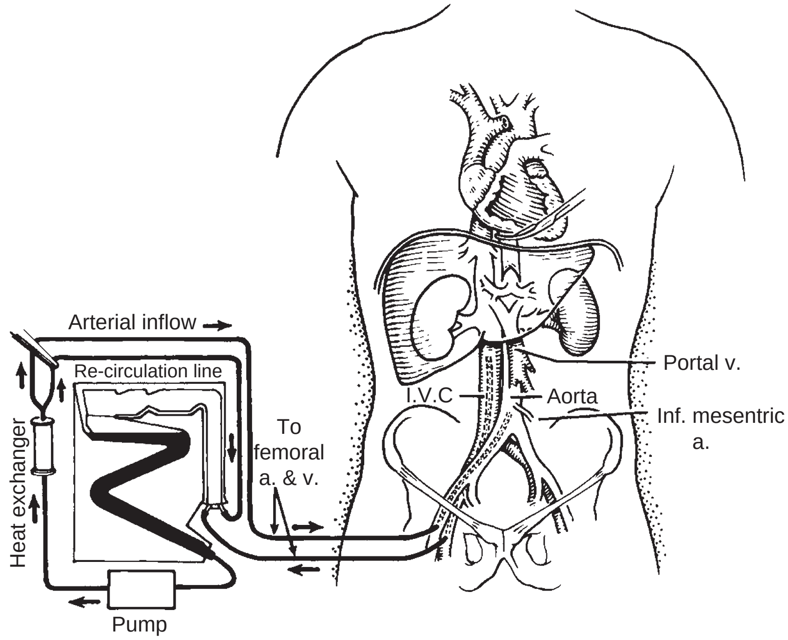
Core cooling in situ, the first critical step in the preservation of all cadaveric whole organs, is done today with variations of the technique described in 1963 by Marchioro and coworkers,[89] which permits in situ cooling to be undertaken[90] (Fig. 45-18). Ackermann and Snell[91] and Merkel and associates[92] popularized in situ cooling of cadaveric kidneys with simple infusion of cold electrolyte solutions into the donor femoral artery or distal aorta. Procurement techniques were eventually perfected that allowed removal of all thoracic and abdominal organs, including the liver, without jeopardizing any of the individual organs (Fig. 45-19).[93] Modifications of this flexible procedure have been made for unstable donors and even for donors whose hearts have stopped beating.[94] During the 5 years between 1980 and 1985, such techniques had become interchangeable in all parts of the world, setting the stage for reliable organ sharing. After the chilled organs are removed, subsequent preservation is possible with prototype strategies: simple refrigeration or continuous perfusion (see later).

## EXTENDED PRESERVATION

### Continuous Vascular Perfusion

Efforts to continuously perfuse isolated organs have proved to be difficult. For renal allografts, Ackermann and Barnard[95] used a normothermic perfusate primed with blood that was oxygenated within a hyperbaric chamber. Brettschneider and colleagues[96] modified the apparatus and were able to preserve canine livers for 2 days, an unprecedented feat at the time. When Belzer and associates[97] eliminated the hemoglobin and hyperbaric chamber components, their asanguineous hypothermic perfusion technique was immediately accepted for clinical renal transplantation but then slowly abandoned

FIGURE 45-18 First technique of in situ cooling by extracorporeal hypothermic perfusion. The catheters were inserted into the aorta and vena cava through the femoral vessels as soon as possible after death. Temperature control was provided with a heat exchanger. Cross-clamping of the thoracic aorta limited perfusion to the lower part of the body. This method of cadaveric organ procurement was used from 1962 to 1969, before the acceptance of brain death criteria. The preliminary stages of this approach provided the basis for subsequent in situ infusion techniques.



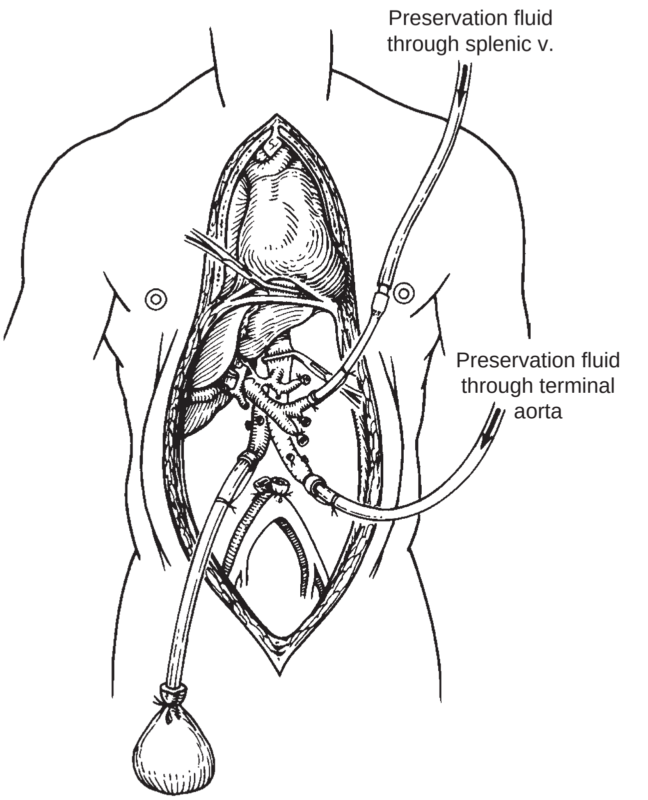


FIGURE 45-19 Principle of in situ cooling used for multiple organ procurement. With limited preliminary dissection of the aorta and of the great splanchnic veins (in this case, the splenic vein), cold infusates can be used to chill organs in situ. In this case, the kidneys and liver were being removed. Note the aortic cross-clamp above the celiac axis.

in most centers when it was learned that the quality of 2-day preservation was not markedly better than that of simpler and less expensive infusion and slush methods (see later). However, refinement of perfusion techniques may someday permit true organ banking.

### Static Preservation

With these "slush techniques," special solutions, such as those described by Collins and coworkers,[98] were instilled into the renal vascular system of kidneys or the vascular system of other organs after their preliminary chilling and separation. The original Collins solution or modifications of it were used for nearly 2 decades before they were replaced with the University of Wisconsin (UW) solution that was developed by the team of Folkert Belzer. Although it was first used for the liver,[99–101] the UW solution provides superior preservation of kidneys and other organs.[102,103] The UW preservation permitted longer and safer preservation of kidneys (2 days) and livers (18 hours), a higher rate of graft survival, and a lower rate of primary nonfunction. With the UW solution, national organ sharing was made economical and practical. This success has refocused efforts on understanding the mechanisms involved in the ischemia/reperfusion injury (deprivation and then restoration of tissue oxygen) that impacts organ function, and has resulted in the development of other preservation solutions (Celsior, HTK: histidine-tryptophan-ketoglutarate) and the inclusion of drugs that act on the mediators of injury.[104]

# Tissue Typing

## ANTIGEN MATCHING

The human leukocyte antigen (HLA) system has an important role in immune regulation and is thus a barrier that must be avoided (with better matching) or modified (with immunosuppressive strategies). HLA class I A, B, and C, and HLA class II DR, DQ, and DP molecules are expressed on various cell types that, when bound to a specific repertoire of peptides, present to CD8+ or CD4+ T cells. Patient and donor matching is of significant importance in bone marrow transplantation in order to prevent lethal GVHD but of variable importance in solid organ transplantation.[105]

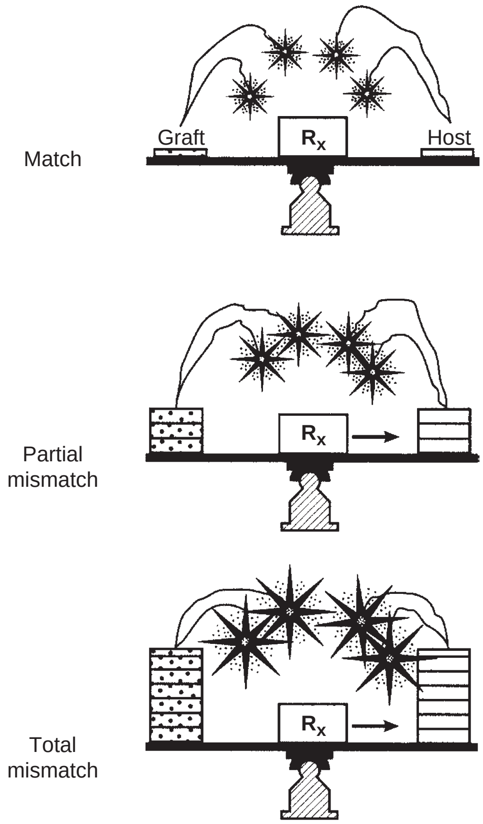

**FIGURE 45-20** The nullification effect of simultaneous host-versus-graft (HVG) and graft-versus-host (GVH) reactions when organs are transplanted to recipients whose immune system has not been cytoablated. The reciprocal induction of tolerance, each to the other, of the coexisting cell populations is the explanation for the poor correlation of human leukocyte antigen (HLA) matching with outcome after organ transplantation.

The first prospective antigen matching trials were begun in 1964 by Terasaki and associates[106] in collaboration with the University of Colorado kidney transplantation team. Although the value of this serologic technology was demonstrable when the kidney donor was a highly compatible family member (the "perfect match"),[107] lesser degrees of matching correlated poorly with renal transplantation outcome.[108] The reasons for this paradox were inexplicable until the discovery of recipient chimerism (Fig. 45-20). However, the belief that matching should be a prime determinant of success resulted in its use as an overriding factor for the allocation of cadaver kidneys in the United States.

The propriety of this kidney allocation policy has been repeatedly challenged on ethical as well as scientific grounds for nearly a third of a century. Those in favor of perpetuating the role of graded HLA matches cite multicenter case compilations in the United States and Europe showing a small gain in allograft survival with histocompatible kidneys, whereas many of the individual contributing centers see no such trend in their own experience.[83,109–111] In a compelling study, Terasaki and associates[112] reported that early survival and the subsequent half-life of kidneys from randomly matched, living unrelated donors was identical to that of parent–offspring (one haplotype–matched) grafts. The inescapable conclusion is that more effective timing and dosage of immunosuppressive therapy, rather than refinements in tissue matching and organ sharing, will be the primary method of improving the results of whole organ transplantation.

### CROSSMATCHING

None of the immunosuppressive measures available today can prevent immediate destruction of kidneys and other kinds of organ grafts in what has been called hyperacute rejection. This complication was first seen with the transplantation of kidneys from ABO-incompatible donors when they were placed in recipients with antidonor isoagglutinins.[113] After the description by Terasaki and associates[114] of hyperacute kidney rejection by a recipient with antidonor lymphocytotoxic antibodies, Kissmeyer-Nielsen and colleagues[115] and others[116–119] confirmed the association of hyperacute rejection with these antigraft antibodies. Although hyperacute rejection can usually be avoided with the lymphocytotoxic crossmatch originally recommended by Terasaki and associates, the precise pathogenesis of such rejection remains poorly understood more than 30 years after its recognition as a complement activation syndrome.[116,117]

## Future Prospects

The revisions in timing and dose control that encourage the seminal mechanisms of clonal exhaustion-deletion and immune ignorance should make it possible to systematically reduce exposure to the risks of chronic immunosuppression. Our prediction is that completely drug-free tolerance will be largely, but not exclusively, limited to recipients of HLA-matched organs. But variable partial tolerance will be more regularly attainable in most of the others, not so much by developing better drugs but by the mechanism-based use of drugs we already have in hand. Xenotransplantation will have to be developed within the same immunologic framework. Here, the problem, in principle, is to create a better interspecies tissue match by transgenic modification. Although the *α-1,3GT* gene responsible for hyperacute rejection of pig organs by higher primates has been knocked out in pigs,[120] it is not yet known what further changes have to be made before porcine organs can be used clinically. Where stem cell biology will fit remains unknown, but it also will have to conform to the same immunologic rules.

CHAPTER 46

# Renal Transplantation

John C. Magee

Transplantation is the preferred treatment for children with end-stage renal disease (ESRD), because it provides the best opportunity for health, growth, and development. Progress continues in pediatric transplantation, and current patient and graft survival is excellent.

Although single-center reports provide insight into many issues, larger registry data provide a more substantive overview of the state of transplantation. The leading registry is the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS).[1,2] In addition, data for all transplantations performed in the United States are collected through the Organ Procurement Transplant Network (OPTN), and they are regularly analyzed by the Scientific Registry of Transplant Recipients (SRTR).[3,4]

## End-Stage Renal Disease in Children

According to the United States Renal Data System (USRDS), 1343 individuals aged 19 years or younger began treatment for ESRD in 2008.[5] The incidence of ESRD in this age group is 15.5 per million per year. Because ESRD is much more uncommon in children, this rate is well below the overall national incidence of ESRD of 362 per million per year.

The etiology of renal disease in the pediatric transplantation population is summarized in Table 46-1. According to these NAPRTCS data, the five most common diagnoses are renal aplasia/hypoplasia/dysplasia, obstructive uropathy, focal segmental glomerulosclerosis (FSGS), reflux nephropathy, and chronic glomerulonephritis.[1] These diagnoses account for just over half the transplantations performed. The causes of renal failure are distinctly different from those in adults; specifically, congenital abnormalities and obstructive uropathy are the leading causes for transplantation. In addition, FSGS is the most common acquired renal disease and is much more common in children compared with adults.

Within the pediatric population, the prevalence of causes varies by age, sex, and race.[1] Congenital causes are more prevalent in younger children, whereas acquired diseases tend to become manifest in older children. Overall, 59.4% of the recipients are male, and males represent the majority of the recipients with obstructive uropathy (85.2%), aplasia/hypoplasia/dysplasia (61.8%), and FSGS (57.8%). Reflux nephropathy, chronic glomerulonephritis, and lupus nephritis are more prevalent in females, with females accounting for 56.7%, 57.0%, and 83.3%, respectively. Regarding race, for black children, FSGS was the most prevalent diagnosis (23.1%), followed by obstructive uropathy (15%) and aplasia/hypoplasia/dysplasia (13.5%). In white recipients, obstructive uropathy was the most prevalent etiology (17.0%), followed by aplasia/hypoplasia/dysplasia (16.9%) and FSGS (9.0%).

## Recipient Evaluation

Any child with ESRD should be considered for transplantation. Absolute contraindications are rare and include untreated malignancy or systemic sepsis. Relative contraindications include severe systemic disease that profoundly limits the patient's life span or a social situation that makes follow-up with post-transplantation care and immunosuppression regimen absolutely impossible. At times, the decision whether to transplant a child with a poor quality of life or significant impairment can be extremely difficult. In such situations, a thorough discussion focused on the expectations and goals for that child is helpful.

All children with progressive chronic renal insufficiency should be evaluated by a multidisciplinary pediatric transplantation team, including a pediatric nephrologist, a transplantation surgeon, social worker, and nutritionist. In addition, many teams include pediatric urologists and clinical psychologists, with other experts included as indicated. Ideally, the child would be fully evaluated before initiating dialysis. This can facilitate evaluation of potential living donors and permit preemptive transplantation, obviating the need for dialysis. Regarding infant size, although it is often stated that approaching 10.0 kg is ideal, it is clear that transplantation can be performed successfully in smaller infants at experienced centers.[6–8] The guiding principle should be to optimize the situation as much as possible but not let an arbitrary weight target compromise the health of the child.

Our standard evaluation process is summarized in Table 46-2. Every effort should be made to optimize the

**Evaluation of Pediatric Kidney Transplantation Candidate**

- History and physical examination
- Laboratory tests:
  - Hematologic (complete blood cell count with platelets; prothrombin time/partial thromboplastin time)
  - Biochemistry (renal function, electrolytes, liver function)
  - Serologic studies (hepatitis herpesvirus B and C, cytomegalovirus, Epstein-Barr virus, varicella-zoster virus, human immunodeficiency virus)
  - ABO blood typing
  - Tissue typing (human leukocyte antigen typing; alloantibody screening)
- Urinalysis
- Chest radiograph
- Electrocardiogram
- Psychosocial assessment
- As indicated evaluations:
  - Voiding cystourethrogram/urodynamic studies
  - Vascular imaging
  - Hypercoagulable workup

medical management of the child with ESRD, including management of bone disease, optimization of nutrition, and completing childhood immunizations. Several aspects of the evaluation of the pediatric recipient are unique and deserve special attention. One is the evaluation and management of bladder function. Urologic anomalies are common, and many will have also undergone previous urologic procedures. Rarely, the bladder may be inadequate for transplantation. Expertise in such issues, or a close working collaboration with pediatric urology, is essential. Nutrition is also of paramount importance to optimize growth and development. Finally, it is important to evaluate and optimize issues related to the psychological state of the child and caregivers.[9] Adequate social support is vital for all involved. The stress of a chronically ill child undergoing a complex procedure places a great strain on all, and the need for ongoing education and reassurance is significant. In older children, it is important to ensure they are actively involved. Adolescents can be particularly challenging, because the risk of noncompliance appears to be greatest in this group.

In addition to these factors, several other issues require special attention. One is the potential need to evaluate the patient's vasculature. As renal replacement therapy has improved, it is now possible to successfully hemodialyze smaller children, including neonates. These therapies require indwelling catheters, leading to increased rates of iliac and vena cava thrombosis. The lack of adequate venous outflow can make transplantation difficult and limit the standard options.[10] Thomas and coworkers proposed a screening algorithm for patients at risk, focusing on young children with a history of femoral vein catheterization or history of any intra-abdominal process associated with inflammation.[11] In addition, patients with a history of venous thrombosis, early graft loss, or recurrent vascular access thrombosis should be under evaluation for a hypercoagulable state. Good results can be obtained in such patients with anticoagulation prophylaxis.[12]

The potential need for native nephrectomy should be addressed. Native nephrectomy is much more common in children compared with adults. Nationally, 22% of children have had all native renal tissue removed before transplantation.[1] Potential indications for native nephrectomy include recurrent severe infections because of reflux nephropathy, uncontrolled hypertension, and congenital nephrotic syndrome. In the case of nephrotic syndrome, the concern centers on these children being hypercoagulable because of the significant proteinuria. Children with polycystic kidney disease may require native nephrectomies if there is recurrent bleeding, infections, or pain. In select cases, nephrectomy may be warranted if the kidneys are so enlarged that the transplanted kidney would be compromised. Some contend that massive polyuria in small infants is an indication for nephrectomy, arguing that postoperative fluid management is made easier, thus decreasing the risk of graft hypoperfusion. Although this may have appeal, careful attention to postoperative management can often avoid this as the sole indication for nephrectomy. In addition, some believe that children with FSGS should undergo native nephrectomy, suggesting it simplifies the diagnosis of recurrent disease, because any proteinuria reflects disease in the graft rather than persistent proteinuria from the native kidneys. In such situations, an attempt at "medical nephrectomy" with nonsteroidal therapy is worth consideration.

In addition to a rational consideration of the risks and benefits of native nephrectomy, the timing of the nephrectomy is important. In children on renal replacement therapy, bilateral native nephrectomies may be safer and easier to accomplish in the weeks before transplantation. In children not on renal replacement therapy, the issue is more complex. We prefer not to perform bilateral nephrectomies at transplantation because this combines two major procedures. We also perform the transplant through a retroperitoneal approach even in small infants, which does not provide access to the contralateral native kidney. For children requiring bilateral native nephrectomy, and who are not yet on dialysis, some will have sufficient renal reserve to tolerate a unilateral left nephrectomy before transplantation and still not require dialysis. In this situation, at transplantation we extend the standard right retroperitoneal incision slightly cephalad and perform a right native nephrectomy. In cases where unilateral native nephrectomy prior to transplantation would require initiation of renal replacement therapy, we typically remove the ipsilateral native kidney during the transplantation procedure. The remaining contralateral native kidney can be removed several months after transplantation if still indicated.

In considering when to perform the transplantation, any child currently on renal replacement therapy should undergo transplantation as soon as a suitable living donor is identified or a deceased donor organ becomes available. In children not yet on dialysis, transplantation should be performed before the onset of symptoms of uremia. It is important to be aware of the impact of ESRD on growth and development. In patients with FSGS or lupus nephritis, transplantation is typically delayed until the disease is quiescent, which may preclude preemptive transplantation. In most other situations, preemptive transplantation provides significant benefit by obviating the need for dialysis. Unfortunately, only 33% of children who receive a living donor transplant and only 13% of deceased donor recipients are transplanted before initiation of dialysis.[13]

## Urologic Issues

The high incidence of urologic issues in children requires careful evaluation of bladder function before transplantation.[14] In addition to dysplasia and bladder outlet obstruction, bladder function may be abnormal because of neuropathy, acquired voiding dysfunction, or acquired bladder pathology. Any previous surgical bladder augmentation will impair normal bladder function. A history of urinary incontinence, frequent urinary tract infections, previous urologic procedures, and the need for bladder catheterization should prompt further investigation. In patients with suspected bladder dysfunction, a voiding cystourethrogram (VCUG) should be obtained with urodynamic measurements. A pressure of less than 30 cm $H_2O$ during the filling portion of the VCUG generally indicates the bladder will be suitable.

The timing of any surgical intervention warrants careful consideration. In some patients with anuria/oliguria, the bladder may not be functional, although it is often too early to tell if it will eventually become suitable. Once bladder augmentation is performed, the patient will need to continue catheterizing long term, because the bladder will not have normal function. Urologic procedures that preserve native renal function for many years are clearly prudent, but interventions before transplantation should be planned by carefully considering the risks and benefits of the procedure and being mindful of the impact on subsequent transplantation and long-term management.

## Dialysis Access

For children who do not undergo preemptive transplantation or who initially present with ESRD, establishment of adequate dialysis access is of paramount importance. Proper dialysis access is necessary for adequate dialysis, which is directly linked to the quality of life and health of the patient. According to USRDS data, at the end of 2008, 60% of patients aged 19 years and younger were on hemodialysis, whereas 40% were on peritoneal dialysis.[5] Both are suitable options, and the choice is best made on an individual basis, considering the patient's and family's preferences and skill levels, as well as the treatment options available at the local site.

Regarding hemodialysis, all attempts should be made to create a primary arterial venous fistula. For patients without adequate veins, a polytetrafluoroethylene graft is required. A native fistula is preferred because of superior patency rates, but they require several weeks to mature before being accessed. For patients in need of urgent hemodialysis, the only option is a temporary catheter. Approximately three fourths of pediatric patients have a temporary catheter at the time of initiation of dialysis.[15] The use of these catheters is associated with increased risks of infection and poor clearance with dialysis. In addition, catheters can lead to central venous stenosis and thrombosis, making future vascular access efforts more difficult. Accordingly, the jugular vein is preferred rather than the subclavian vein for catheter placement.

Peritoneal dialysis requires placement of a Tenckhoff catheter. A double-cuffed peritoneal dialysis catheter is inserted with the loop of the catheter placed in the pelvis. During the procedure, it is important to ascertain that fluid can instill and drain easily. The use of double-cuffed catheters and orienting the catheter so that it exits the skin pointing downward are associated with a lower incidence of infection.[15]

## Donor Selection

Living donor transplantation is the preferred option for all patients with ESRD. Living donor transplantation offers the best outcomes, compared with deceased donor transplantation.[4,16] In addition, living donor transplantation can be performed as soon as a suitable donor is identified, minimizing exposure to ESRD. Living donors may be either genetically related or unrelated to the potential recipient. The results from both types of living donors are equivalent, and both are superior to outcomes from deceased donors. Potential living donors should undergo a full evaluation by a transplant center experienced in this process. The donor must be willing, be in good health, and have two normal kidneys. In addition, the donor and recipient must be ABO compatible. Although there is a growing interest in strategies to cross this barrier, efforts are relatively limited in the pediatric population.[17]

The recipient should also have a negative lymphocytotoxic crossmatch with the potential donor. Crossmatching is done to determine that the recipient does not have preformed antibodies directed against the donor's human leukocyte antigens (HLA), which would likely cause hyperacute rejection and rapid graft loss. The most common causes of anti-HLA antibodies are blood transfusions, previous transplantation, and pregnancy. Strategies to manipulate antidonor antibodies are being investigated and include intravenous immunoglobulin, plasmapheresis, and other agents designed to alter B-cell responses and/or complement.[18–21] Transplanting recipients who are either ABO or anti-HLA antibody incompatible with their donors requires additional immunologic manipulation, with its attendant risks, and the long-term results appear inferior compared with compatible transplantations. Accordingly, there is growing interest in paired kidney exchange programs, which offer a larger living donor pool and the possibility of finding a more compatible donor.[22]

## EVALUATION OF THE POTENTIAL LIVING DONOR

Evaluation of potential living donors should occur independent of the recipient's evaluation, giving donor safety the highest priority. Our standard evaluation process is summarized in Table 46-3. Although HLA matching has traditionally played an important role in choosing which living donor to evaluate, current immunosuppression has minimized the impact of matching, and we believe the best potential living donor is the individual who is most motivated. Lacking that distinction, and all other factors being equal, we would choose the donor with the best HLA match. It is also important to consider other issues unique to each donor, including psychosocial concerns (such as the need to care for other children), the need to care for the recipient, and what options would be least disruptive to the family unit. When discussing the situation with the family, it is important to consider other siblings who may also need renal transplantation in the future, because this can play a role in deciding which donor donates to which recipient.

Living-kidney donation appears to be safe and has been practiced for more than 50 years. The risk of operative mortality appears to be 3 in 10,000.[23,24] After the procedure, living kidney donors appear to do well over the long term as well. The introduction of laparoscopic donor nephrectomy has been a significant step forward for the individuals who consider kidney donation. For the donor, the laparoscopic procedure is associated with quicker recovery and appears as safe as open-donor nephrectomy. Although there was some concern that laparoscopic donation might result in inferior outcomes compared with open-donor nephrectomy, particularly in small infants, this concern has not been substantiated.[25–27]

## EVALUATION OF THE DECEASED DONOR

For children who do not have a living donor, deceased donor transplantation is the only option. Deceased donors are individuals who have either suffered brain death or whose heart has irreversibly stopped beating. The latter group has often been referred to as "DCD" for donation after cardiac death. In the United States, deceased donor organ allocation is governed by policies established by the OPTN. These policies undergo constant refinement as data support more rational and fair allocation strategies. After a potential deceased donor is identified, the blood type, HLA type, and other relevant donor factors are entered into the national database maintained by the United Network for Organ Sharing (UNOS). Kidney allocation is driven by a point system based on HLA matching, the level of anti-HLA antibodies in the candidate, and waiting time. Waiting times in many areas of the country for adults are 5 or more years.

The OPTN has recognized the special needs of children with end-stage organ disease and continuously reviews policy in an effort to provide them optimal access to deceased donors. In 2005, the kidney allocation system was changed from a system that provided pediatric priority points based on age and waiting time to a system that provides relative priority to donors less than 35 years of age. At present, candidates who are listed at less than 18 years of age are offered kidneys from donors less than age 35 after any zero mismatch candidates, candidates with a panel reactive antibody greater than 80%, or candidates receiving a kidney with a nonrenal organ. The rationale for this modification was based on the observation that pediatric waiting times remained substantial despite the efforts to provide priority. In addition, in an effort to optimize outcomes, centers were waiting for the best donors. The donor age threshold was based on an analysis demonstrating donor age between 5 and 35 years had the lowest relative risk of graft failure.[28,29]

The new policy has decreased pediatric waiting time while maintaining access to the best deceased donors. As was expected, the shorter waiting time has been associated with lower HLA matching, reflecting the greater priority for transplantation compared with HLA matching. The decrease in HLA matching is small, and there appears to be no adverse impact on outcomes.[28] Waiting for a better-matched kidney is not prudent, because there is no advantage, and it only delays the benefit of transplantation. In addition, because of the relatively good access to the best deceased donors, the need to use expanded criteria kidneys,[30] DCD kidneys,[31] and en-bloc kidneys from small pediatric donors[32] is less than in the adult population. An important exception might be the highly sensitized recipient who has waited for a long period of time. In such situations, the decision needs to consider the risks and benefits of the options available.

The improved access to deceased donors has been associated with a decrease in the number of living donor transplantations performed in children. Prior to 2005, living donors accounted for more than half of the pediatric transplantations. This proportion has fallen to less than 40% in recent years and is a source of concern. Although greater access to the best deceased donors is appealing, it is important to note that outcomes are significantly better with living donors compared with deceased donors. Specifically, living donors up to 55 years of age provide greater long-term survival compared with even the ideal deceased donor.[16]

# Transplantation

## PREOPERATIVE PREPARATION

Deceased donor recipients are admitted once a kidney is accepted. We typically also admit our living donor recipients, although they can be admitted on the day of surgery if their dialysis regimen is stable or if they are not on dialysis. On admission, the need for dialysis is assessed. It is important to ask about intervening health issues since the last visit, as well as examining for any evidence of ongoing infection.

## ANESTHESIA

Close coordination with the anesthesia team is vital to the conduct of any operation, and it is particularly important in kidney transplantation in small infants. Maintaining adequate volume status is critical. Because a kidney from an adult donor is typically used, blood flow to the graft often equals the entire cardiac output of the recipient. Hypotension can be particularly problematic. Many children have an obligate polyuria that can cause hypovolemia if not carefully monitored. After reperfusion, the new kidney can also sequester several hundred milliliters of blood, further aggravating hypovolemia.

## OPERATIVE PROCEDURE

After induction of general anesthesia, adequate intravenous access is established. In children larger than 20 kg, we do not place a central venous line if adequate peripheral access can be established. For smaller children, we find central venous access useful, both for fluid administration as well as for monitoring central venous pressure. In these smaller children, we also place an arterial line to permit constant blood pressure monitoring. The child is positioned supine. A Foley catheter is inserted and connected to a three-way irrigation system, using dilute providone-iodine (Betadine) in saline. In other centers, an antibiotic solution may be preferred. This arrangement allows the bladder to be filled and drained outside of the operative field as necessary. The child's temperature should be monitored closely, especially with small children who may become hypothermic with either fluid resuscitation or the perfusion of the cold kidney. In addition to routine monitoring, ongoing attention must be directed to volume status. It is vital that the arterial blood pressure and central venous pressure are adequate when the kidney is reperfused. For infants and small children, the central venous pressure is usually maintained in the range of 12 to 18 cm $H_2O$ by administration of crystalloid and/or colloid as necessary. Near completion of the vascular anastomoses, we typically give 0.5 mg/kg of mannitol intravenously. We do not routinely employ a loop diuretic.

## OPERATIVE TECHNIQUES

### Small Children (<20.0 kg)

Historically, many have performed kidney transplantations intra-abdominally in infants and small children using a midline incision. Since 1998, we have used a retroperitoneal approach similar to that used in adults, even in infants. Placing the kidney on the right side is preferable, because this gives the easiest access to the vena cava. A curvilinear skin incision is made in the lower quadrant. The abdominal wall musculature is divided, and the preperitoneal space is entered. Attempts are made to stay extraperitoneal. The spermatic cord is mobilized and preserved in males, whereas the round ligament is routinely divided in females. The dissection is carried medially until the common iliac vessels, the distal aorta, and vena cava are visualized. If a right native nephrectomy is necessary, this is performed at this point.

The site of the vascular anastomosis depends on kidney size as well as the size of the child. In general, in small children, the renal vein is anastomosed to the vena cava, and the renal artery is anastomosed to either the distal aorta or the common iliac artery. The lymphatics overlying these vessels are divided between ties in an effort to minimize the risk of a lymphocele. When an aortic anastomosis is planned, the aorta is mobilized from below the inferior mesenteric artery to the bifurcation. Lumbar branches are controlled with Pott ties rather than ligated. The common iliac arteries are controlled just distal to the aortic bifurcation. The vena cava is mobilized to allow placement of a side-biting vascular clamp, which can require ligation of several lumbar veins. Once the recipient's vessels have been exposed, the donor kidney is brought into the operative field. The kidney should be inspected for any evidence of unsuspected pathology. The renal vessels are examined. After preparing the kidney, thoughtful consideration needs to be given for the fit of the kidney in the recipient's body cavity. Particular attention must be focused on the length of the renal vessels as well as their orientation. It is important to consider the final resting position of the kidney after it is perfused, the retractor is removed, and the fascia closed.

The venous anastomosis is performed first. The vena cava or iliac vein is controlled with a side-biting clamp. A longitudinal venotomy is made along the anterolateral or lateral aspect of the vein. The renal vein is cut to length, again after considering the ultimate lie of the kidney, and mindful that a redundant renal vein may predispose to thrombosis. We place two corner sutures of 5-0 Prolene. The anastomosis is performed in a running manner. An end-to-side arterial anastomosis is then performed to the recipient's distal aorta or common iliac artery. The recipient vessels are controlled using vessel loops or gentle spring clips. A longitudinal arteriotomy is made, mindful of the final orientation of the renal artery. We enlarge the arteriotomy using a 4.0-mm aortic punch. The renal artery is then sewn end-to-side using a running 6-0 Prolene suture. We typically perform the procedure with loupe magnification.

If multiple renal arteries are present, they can either be implanted separately or syndactylized before reimplantation. When the vessels are syndactylized, it is important to consider if this will allow the vessels to lie in good position, because syndactylization will fix the vessels relatively firmly in two dimensions. This can limit the options of where the anastomosis can be suitably performed or lead to kinking of one or both of the donor arteries if the final position of the kidney is not anticipated.

Before completion of the arterial anastomosis, the hemodynamic state of the patient should be considered. Intraoperative assessment of the vascular volume by direct assessment of the vena cava is possible. Mannitol is also given at this time. Because of the size of the adult kidney, it can be both slow to perfuse as well as sequester a significant volume of blood. The anesthesiologist must be ready to give volume replacement promptly as indicated. At this point, the clamp is removed from the vein and bleeding assessed. Next, while the renal artery is gently compressed with vascular pickups, the arterial clamps are removed, restoring distal blood flow. After a few seconds, flow is established to the kidney. In small children, we occasionally will briefly reclamp the recipient's vessels distal to the arterial anastomosis to provide preferential flow to the kidney. The field is carefully examined for bleeding. The color and turgor of the graft are assessed. The renal artery should have a good pulse, and a thrill can usually be appreciated as well. Both the lower and upper poles should be assessed for perfusion. The renal vein should be full but not tense, with a turgor similar to the vena cava. The lie of the kidney is again examined.

Attention is then directed to the ureteroneocystostomy. We generally perform the ureteral anastomosis as an extravesical ureteroneocystostomy,[33–35] although others routinely prefer the transvesical Politano-Leadbetter approach.[7,36] The Foley catheter is clamped and the bladder is filled. A site on the dome of the bladder is selected where the ureter will sit without any angulation. The muscle wall of the bladder is divided, exposing the bladder mucosa. An opening is then made in the mucosa. The donor ureter is trimmed to length. Care should be taken to make sure it is sufficient to allow a tension-free anastomosis, but excessive length should be avoided because of the risk of ureteral obstruction or stricture resulting from inadequate perfusion of the distal ureter. The end of the ureter is spatulated, and a mucosa to mucosa anastomosis is performed using running 5-0 polydioxanone (PDS) suture. The caveat with running suture is that care must be taken to avoid cinching on the suture line, because this results in a purse-string effect causing stenosis. To prevent vesicoureteral reflux, the bladder muscle wall is approximated over the anastomosis using interrupted 4-0 PDS suture. This allows the ureter to take a tangential course under the bladder wall so that during micturition, the transvesical portion of the ureter is compressed by the overlying bladder wall. An adequate length for this tunnel is essential to prevent vesicoureteral reflux. In patients with a normal bladder and a good blood supply to the distal ureter, we do not routinely place a stent. If there is any concern regarding the ureteral anastomosis, either because of the donor ureter or the quality of the recipient's bladder, we place a double-J ureteral stent, which is removed after a few weeks as an outpatient procedure.

After completing the ureteral anastomosis, the kidney is again inspected with attention to the renal vessels and the lie of the kidney once the retractor is removed. Careful planning and attention to detail before performing the anastomosis is usually rewarded at this point. The fascia is closed in one layer with a running suture. The skin is closed using a running absorbable suture. The urinary catheter is flushed with saline to remove any clots that might obstruct the catheter. For small infants, the volume resuscitation required to ensure excellent renal perfusion, combined with the size of the kidney decreasing respiratory excursion, may make ventilatory support in the immediate postoperative period necessary. If the patient's oxygen saturation and pulmonary mechanics are satisfactory, the patient can be extubated in the operating room.

### Larger Children (≥20.0 kg)

The technique for transplantation in larger children is similar to that in adults. We prefer to put the kidney on the right side when possible. An incision is made in the right lower quadrant, extending from one to two fingerbreadths above the pubis to just lateral of the rectus sheath. As in smaller children, the placement of the arterial and venous anastomoses depends on the size of the child and the renal vessels. The venous anastomosis can be done to the vena cava, the common iliac, or the external iliac vein. The arterial anastomosis is performed to the distal aorta, the common iliac, or the external iliac artery. After revascularizing the kidney, the ureteroneocystostomy is performed using an extravesicular technique. At the completion of the operation, these larger children are extubated.

### Ureteral Reconstruction in Patients with Previous Urologic Procedures

The ideal urinary reservoir stores a reasonable volume at a low pressure, does not leak, and empties nearly completely with voiding.[14] In the majority of cases, the ideal reservoir is the patient's bladder. If the bladder functioned normally before development of oliguria, it is likely to function adequately after transplantation. Nonetheless, up to 30% of pediatric recipients will not have normal bladder function, and frequently a surgical augmentation or other urologic procedure has been performed before referral for transplantation.

Drainage into an augmented bladder or urinary conduit is an appropriate management strategy when the native bladder is unsuitable or absent.[37,38] When indicated, we prefer to have the intended urinary reservoir created and suitable for use before the transplant procedure. Intraoperatively, when planning the ureteroneocystostomy to an augmented bladder, it is important to consider the blood supply to the augmented section so as not to compromise it during the transplant. It is preferable to perform the ureteroneocystostomy to the native bladder, and this can be accomplished in most situations. An antireflux ureteroneocystostomy is essential, and it is most readily performed with the bladder wall.

Patients with an augmented bladder or urinary conduit are at increased risk for urine infection, but compared with historical controls, graft survival is not adversely affected.[39] The rate of surgical complications related to the ureteral anastomosis is higher in these patients, approximately 20%.[39–41] Regardless of the etiology of the bladder dysfunction, these patients require regular clean intermittent straight catheterization after transplantation.

Children with obstructive uropathy from posterior urethral valves will not have normal bladder function, and this can contribute to renal dysfunction after transplantation.[37]

Awareness of these issues is vital, and evaluation with follow-up urodynamic studies is frequently indicated in children with voiding disorders. Bladder dysfunction, such as hypocompliance and/or hyper-reflexia, requires medical or surgical treatment.

## Postoperative Care

Attention to detail in the postoperative period is essential. Special care must be directed to the fluid and electrolyte status. Many children are polyuric before transplant, and this obligate urine loss will continue in the immediate postoperative period. Intravenous fluids are administered, taking into account urine output as well as insensible losses. The composition of these solutions is adjusted as needed, depending on regular measurement of serum electrolytes. Serum sodium, potassium, and calcium levels are followed closely and replaced as necessary. Heart rate, blood pressure, and central venous pressure are carefully monitored. No single factor alone is entirely reliable in assessing intravascular volume.

For patients who were oliguric or who had native nephrectomies before transplantation, monitoring urine output is an excellent monitor of graft function. For patients who made significant urine before transplantation, evaluation of graft function is more difficult. The volume of urine production may be suggestive. In addition, the serum creatinine concentration should fall with time. Recipients with oliguria should be rapidly evaluated. The urinary catheter should be flushed with small volumes of sterile saline. The volume status of the patient should be carefully assessed. A fluid bolus is usually warranted, both as a diagnostic test and as therapeutic intervention. Doppler ultrasonography will confirm adequate arterial flow and venous outflow. Ultrasonography will also show evidence of fluid or blood around the kidney, as well as assess for possible ureteral obstruction. In patients who appear to be adequately volume loaded and hemodynamically stable, a dose of diuretic can be given. It is important to do this carefully, because sudden massive urine output can cause significant intravascular volume depletion, which can then lead to problems with renal perfusion. In patients who are massively volume overloaded or have significant electrolyte abnormalities, dialysis may be indicated.

If ventilated postoperatively, the smaller children are weaned from the ventilator generally within the first 24 hours. Enteral feedings can be started at a slow rate almost immediately after the extraperitoneal approach. Infants who were on tube feedings before transplantation should resume these tube feedings, because they usually will not feed orally in the immediate post-transplantation period. Hypertension can be problematic. The volume loading associated with the procedure as well as the use of calcineurin inhibitors (CNIs) for immunosuppression can result in significant hypertension, which can be severe and require aggressive therapy to prevent seizures and other sequelae.

To monitor and replace urine output on an hourly basis, we admit our children to the intensive care unit (ICU). If this can be accomplished on a surgical floor unit, larger children could be admitted to an area specializing in the care of renal transplant patients. Children who are admitted into the ICU are typically transferred to the floor unit within 1 to 2 days. Most children leave the hospital 5 to 7 days after transplantation, assuming the family is comfortable with the immunosuppression regimen.

## Evaluation of Early Allograft Dysfunction

Ideally, the donor kidney should begin to make urine shortly after revascularization. The likelihood of this occurring depends on multiple factors, beginning with the quality of the donor organ. Living donor kidneys will generally function immediately because of the healthy state of the donor as well as the shorter cold ischemic time for the kidney. For deceased donor kidneys, the cold ischemic time is generally longer. In addition and more important, there are multiple factors associated with the donor death, including hypotension, the potential need for high doses of vasopressors, and other issues related to the overall health of the donor.

Regardless of the donor source, the assessment of the graft begins in the operating room, evaluating the graft for color and turgor as well as vascular anastomoses. Particular attention should be directed to considering how the kidney is positioned once the abdomen is closed and how this could impact the vasculature. The renal artery will often have a thrill suggestive of excellent flow and low intrarenal resistance. Assuming the technical aspects of the procedure appear satisfactory, additional volume for the kidney not making urine is the best option. Once the patient is adequately volume loaded, loop diuretics may be used to gently encourage a diuresis. In patients who were anuric before the procedure, continued failure to make urine in the postoperative period should prompt a bedside Doppler ultrasound examination. For patients who made urine before the transplantation, determining whether the transplanted kidney is making urine is more difficult, although sometimes the amount of volume being produced will give a sign that the kidney is working. During the first 24 hours, the serum creatinine level should fall as well. If there is still concern about function, a Doppler ultrasound study should be obtained, and any suggestion of problems with the arteriovenous signal should initiate a prompt return to the operating room. In general, the ultrasound evaluation will be fine, or, occasionally, there will be a modest reduction in flow suggestive of increased intrarenal resistance, most commonly because of acute tubular necrosis. This condition resolves without any specific intervention. Other diagnostic studies are less frequently required. Renal arteriography is rarely indicated. Radionucleotide scans are used by some centers, but we find them less helpful than ultrasonography. A radionucleotide scan may be helpful in documenting a suspected urinary leak.

Complications related to the ureteral anastomosis include leaks and obstruction. The risk of ureteral complications is approximately 7% to 9%.[7,42,43] A leak at the ureteral anastomosis generally manifests in the first few days after the transplant. Leaks detected in the first 2 to 3 days may be repaired operatively. Leaks detected later can generally be managed nonoperatively with a percutaneous nephrostomy. This stent is subsequently advanced across the anastomosis into the bladder. The stent is usually left to external drainage for

several days and is then capped. If a large urinoma is present, separate drainage of this collection may be required.

Obstruction of the urinary system can occur at any time. An early obstruction is usually related to technical problems with the anastomosis or other mechanical issues, such as torsion of the ureter, while later obstruction often reflects ischemic stricture. Because the ureter relies on small arterial vessels from the lower pole of the kidney, it should be no longer than necessary. Late ureteral stenoses generally require operative intervention, with resection of the stenotic segment and reconstruction. Vesicoureteral reflux may cause recurrent urinary tract infections or graft dysfunction, and require operative intervention in up to 5% of patients.[44]

Another complication after retroperitoneal kidney transplantation is lymphocele. Lymphoceles may produce discomfort or allograft dysfunction. The diagnosis is established by ultrasound-guided percutaneous aspiration of clear fluid with a creatinine concentration equivalent to serum. Percutaneous drainage is associated with a very high incidence of recurrence, and the preferred treatment is creation of a peritoneal window. This can be accomplished laparoscopically or through a small open incision, with drainage of the lymphocele into the peritoneal cavity.

In instances of renal vein thrombosis, the graft is usually not salvageable. The causes of renal vein thrombosis are several, and the exact mechanism may be difficult to ascertain but include immunologic factors, a hypercoagulable state, and technical issues.

# Immunosuppression

Significant advances have been made in understanding the immune response and several new immunosuppressive agents have been developed. The introduction of new agents has permitted consideration of avoidance, conversion, and minimization strategies in an effort to minimize toxicities associated with specific agents. There are several potential regimens, but all require a balance between prevention of rejection and unwanted side effects of immunosuppression. Most centers use standardized protocols for recipients based on immunologic risk. Immunosuppressive agents are used for induction, maintenance, and treatment of rejection episodes.

## ANTIBODY PREPARATIONS

### Antilymphocyte Antibodies

Antilymphocyte antibodies include polyclonal preparations, such as equine antithymocyte globulin (ATGAM) and rabbit antithymocyte globulin (Thymoglobulin), and the monoclonal antibody preparations muromonab-CD3 (OKT3) and anti-CD52 (Alemtuzumab). Of these antilymphocyte agents, Thymoglobulin is currently predominant, and the use of the others is either rare or of historic interest. Antilymphocyte antibodies act by lymphodepletion, as well as by interactions with cellular receptors. The use of antilymphocyte induction regimens has declined precipitously with time.[1,2] We currently restrict the use of Thymoglobulin to recipients at higher risk for immunologic graft loss, such as patients requiring retransplantation, highly sensitized patients, or black recipients. These agents are also effective in the treatment of acute cellular rejection.

### Anti–interleukin-2 Receptor Monoclonal Antibodies

Two monoclonal antibodies have been developed that bind to the alpha subunit of interleukin (IL)-2 receptor (CD25) and inhibit IL-2–mediated lymphocyte proliferation. Basiliximab (Simulect) and daclizumab (Zenapax), received approval by the U.S. Food and Drug Administration (FDA) in 1998, though only basiliximab is currently marketed. Basiliximab is a chimeric human/mouse monoclonal antibody that is effective in reducing the incidence of acute cellular rejection, with good long-term results and no evidence of increased risk of infection or malignancy.[45–47] The IL-2 receptor antibody is used in induction regimens but is not effective in treating rejection.

## CALCINEURIN INHIBITORS

The introduction of cyclosporine after its FDA approval in 1983 was one of the most significant advances in transplantation. Tacrolimus received FDA approval in 1994. Both agents act through inhibition of calcineurin activity. They first bind to specific cytoplasmic proteins; cyclosporine binds to cyclophilin, and tacrolimus binds to tacrolimus binding protein (also known as FK-binding protein). Both drug-protein complexes then bind to calcineurin, a phosphatase that controls the transport of transcriptional regulator factors across the nuclear membrane. By inhibiting the translocation of these factors into the nucleus, both drugs inhibit transcription of several early T-cell activation genes, most significantly IL-2.

Both cyclosporine and tacrolimus are effective at preventing rejection. A randomized prospective open-label trial performed in Europe in pediatric renal recipients compared tacrolimus with cyclosporine, along with azathioprine and steroids. There was a significantly lower incidence of acute rejection in the tacrolimus group (36.9%) compared with cyclosporine therapy (59.1%).[48] In contrast with this observation, a retrospective analysis of NAPRTCS data comparing cyclosporine with tacrolimus, along with mycophenolate mofetil and corticosteroids, showed equal rates of rejection and graft survival. Although rejection rates were similar, tacrolimus therapy was associated with improved graft function at 1 and 2 years after transplant.[49] Currently, approximately 70% of pediatric recipients are reported as being discharged on tacrolimus compared with 10% on cyclosporine.[1,2]

Cyclosporine side effects include hirsutism and gingival hyperplasia, whereas tacrolimus is associated with increased incidence of post-transplantation diabetes and neurotoxicity. In children who develop a problematic side effect from one agent, conversion to the other agent is appropriate. Both calcineurin inhibitors have significant nephrotoxicity that impact graft function with time.

## MYCOPHENOLATE

Mycophenolate mofetil (MMF) (CellCept) and mycophenolic acid (MPA) (Myfortic) inhibit purine synthesis. MMF is converted in vivo to mycophenolic acid, a noncompetitive inhibitor of inosine monophosphate dehydrogenase (IMPDH), which is a key enzyme in de novo purine biosynthesis. Although most cells can synthesize purines by either the de novo or the salvage pathway, B and T lymphocytes lack the

salvage pathway. Mycophenolate is thus a selective inhibitor of lymphocyte proliferation, and it has replaced azathioprine (Imuran) as the primary antiproliferative agent.[50] MMF has been demonstrated to be safe and effective in pediatric patients.[51] Experience with MPA in children is more limited, though it appears equivalent.[52,53] The primary side effects are related to leukopenia and gastrointestinal intolerance.

### PREDNISONE

Glucocorticoids have played an integral role in immunosuppression regimens since the earliest days of transplantation. They act primarily through transcriptional regulation, diffusing across the plasma membrane and binding to cytoplasmic steroid receptors. This complex is translocated to the nucleus, where it binds to specific gene promoters and other regulatory regions, inhibiting cytokine synthesis. Corticosteroids are also lymphocytotoxic and possess significant anti-inflammatory activity, inhibiting macrophage function and other nonspecific aspects of the inflammatory response.

Long-term corticosteroid therapy is associated with increased risk of hypertension, hyperlipidemia, diabetes, bone loss, cosmetic disfigurement, and cataracts. Attempts at minimizing corticosteroids have not had a significant effect on these side effects, and efforts are being directed to corticosteroid avoidance. Although it is appealing to consider withdrawal of corticosteroids with time, late corticosteroid withdrawal appears associated with increased risk of acute and chronic rejection. Early corticosteroid withdrawal and corticosteroid-free regimens, with and without antibody induction, have shown promise. Sarwal and associates, at Stanford University, have reported excellent results in a corticosteroid-free protocol using an extended induction with daclizumab, tacrolimus, and MMF.[54] In their recent report, 129 recipients have been treated with a mean follow-up of 5 years. One-year graft and patient survival were 93% and 96%, respectively. The rate of acute rejection was 12% during the first year. Significant improvements in post-transplantation growth and avoidance of steroid side effects were noted. This experience led to a prospective, multicenter randomized study that has been completed, though the results have not yet been published. Similar results have also been reported by the Stanford group in 13 recipients using Thymoglobulin induction in place of daclizumab.[55]

Another large randomized multicenter international trial with 196 pediatric kidney recipients compared rapid steroid withdrawal in children treated with daclizumab, tacrolimus, and MMF with recipients maintained on steroids along with tacrolimus and mycophenolate.[56] Early steroid withdrawal was associated with improved growth and metabolic profiles, with similar acute rejection rates (10.2% vs. 7.1%, respectively) and equivalent graft and patient survival during the first 6 months.

Although encouraging, efforts to withdraw steroids while maintaining acceptable rejection rates have also resulted in regimens with a greater rate of complications of immunosuppression. One multicenter randomized trial of steroid withdrawal after 6 months in recipients treated with basiliximab induction, cyclosporine or tacrolimus, sirolimus, and steroids was halted early because of a high rate of post-transplantation lymphoproliferative disorder (PTLD).[57]

It appears steroid avoidance or early withdrawal is possible in selected patients with good short-term results. Longer-term data are needed, and striking the correct balance of immunosuppression and other side effects remains critical.

### PROLIFERATION SIGNAL INHIBITORS

Proliferation signal inhibitors are a relatively new class of immunosuppressants. Sirolimus (rapamycin) and everolimus are macrolide agents that inhibit a protein, mammalian target of rapamycin (mTOR), which is a critical regulatory kinase controlling cytokine-mediated proliferation. A potential role for sirolimus in renal transplantation has been established.[58] Everolimus also appears effective.[59] There is interest in using mTOR inhibitors to avoid or minimize calcineurin inhibitors and/or corticosteroids, though the optimal strategy remains elusive. Experience to date suggests that complete CNI avoidance is often associated with higher rejection rates, while late CNI replacement or minimization may not offer any benefit with respect to reversing CNI nephrotoxicity.

Sirolimus interacts with calcineurin inhibitors, particularly cyclosporine, and careful monitoring is essential. Like many other immunosuppressive agents, there is evidence to suggest more rapid metabolism of sirolimus in children compared with adults.[60]

### TREATMENT OF REJECTION

Suspected rejection should be confirmed by biopsy. The first-line therapy for acute cellular rejection is pulse corticosteroids. Typically, intravenous methylprednisolone is administered for 3 days, with doses ranging from 5.0 to 25.0 mg/kg/day (maximum dose, 1.0 g). We use 10.0 mg/kg for children younger than aged 6 years and 5.0 mg/kg for children aged 6 years and older, with a maximum dose of 500 mg/day. Severe rejection or rejection refractory to corticosteroids is treated with Thymoglobulin. Treatment of acute rejection is nearly always successful, although late episodes of rejection are less likely to respond. After successful treatment, many consider altering maintenance immunosuppression, including changing to the other calcineurin inhibitor, or substituting sirolimus for MMF; however, there is little evidence to support this approach. An assessment of adherence to the immunosuppression regimen should also be initiated. If the patient's creatinine level does not return to baseline, a follow-up biopsy should be strongly considered. Although most acute rejection episodes reflect primarily T-cell–mediated processes, there is growing recognition of the role of B cells and alloantibodies in immunologically mediated graft injury.

## Outcomes

### GRAFT AND PATIENT SURVIVAL

There are approximately 800 pediatric kidney transplantations performed annually in the United States. In 2009, there were 866 transplantations, with 38.8% living donor and 61.2% deceased donor kidneys. Short-term graft and patient survival after transplantation is excellent. Current graft survival for living donor and deceased donor kidney transplantations in children, stratified by recipient age, is summarized in

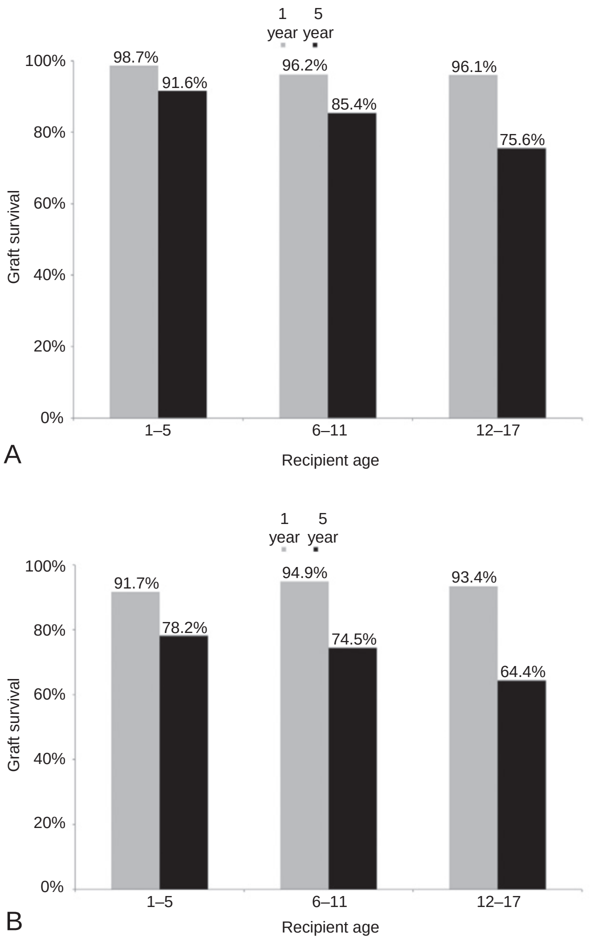

**FIGURE 46-1** **A,** One- and 5-year graft survival of living donor kidney transplantations by recipient age. **B,** One- and 5-year graft survival of deceased donor kidney transplantations by recipient age. (From Organ Procurement Transplant Network/Scientific Registry of Transplant Recipients: 2009 Organ Procurement Transplant Network/Scientific Registry of Transplant Recipients Annual Report: Transplant data 1999-2008. Health and Human Services/Health Resources and Service Administration/Special Pathogens Branch/Department of Transportation. Available at www.ustransplant.org. Accessed September 29, 2010.)

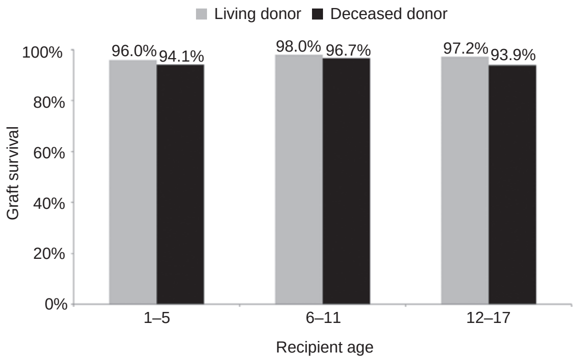

**FIGURE 46-2** Five-year patient survival of living donor and deceased donor kidney transplantations by recipient age. (From Organ Procurement Transplant Network/Scientific Registry of Transplant Recipients: 2009 Organ Procurement Transplant Network/Scientific Registry of Transplant Recipients Annual Report: Transplant data 1999-2008. Health and Human Services/Health Resources and Service Administration/Special Pathogens Branch/Department of Transportation. Available at www.ustransplant.org. Accessed September 29, 2010.)

Figure 46-1. Recipient survival stratified by age range is summarized in Figure 46-2. The leading causes of death are infection (28.9%), cardiopulmonary (15.7%), and malignancy (11.0%).[2] Although patient survival is good, it is important to realize that even with transplantation, these children face a significantly increased risk of mortality compared with the general population.[61]

With time there has been improvement in outcomes for all pediatric age ranges. This improvement is particularly noteworthy in children younger than 2 years of age who previously had the worst graft survival but now have outcomes that equal the outcomes of any age group.[13,50] In fact, the longest transplant half-lives of all recipients are now the youngest recipients, especially if the pediatric recipient receives an adult kidney that functions immediately.[62] These improvements likely reflect better donor selection, improvement in surgical techniques, better immunosuppression agents, and a better understanding of immunosuppression management in children.

Although short-term graft survival in children is excellent, it is important to appreciate that long-term graft survival in the adolescent group (ages 11 to 17 years) is poor (see Fig. 46-2). Adolescent graft survival is less than in all recipient age groups except adults older than 65 years.[4] The reasons behind this significant rate of graft loss are speculative, but noncompliance likely plays a significant role.[63] The higher incidence of recurrent FSGS in this age group may also contribute to graft loss. Regardless of the cause, improving the long-term outcomes in this patient population represents an important focus.

## POST-TRANSPLANTATION OUTCOMES AND RISK FACTORS ASSOCIATED WITH GRAFT LOSS

Smith and coworkers reported that the most common causes of allograft failure reported to NAPRTCS for transplantations performed between 2000 and 2005 are chronic rejection (41.3%), vascular thrombosis (8.1%), recurrence of the primary disease (7.9%), acute rejection (6.3%), and discontinuation of immunosuppression (6.3%).[2] Analysis of large single-center experiences and registry data has revealed risk factors associated with specific post-transplantation outcomes.[2,13,64] For a given child, some of these risk factors, such as their race, age, or primary disease, are not modifiable. Other factors are potentially modifiable, and efforts should be made to mitigate risk.

The type and timing of the transplant affect outcomes. Living donor transplantation is associated with better graft survival compared with deceased donor transplantation.[2,4] Preemptive transplantation is associated with better graft survival compared with patients on dialysis at the time of transplantation. For children on dialysis, the choice of dialysis therapy does not impact graft survival, although graft loss from vascular thrombosis is more common in children on peritoneal dialysis compared with hemodialysis.[65]

## DELAYED GRAFT FUNCTION

Delayed graft function (DGF) is defined as the need for dialysis during the first week after transplantation and is a manifestation of acute tubular necrosis (ATN). DGF is more common in recipients of deceased donor kidneys compared with living donors, because of the impact of cold ischemic time and donor

quality. Nationally, the incidence of DGF after deceased donor renal transplantation is 12.5% in pediatric recipients compared with 23.4% in adult recipients,[50] reflecting the differential donor selection made possible by the allocation system. An analysis of more than 5000 pediatric transplantations has demonstrated that DGF is an independent risk factor for subsequent graft loss.[66] DGF is also associated with increased risk for acute and chronic rejection, likely reflecting the impact of renal injury on the subsequent immune response. DGF limits the ability to use renal dysfunction as a sign of acute rejection, potentially delaying the diagnosis of rejection. We believe that all recipients with DGF longer than 5 to 7 days should be biopsied, and even earlier in patients with increased risk of rejection.

## VASCULAR THROMBOSIS

Vascular thrombosis is currently the second most common reported cause of graft loss.[2] Risk factors include donor age younger than 6 years, cold ischemic time greater than 24 hours, prior transplantation, and peritoneal dialysis before transplantation.[65] Careful consideration of donor quality, along with efforts to ensure adequate perfusion to the graft, may minimize the risk of thrombosis. Patients with ESRD have a higher incidence of hypercoagulable conditions, and any history of thrombosis, including recurrent or unexplained thrombosis of hemodialysis access, should prompt further evaluation.

## ACUTE REJECTION

Acute rejection typically occurs between 1 week and 3 months after transplantation, although it can happen at any time. A rise in the serum creatinine level is frequently the first sign of rejection. Findings such as low-grade fever, graft tenderness, hypertension, or decreased urine output are infrequent. Any renal dysfunction should be promptly investigated. A percutaneous biopsy should be obtained to confirm the diagnosis, because many other processes can lead to allograft dysfunction, including calcineurin inhibitor toxicity, ureteral obstruction, infection, renal artery stenosis, and recurrence of original disease. Acute rejection episodes are treated by either pulse corticosteroids or antilymphocyte antibodies as detailed previously.

Risk factors associated with acute rejection include African-American race, delayed graft function, and a history of allosensitization. Acute rejection, and, in particular, late acute rejection episodes occurring more than 1 year after transplant, are independent risk factors for graft loss because of chronic rejection.[67] One episode of acute rejection increases the risk of graft loss from chronic rejection graft failure threefold, and two episodes of acute rejection increase the risk 12-fold. The incidence of acute rejection is decreasing with time. In the 2003 to 2005 NAPRTCS cohort, 12.2% of living donor recipients and 15.8% of deceased donor recipients had a rejection episode in the first year after transplant.[2]

Acute rejection, even if successfully treated, impacts graft survival and all efforts to minimize this risk are important. Unfortunately, intensifying the immunosuppression regimen is limited by the consequences of nonspecific systemic immunosuppression. Ensuring the patient remains on therapeutic immunosuppression is vital, because noncompliance can be disastrous. Prompt recognition and treatment of rejection is important. Because serum creatinine is a relatively insensitive indicator, particularly in small children with an adult kidney, many advocate protocol biopsies to detect subclinical rejection that may benefit from treatment.

## CHRONIC ALLOGRAFT NEPHROPATHY

Whereas short-term results are excellent, progressive renal dysfunction frequently occurs and is the leading cause of graft failure. This process of chronic allograft nephropathy, often called “chronic rejection,” involves both immunologic and nonimmunologic factors. Although acute rejection episodes are a major risk factor for chronic allograft nephropathy, it is clear other processes can contribute as well. Evidence of antibody-mediated injury is also present in 57% of patients with late allograft dysfunction.[68] Efforts to reduce chronic allograft nephropathy are limited by our understanding of the process. Aside from graft loss, the gradual renal dysfunction associated with chronic allograft nephropathy also adversely impacts the recipient’s general health.

## NONADHERENCE

Adherence with the medical regimen is essential for the success of transplantation. Nonadherence is believed to be largely responsible for the poorer long-term graft survival seen in adolescent recipients. Shaw and coworkers reviewed 112 pediatric renal transplant recipients and found one third had clinically significant periods of medication nonadherence.[69] Nonadherence was significantly more common in adolescents compared with younger recipients. Nonadherence was associated with both acute and chronic rejection, as well as graft loss. The relative lack of reliable measures of adherence and effective interventions has focused research in the field.[70,71] Improved parental involvement and discussion of the child–parent relationship may improve adherence.

## RECURRENT DISEASE

The recurrence of the patient’s primary disease is variable, and recurrence may or may not lead to graft loss. Recurrent disease is a more significant issue in the pediatric population, because of the diagnoses leading to ESRD and their association with higher rates of graft loss after recurrence. FSGS is the most prevalent and clinically significant disease to recur after renal transplantation. In children, the recurrence rate can be as high as 40% to 50%.[72] It can recur almost immediately after transplant, and most recurrences are within the first month. Patients with FSGS should be followed closely after transplantation with urine protein measurements. Graft survival is often worse in adolescents with recurrent FSGS, with up to a 38% risk of graft loss.[73] A circulating permeability factor is believed to play a critical role in the pathogenesis of FSGS. Plasmapheresis is the most frequently used therapy for recurrence, although controlled trials supporting its efficacy are lacking. Some have proposed a role for preoperative plasmapheresis to decrease the risk of recurrence.[74] Others have suggested a role for intensifying the immunosuppression and potentially rituximab. In addition to FSGS, other primary renal causes associated with recurrent disease include membranoproliferative glomerulonephritis types 1 and 2 and IgA nephropathy.[75]

Again, the risk of graft loss is variable, and none constitute an absolute contraindication to transplantation.

In addition to these primary glomerulopathies, other recurrent diseases disproportionately affect the pediatric population. Hemolytic-uremic syndrome can recur after transplantation. Nearly all the risk of recurrence and subsequent graft loss is in those with atypical nondiarrhea-associated hemolytic-uremic syndrome.[76] The risk of recurrence appears related to specific defects of complement activation, and screening for these defects is recommended pre-transplant.[77] Henoch-Schönlein purpura can also recur. The overall risk of renal recurrence after transplantation is 29%, and the risk for graft loss appears equivalent to that observed in IgA nephropathy.[78]

Oxalosis (primary hyperoxaluria type 1) is a metabolic disease caused by a defect in hepatic peroxisomal alanine:glyoxylate aminotransferase, which leads to increased synthesis and excretion of oxalate. The excessive oxalate load leads to urolithiasis, medullary calcinosis, and eventual ESRD. The primary metabolic defect is not corrected by kidney transplantation, and the persistent oxalate load causes subsequent renal graft loss. Simultaneous liver-kidney transplantation is generally advocated as the primary treatment.[79,80] Kidney transplantation alone is uncommon, but has been advocated in selected patients, most notably those who are pyridoxine sensitive or those with lower oxalate burdens.[81]

## MEDICAL COMPLICATIONS

### Infection

Infection is a constant risk of immunosuppression and is one clinical representation of the precarious balance between overimmunosuppression and underimmunosuppression. Great vigilance should be maintained during periods of heaviest immunosuppression, as occurs immediately after transplantation or during treatment of rejection. Additional prophylaxis is warranted during these periods of greatest risk.[82]

Post-transplantation infection accounts for more hospitalizations than acute rejection, even in the first 6 months after transplantation.[83] Post-transplantation infections are predominantly bacterial and viral. Fungal infections, although accounting for 0.2% to 2.7% of infection-related hospitalizations, can be particularly dangerous. Pediatric recipients are often at higher risk, reflecting the fact that they are more likely to be naïve to a particular pathogen than the general population. Younger age and the use of antibody induction immunosuppression are significant independent risk factors for infectious complications.[84]

### Cytomegalovirus

Cytomegalovirus (CMV) represents the most common viral infection after transplantation. CMV infection can occur in any recipient, although the risk is highest when a seronegative recipient receives a kidney from a seropositive donor. Infection occurs in seropositive recipients as well because of activation of latent virus. The incidence and the severity of CMV have declined with more effective prophylaxis. The severity of CMV infection may range from asymptomatic to organ involvement and death. The typical presentation occurs 1 to 6 months after transplantation, with the patient feeling relatively well but having fevers or sometimes flulike symptoms. Leukopenia is common. Patients with tissue-invasive CMV disease will appear toxic, and there will be evidence of end-organ dysfunction. The diagnosis is confirmed using either a CMV pp65 antigenemia assay or the CMV polymerase chain reaction (PCR) assay. Both methods allow monitoring of the response to therapy. Valganciclovir is effective for both the prophylaxis and treatment of CMV disease.[85] In more severe cases, treatment with intravenous ganciclovir and CMV hyperimmune globulin may be helpful.

### Varicella-Zoster Virus

In pediatric recipients, there is high risk of a primary chickenpox infection. Treatment is with intravenous acyclovir until the lesions crust over, then conversion to oral acyclovir. Primary infections can be severe. We immunize our candidates who are seronegative for varicella-zoster virus (VZV) before transplantation. For seronegative recipients who have a defined exposure, we administer VZV immune globulin.

### BK Virus

BK virus is a ubiquitous polyomavirus that is a significant concern in renal transplantation.[86] There is a high incidence of seroconversion by late childhood, and the virus is dormant in the renal epithelium until reactivated. BK virus appears to be an under-recognized cause of allograft dysfunction, with BK interstitial nephritis resulting in a graft loss in 45% to 70% of affected recipients.

The incidence of BK virus-associated transplant nephropathy is estimated to be 4% to 7%.[86] Smith and coworkers evaluated a single-center cohort of 173 pediatric renal recipients and identified BK nephropathy in 6 children (3.5%).[87] The diagnosis was made on biopsy at a median of 15 months after transplantation. There was a strong association between BK nephropathy and recipient seronegativity. In a subsequent analysis of the NAPRTCS database from 2000 to 2004, the incidence of BK nephropathy was 4.6% with a median onset of 10.1 months post-transplantation. Graft failure occurred in 24% of patients at a mean of 24 months after diagnosis. There was an association with polyclonal antibody induction therapy.[88]

BK nephropathy should be considered in the evaluation of renal allograft dysfunction. BK nephropathy can be definitively diagnosed on biopsy using immunohistochemistry, but the histology can be confused with acute rejection. Treatment with additional immunosuppression does not improve renal function and often will cause further deterioration. The initial treatment for BK nephropathy consists of decreasing immunosuppression. The addition of antiviral therapy and intravenous immunoglobulin has been reported, but there are no controlled trials and compelling data are lacking.[89] Measurement of BK virus by PCR helps with diagnosis and subsequent monitoring of the response to treatment. It is hoped that improved awareness, prompt diagnosis, and treatment may reduce the risk of graft loss initially associated with this disease process.

### Malignancy

Transplant recipients face an increased risk of de novo malignancy related to their immunosuppression. Lymphomas, specifically post-transplantation lymphoproliferative disorder (PTLD), are the most common, with an incidence of 1% to 4% in renal transplantation.[90–92] PTLD actually represents a spectrum of pathology, and the treatment and prognosis

depends on the histology.[90,93] Epstein-Barr virus (EBV) is believed to be the causative agent in the progression to PTLD, especially in B-cell lymphomas. A wide variety of factors have been proposed to be associated with an increased risk, including the use of antilymphocyte induction therapy, EBV-seronegative recipient, EBV infection, and era of transplant. Young white males appear to be at greatest risk.[92] The incidence of PTLD is associated with the overall intensity of immunosuppression.[91,92,94,95]

The second most common cancer in pediatric recipients is skin cancer. Squamous cell carcinoma accounts for the majority, followed by malignant melanoma and basal cell carcinoma. The best strategy combines sunblock and sun avoidance. All recipients should undergo regular dermatologic follow-up, specifically focusing on this risk. Long-term immunosuppression is also associated with increased risks of cervical, vulvar, and anal carcinoma.

### Other Medical Issues

In addition to the risks of infection and malignancy, transplant recipients face many other risks secondary to their history of ESRD, their underlying renal disease, and the individual risks associated with all their medications.

Renal transplant recipients are at high risk for cardiovascular disease.[96] Preexisting renal insufficiency, time on dialysis, and immunosuppressive medications after transplantation all contribute to this risk. In addition, the prevalence of hypertension in pediatric kidney recipients is 50% to 80%.[97,98] The incidence of left ventricular hypertrophy at initiation of renal replacement therapy ranges from 54% to 82%, though it generally improves after transplantation.[99–101] Many children and adolescents will have additional cardiovascular risk factors, including hyperlipidemia, hyperhomocysteinemia, anemia, malnutrition, and chronic inflammation.

Although there are few data examining the magnitude of the risk in pediatric patients, young adult patients with ESRD have a 1000-fold higher risk of cardiovascular death compared with the general population. Although the risk of cardiovascular death decreases after successful transplantation compared with dialysis, it does not become normal.[102] In addition to contributing to cardiovascular risk, hypertension is associated with a higher risk of graft dysfunction and graft loss.[98,103]

Transplantation recipients also face significant problems with bone metabolism and growth because of a history of chronic renal insufficiency, malnutrition, graft dysfunction after transplantation, and immunosuppressive medications. Renal osteodystrophy is a substantial problem, but proper calcium and vitamin D supplementation, along with other agents, has improved overall bone health. The risk of osseous complications has decreased with time, and the risk decreases after transplantation compared with dialysis therapy.[104] The impairment in linear growth impacts final adult height, but significant progress has been made.[105,106] Height at transplantation is one of the best predictors of final adult height, and better management prior to transplantation, including nutrition and the use of recombinant human growth hormone, have improved height z-scores at transplantation. Catch-up growth post-transplantation occurs, but appears limited to recipients less than 6 years of age at transplantation. Steroid avoidance protocols are also associated with catch-up growth, adding a potential benefit to consider with respect to immunosuppression regimens.

### Cognitive and Psychosocial Development

The negative impact of ESRD on cognitive development has diminished because of significant improvements in medical management and renal replacement therapy. Children with ESRD who undergo transplantation appear to have improvement in their level of cognitive function.[107] Psychosocial development tends to be below the healthy population, though transplantation offers benefit compared with dialysis. Overall quality of life for the child and family appears to be better after transplantation compared with dialysis, although again, when compared with the normative population, there are disparities.[108–111]

CHAPTER 47

# Pancreas and Islet Cell Transplantation

David E. R. Sutherland, Angelika C. Gruessner, Bernhard J. Hering, and Rainer W. G. Gruessner

Type 1 diabetes is an autoimmune disease in which the pancreatic islet insulin-producing beta cells are selectively destroyed.[1] It most commonly presents in childhood and continues to represent a therapeutic challenge. Secondary diabetes complications, observed in 30% to 50% of patients who live more than 20 years after onset of the disease, result in poor quality of life, premature death, and considerable health care costs.[2] The principal determinant of the risk of devastating diabetes complications is the total lifetime exposure to elevated blood glucose levels.[3] Therefore establishing safe and effective methods of achieving and maintaining normoglycemia will have substantial implications for the health and the quality of life of individuals with diabetes.

The Diabetes Control and Complications Trial (DCCT) demonstrated that, given a qualified diabetes care team and intensive insulin treatment control, near-normalization of glycemia could be achieved and sustained for several years.[4] However, such a near-perfect level of treatment would increase a patient's burden of day-to-day diabetes management, be difficult to implement for many patients, require more attention and medical services than are routinely available in clinical practice,[5] and be accompanied by an increased frequency of severe hypoglycemia.[4] Currently, the only way to restore sustained normoglycemia without the associated risk of hypoglycemia is to replace the patient's glucose-sensing and insulin-secreting pancreatic islet beta cells[6,7] either by the transplantation of a vascularized pancreas[8,9] or by the infusion of isolated pancreatic islets.[10–12] The trade-off is the need for immunosuppression to prevent rejection of allogenic tissue, and for this reason, most pancreas or islet transplant recipients have been adults. However, the potential for application earlier in the course of the disease exists, particularly in diabetic children already on immunosuppression for other indications.[13] Of the nearly 24 million people estimated to have diabetes mellitus in the United States, 5% to 10% have type 1 diabetes mellitus,[14] and the prevalence in children is increasing.[15]

## Pancreas Transplantation

### HISTORY

The first clinical pancreas transplantation was performed in 1966 by Drs. William Kelly and Richard Lillehei, simultaneous with a kidney transplantation, in a uremic diabetic patient at the University of Minnesota.[16] Shortly thereafter, a few institutions around the world began to perform pancreas transplantations, as detailed in a comprehensive history in another book.[17]

The success rate (long-term insulin independence) with pancreas transplantation was initially low but increased considerably in the 1980s, leading to increased application (Fig. 47-1). Innovations in both surgical techniques and immunosuppression were responsible for the improvements.

The first pancreas transplantation was a duct-ligated segmental (body and tail) graft,[16] but this approach was associated with multiple complications. In a series of 13 more pancreas transplantations between 1966 and 1973 at the University of Minnesota,[18,19] Lillehei devised the whole pancreas–duodenal transplantation technique to the iliac vessels with enteric drainage through a duodenoenterostomy to native small bowel, which is now routine at most centers. The initial results, however, were not as good as today, and several surgeons devised alternative techniques during the 1970s and early 1980s.[17] Dubernard, in Lyon, France, introduced duct injection of a synthetic polymer as a method to block secretions and cause fibrosis in the exocrine pancreas of a segmental graft, with sparing of the endocrine component,[20] and many pioneering centers adopted this technique, although it is little used today. Gliedman introduced urinary drainage through a ureteroductostomy for segmental grafts,[21] and Sollinger later modified this approach with direct anastomosis of a duodenal patch of a whole pancreas graft to the recipient bladder.[22] Drs. Dai Nghiem and Robert Corry did further modification of urinary drainage,[23] retaining a bubble of duodenum for duodenocystostomy, as Lillehei had done for duodenoenterostomy.[18] From the early 1980s until the mid-1990s, the bladder-drainage technique with duodenocystostomy was the predominant technique for pancreas transplantations. The bladder-drainage technique had a low acute complication rate and was helpful in monitoring for rejection by detection of a decline in urine amylase activity, but chronic complications, such as recurrent urinary tract

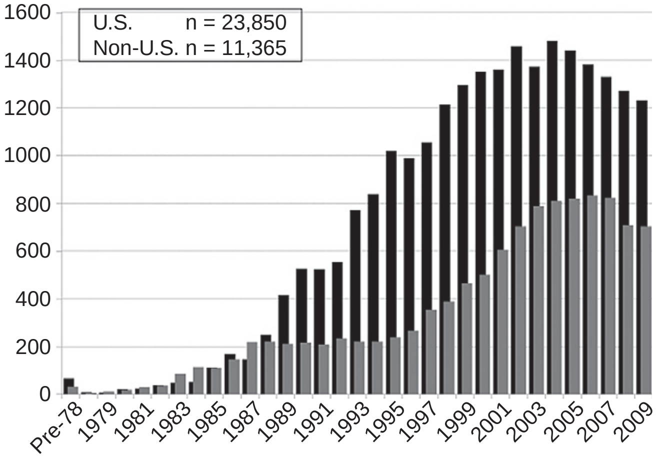

FIGURE 47-1 Annual number of U.S. and non-U.S. pancreas transplantations reported to the International Pancreas Transplant Registry (IPTR), 1978-2009.

infections or dehydration from fluid loss through the exocrine secretions, were common. Thus in the mid-1990s, described by Lillehei and colleagues,[18] a change occurred and enteric drainage, which was never totally out of fashion,[24,25] overtook bladder drainage as the predominant drainage procedure. In addition, portal rather than systemic venous drainage was used by some groups for enteric-drained whole pancreas–duodenal transplantations.[26] Portal venous drainage was originally introduced by Calne in 1984 for segmental pancreas grafts as a more physiologic technique[26] and was applied by several groups sporadically over the years.[17]

With advances in immunosuppression, including the introduction of cyclosporine by Calne and coworkers in 1979,[27] tacrolimus by Starzl and associates in 1989,[28] and mycophenolate mofetil by Sollinger and coworkers in 1995,[29] bladder drainage had become less important for monitoring rejection. Furthermore, in recipients of simultaneous pancreas and kidney transplants from the same donor, the kidney could be monitored for rejection episodes (elevation of serum creatinine) as a surrogate marker for pancreas rejection before there was sufficient pancreatic damage to cause hyperglycemia. However, in solitary pancreas transplants, serum creatinine could not be used as a marker for rejection, and in such cases, bladder drainage is useful and continues to be used.[17]

## DETAILS OF SURGICAL TECHNIQUES

As mentioned in the history section, a variety of techniques have been used for management of the exocrine secretions and venous drainage of pancreas transplants.[30,31] The majority of pancreas grafts are procured from multiorgan deceased donors, and because the liver and pancreas share the origins of their arterial blood supply, a whole organ pancreas graft usually requires reconstruction.[32,33] The blood supply to the tail of the pancreas is supplied by the splenic artery, originating from the celiac axis, and the head of the pancreas is supplied by the pancreaticoduodenal arcades, originating from the superior mesenteric artery and the hepatic artery. Because the latter goes with the liver, along with the celiac axis, the usual approach is to attach an arterial Y-graft of the donor iliac vessels, with anastomosis of the hypogastric artery to the graft splenic artery and the external iliac artery to the graft superior mesenteric artery, leaving the common iliac artery segment of the Y-graft for anastomosis to the recipient arterial system, usually the right common iliac artery. The portal vein of the donor is usually divided midway between the upper border of the pancreas and the liver, leaving adequate length for transplantations of both organs, but if necessary, an extension graft of donor iliac vein can be anastamosed to the pancreatic graft portal vein portion. In the recipient, the pancreas graft portal vein, with or without an extension graft, can be anastomosed to the systemic venous system (usually the iliac vein or vena cava) or to the portal system (usually the superior mesenteric vein).

When venous drainage is to the recipient's iliac vein, the whole pancreas graft can be oriented with the head directed into either the pelvis or the upper abdomen. When directed cephalad, enteric drainage is the only option. When directed caudad, the duodenum can be anastomosed to either the bladder (Fig. 47-2) or bowel (Fig. 47-3). Figure 47-2

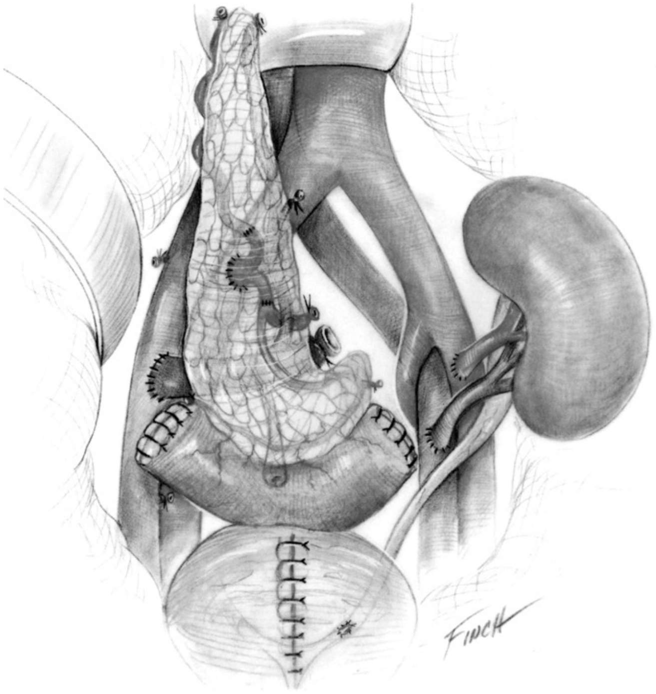

FIGURE 47-2 Simultaneous pancreas and kidney (SPK) transplantation using a whole pancreas/duodenal graft from a deceased donor with systemic venous drainage to the right iliac vein and bladder drainage of the pancreas exocrine secretions through a duodenocystostomy. Both the pancreas and kidney are placed in the peritoneum through a midline incision. The donor splenic artery, supplying the pancreatic tail, and the donor superior mesenteric artery, supplying the pancreatic head, have been joined by a Y-graft constructed from the donor common external/internal iliac artery complex during a bench procedure, and the base of the Y-graft is anastomosed to the recipient common iliac artery. The mid-duodenum is anastomosed to the posterior dome of the bladder, and the duodenal stumps are oversewn. The kidney graft could be from a living donor or the same deceased donor as the pancreas graft, but, in either case, is preferentially placed to the left iliac vessels so that the right side, with its more superficial vessels, can be used for the pancreas transplant. In this particular illustration, the donor ureter was implanted into the bladder using the Politano-Leadbetter technique through an anterior cystotomy, a technique that also allows the duodenocystostomy to be performed with an end-to-end anastomosis (EEA) stapler, with internal oversewing of the anastomotic line using an absorbable suture to cover the staples, followed by closure of the cystotomy. However, when enteric drainage is used for an SPK transplantation, an external ureteroneocystostomy is usually performed. (Reproduced from Gruessner RWG, Sutherland DER [eds]: Transplantation of the Pancreas. New York, Springer-Verlag, 2004.)

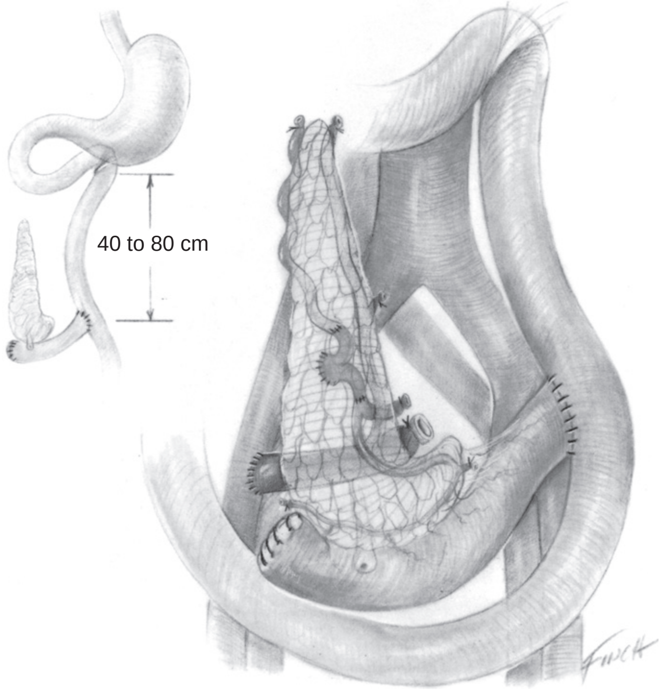

**FIGURE 47-3** Pancreas-duodenal transplantation using a deceased donor with systemic venous drainage and enteric drainage of graft exocrine secretions to a proximal loop of recipient jejunum. In this particular case, an end-to-side two-layer duodenojejunostomy, using the distal end of the graft duodenum, is illustrated, and the anastomosis is located 40 to 80 cm distal to the ligament of Treitz *(inset)*. Alternatively, a side-to-side stapled or handsewn duodenojejunostomy, with or without a Roux-en-Y loop, can be done. (Reproduced from Gruessner RWG, Sutherland DER [eds]: Transplantation of the Pancreas. New York, Springer-Verlag, 2004.)

shows the bladder-drainage technique and also depicts a kidney transplantation to the left iliac vessels, but, as mentioned, with a kidney transplantation, enteric drainage is more common than bladder drainage.

With the bladder-drainage technique, the anastomosis may be handsewn or performed with an end-to-end anastomosis (EEA) stapler brought through the distal duodenum (which is subsequently stapled closed) for connection to the post of the anvil projected through the posterior bladder by an anterior cystotomy (see Fig. 47-2). The inner layer is then reinforced with a running absorbable suture for hemostasis and for burying the staples under the mucosa.

With enteric drainage/systemic venous drainage, the anastomosis may be handsewn in an end-to-side fashion (see Fig. 47-3), or it can be done in a side-to-side fashion by handsewing or by using an EEA stapler.[34] The barrel of the EEA stapler is inserted into the end of the graft duodenum, and the post is projected through the side wall. The anvil is inserted into the recipient bowel through an enterotomy secured around the connecting post by a purse-string suture. The two posts are connected and the stapler is fired, creating the anastomosis. The end of the duodenum is then closed with a simple stapler. The enteric anastomosis can be done directly to the most convenient proximal small bowel loop of the recipient or to a Roux-en-Y segment of recipient bowel that is created at the time. Outcome analyses do not show any statistical advantage of a Roux-en-Y loop.

For portal drainage of the pancreas graft venous effluent (Fig. 47-4), the head and duodenum of the graft is oriented

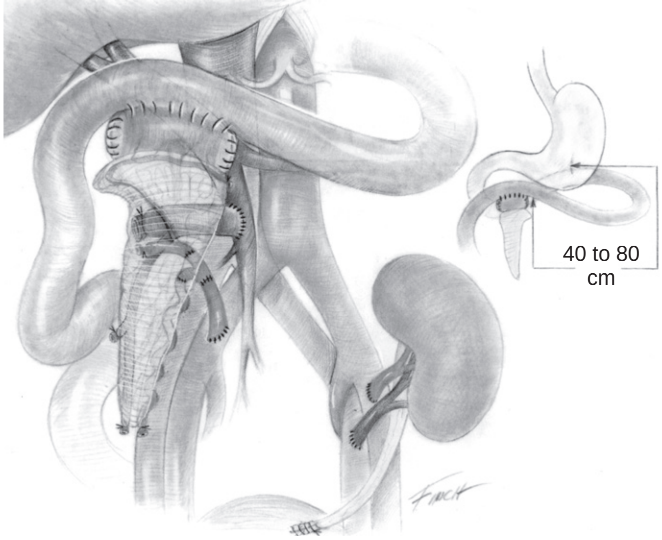

**FIGURE 47-4** Whole pancreas/duodenum transplantation using a deceased donor with portal venous drainage with an end-to-side anastomosis to the recipient superior mesenteric vein, accessed below its confluence with the splenic vein. Drainage of exocrine secretions is through a side-to-side duodenojejunostomy, 40 to 80 cm distal to the ligament of Treitz. Note that the cephalad position of the pancreatic head, when portal venous drainage is used, as opposed to the caudal orientation possible with systemic venous drainage, is no different than that needed when bladder drainage is done. In this particular illustration, the pancreas graft overlies the root of the small bowel mesentery, with the duodenal segment below the transverse colon, and the arterial Y-graft is anastomosed to the recipient common iliac artery through a mesenteric tunnel. However, a retroperitoneal approach under the right colon is also possible, in which case the arterial Y-graft can be anastomosed directly to the recipient iliac artery, but the enteric anastomosis must be through a Roux-en-Y limb of recipient bowel brought through the mesentery. If a kidney is simultaneously transplanted to the left iliac vessels, the ureter can be implanted into the bladder using the extravesical ureteroneocystostomy (Lich) technique, as illustrated. (Reproduced from Gruessner RWG, Sutherland DER [eds]: Transplantation of the Pancreas. New York, Springer-Verlag, 2004.)

cephalad, and the graft portal vein is anastomosed directly to the recipient superior mesenteric vein. In the illustration, the pancreas graft is ventral to the recipient small bowel mesentery so that the venous anastomosis is to the ventral side of the vein, and the arterial Y-graft must be brought through a window of mesentery for anastomosis to the recipient's aorta or common iliac artery. The graft duodenum is anastomosed to recipient's small bowel by the same techniques described for systemic venous drainage, with or without (as depicted) a Roux-en-Y loop of recipient bowel.

An alternative approach for portal venous drainage of the pancreas graft effluent is to place the pancreas retroperitoneally by reflecting the right colon to the left and exposing the dorsal surface of the superior mesenteric vein, as described by Boggi and associates.[35,36] The arterial Y-graft can then be anastomosed directly to the right common iliac artery, but this approach does mandate creation of a Roux-en-Y limb of recipient bowel to bring through the small bowel or transverse colon mesentery for a graft duodenoenterostomy.

Other techniques can be used, including duct injection for a segmental graft. Segmental grafts are rarely used, except in the few cases of living donor pancreas transplantations,[37–42] and most of these have the exocrine secretions managed by either a ductoenterostomy to a Roux-en-Y limb of recipient bowel or a ductocystostomy to the recipient's bladder

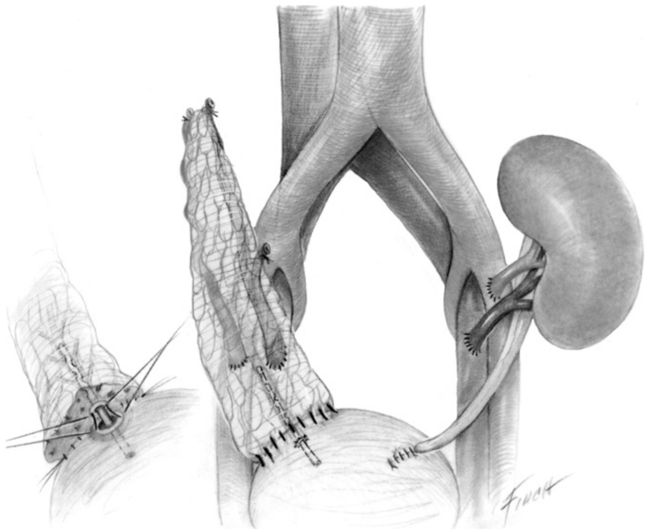

FIGURE 47-5 Living donor segmental (body and tail) pancreas transplantation to right iliac vessels (systemic venous drainage) and bladder drainage of exocrine secretions through a ductocystostomy by means of an intraperitoneal approach. The donor splenic artery and splenic vein are anastomosed end to side to the recipient external iliac artery and vein after ligation and division of all hypogastric veins to bring the main vein as superficial as possible. The splenic artery anastomosis is lateral and proximal to the splenic vein anastomosis. A two-layer ductocystostomy is constructed: The pancreatic duct is approximated to the urothelial layer (inner layer) using interrupted 7-0 absorbable sutures over a stent *(inset)*. If the kidney is transplanted simultaneously, the donor ureter is implanted into the bladder using the extravesical ureteroneocystostomy (Lich) technique. (Reproduced from Gruessner RWG, Sutherland DER [eds]: Transplantation of the Pancreas. New York, Springer-Verlag, 2004.)

(Fig. 47-5). Segmental pancreas transplantations from living donors, with or without a kidney transplantation, are particularly useful in candidates who would otherwise have a long wait for a deceased donor organ, such as those with a high level of human leukocyte antigen (HLA) antibodies but with a negative crossmatch to a living volunteer.[40] However, there are circumstances where a segmental graft from a deceased donor is still appropriate for technical reasons, particularly for retransplantations where conventional sites have been used previously in such a way they cannot be reused and one has to use unconventional sites, even orthotopically.[43] For more details concerning the variety of surgical techniques in pancreas donors (deceased and living) and recipients, the reader is referred to work by Benedetti and colleagues.[44]

## GENERAL INFORMATION, PANCREAS TRANSPLANTATION CATEGORIES, AND IMMUNOSUPPRESSION

By the late-1990s, more than 2500 pancreas transplantations were being done annually worldwide (see Fig. 47-1), as reported to the International Pancreas Transplant Registry (IPTR).[45] By 2010, more than 35,000 vascularized pancreas transplantations had been performed, more than half in the United States, with very large series at some centers,[25,46–48] more than 2000 total at the University of Minnesota,[49] and more than 1000 simultaneous pancreas and kidney (SPK) transplantations at the University of Wisconsin.[47] The vast majority were done to establish insulin independence in patients with de novo type 1 diabetes mellitus, but enteric-drained pancreas transplantations have been used to correct both endocrine and exocrine deficiency after total pancreatectomy in some patients[51–53] and to treat diseases such as cystic fibrosis in others.[54]

Specialists in more than 150 institutions in the United States, and nearly the same number elsewhere, have performed pancreas transplantations.[55] The IPTR was founded in 1980 to analyze the results.[56] In 1987, reporting of U.S. cases became obligatory through the United Network for Organ Sharing (UNOS), and near-annual reports have been made thereafter.[57–60]

There are three categories of pancreas transplantation recipients: (1) uremic diabetic patients who undergo a simultaneous pancreas and kidney transplantation from either a deceased or living donor[61]; (2) nephropathic patients who already have had renal insufficiency corrected, usually by a living donor kidney transplantation, and then undergo a pancreas after kidney (PAK) transplantation[62–64]; and (3) nonuremic diabetic patients who undergo a pancreas transplantation alone (PTA).[65] The Pancreas Transplant Registry has compared outcomes in the three categories spanning several eras of data collection.[57–60,66,67]

The majority of pancreas transplantations have been in the SPK category, but in recent years, there has been an increased emphasis in performing living donor kidney transplantations to preempt the need for dialysis in diabetics with nephropathy.[68] Thus until 2004, the number of PAK transplantations increased, but the number of SPK transplantations did not change (Fig. 47-6). Concomitantly, there has also been an increase in the number of PTA cases to treat diabetics without advanced nephropathy who have diabetic management problems justifying immunosuppression, and to treat patients who would also be candidates for islet transplantation, given the conditions discussed later. Although most pancreas transplantation recipients have type 1 diabetes, insulin-treated type 2 diabetics also become insulin-independent after a pancreas transplantation.[69–71]

Immunosuppression management of pancreas transplantation recipients is similar to that of recipients of other solid organs, including kidneys, which the majority of pancreas recipients also receive.[72] Thus induction immunosuppression

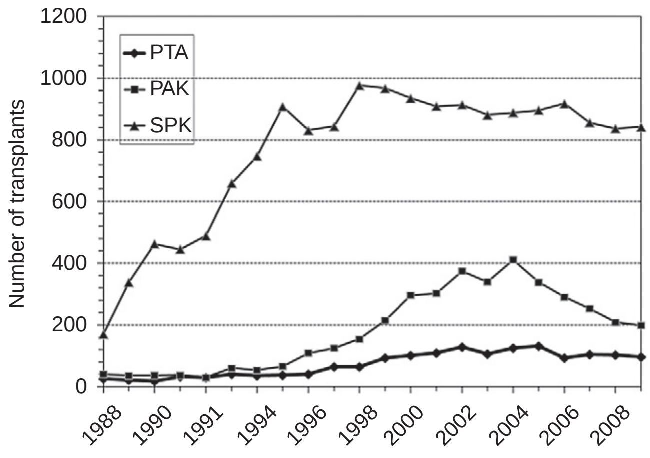

FIGURE 47-6 Number of pancreas transplantations performed annually in the United States from 1988 through 2009 by recipient category. PAK, pancreas after kidney transplantation; PTA, pancreas transplantation alone; SPK, simultaneous pancreas and kidney transplantation.

with anti–T-cell monoclonal or polyclonal depleting or nondepleting agents may be used or reserved for rejection episodes.[73] Maintenance immunosuppression usually consists of a combination of a calcineurin inhibitor (cyclosporine or tacrolimus), with the dose and blood levels adjusted to minimize nephrotoxicity, and an antiproliferative agent (mycophenolate mofetil or sirolimus), with or without prednisone. Corticosteroid-free regimens are now quite common for all organ transplantations, including the pancreas.[74–83] Suspected pancreas allograft rejection episodes, based on transient rise of serum amylase or lipase in enteric-drained grafts or on a decline in urine amylase in bladder-drained grafts, or by a rise in serum creatinine in SPK transplantations, can be confirmed by biopsy of the graft.[84,85]

## PANCREAS TRANSPLANTATION OUTCOMES

Current outcomes with deceased donor pancreas transplantations, according to recipient categories, surgical technique, and immunosuppression protocol, for U.S. cases as reported to UNOS from January 2005 to December 2009, are summarized here.[55] During this period, 5567 primary deceased donor pancreas transplantations were reported to UNOS, including 4155 SPK, 947 PAK, and 465 PTA transplantations.

The primary transplantation patient survival rates in the three recipient categories are shown in Figure 47-7. At 1 year, 96% of the SPK, 97% of the PAK, and 97% of the PTA recipients were alive; at 3 years, 92%, 91%, and 92%, respectively, were alive. The highest patient survival rate could be found in PTA subgroups, presumably because this group had less advanced complications before transplantation.

The primary pancreas graft survival rates in the three recipient categories are shown in Figure 47-8. At 1 year, 85% of the SPK, 79% of the PAK, and 78% of the PTA recipients were totally insulin-independent; at 3 years, 79%, 68%, and 62%, respectively, were insulin-independent ($P < 0.001$). The highest pancreas graft survival rates are in the SPK category, presumably because the kidney graft (usually from the same donor as the pancreas) can be used to detect rejection episodes earlier than in the other categories, where only the pancreas can be monitored. Support for this hypothesis comes

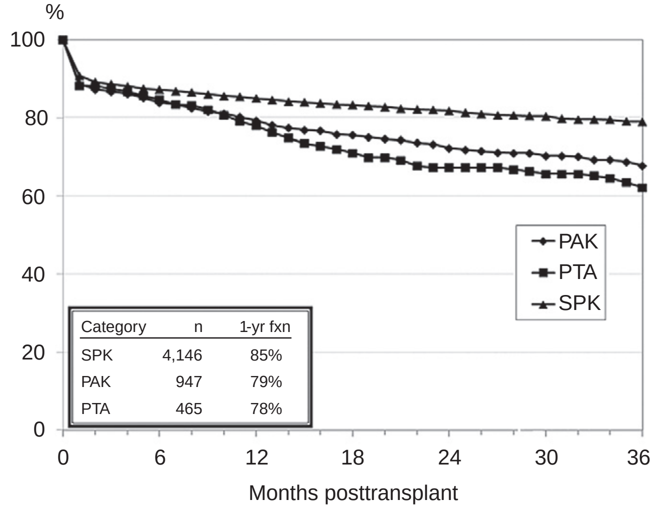

**FIGURE 47-8** Pancreas graft functional survival rates (insulin independence) for 2005 to 2009 U.S. deceased donor primary transplantations by recipient category. Fxn, function; PAK, pancreas after kidney transplantation; PTA, pancreas transplantation alone; SPK, simultaneous pancreas and kidney transplantation.

from Registry data showing significantly higher early technical failure rates and also large differences in rejection loss rates for solitary transplants.

Of the 2005 to 2009 primary pancreas grafts, 6% of SPK and 9% of solitary transplants failed for technical reasons, with thrombosis being the highest risk for technical loss (5%); infection, pancreatitis, and anastomotic leak made up the rest. Technical graft loss was significantly higher in solitary transplants than in SPK ($P = 0.0009$).

The primary pancreas graft failure rates from rejection are shown in Figure 47-9. At 1 year, 2% of the SPK, 4% of the PAK, and 6% of the PTA recipients of technically successful grafts had to resume exogenous insulin (significantly lower in the SPK category; $P = 0.0001$).

Regarding management of pancreatic duct exocrine secretions for the 2005 to 2009 cases, enteric drainage predominated

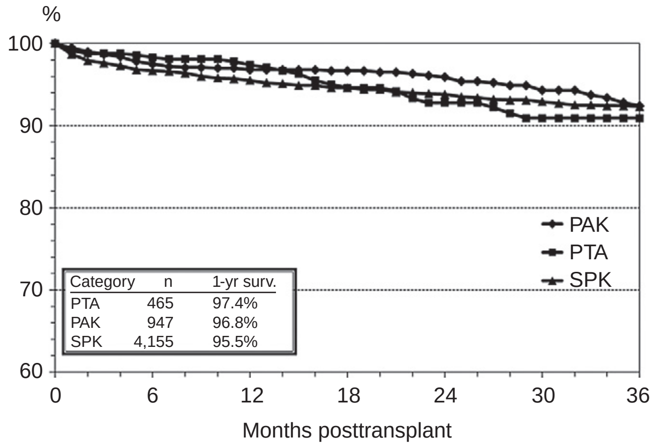

**FIGURE 47-7** Patient survival rates for 2005 to 2009 U.S. deceased donor primary transplantations by recipient category. PAK, pancreas after kidney transplant; PTA, pancreas transplant alone; SPK, simultaneous pancreas and kidney transplantation; surv., survival.

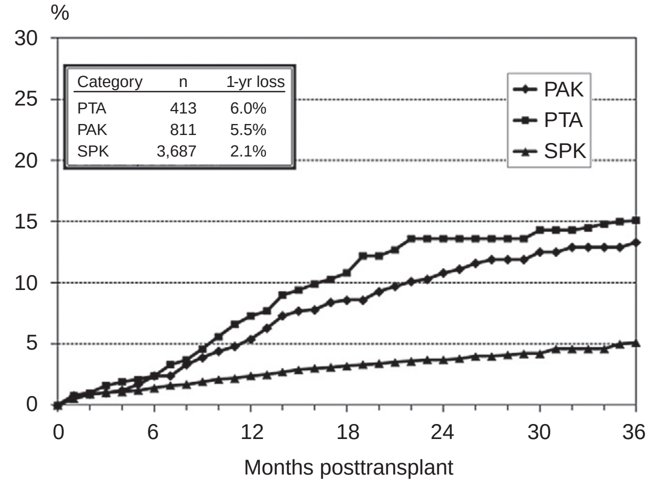

**FIGURE 47-9** Technically successful pancreas graft immunologic failure rates (return to exogenous insulin) for 2005 to 2009 U.S. deceased donor primary transplants by recipient category. PAK, pancreas after kidney transplantation; PTA, pancreas transplantation alone; SPK, simultaneous pancreas and kidney transplantation.

for SPK transplants (91%); for PAK and PTA, the proportion that were enteric drained was slightly lower (86% and 79%, respectively). Overall, the technical failure rate was significantly higher with enteric-drained SPK than with bladder-drained SPK (7% vs. 4%) transplants. No difference was found for solitary transplants. Pancreas graft survival rates, however, were not significantly different for enteric-drained versus bladder-drained transplantations in any of the categories: At 1 year, the rates were 85% ($n$ = 3665) versus 86% ($n$ = 366) for SPK, 79% ($n$ = 790) versus 82% ($n$ = 130) for PAK, and 80% ($n$ = 366) versus 75% ($n$ = 99) for PTA cases. No difference in the failure rate from rejection for technically successful grafts for enteric-drained versus bladder-drained transplantations could be found anymore.

In the SPK category, bladder drainage and enteric drainage would be expected to give similar results: In most cases, both grafts come from the same donor, and monitoring of serum creatinine serves as a surrogate marker for rejection in the pancreas transplant, allowing easy detection and reversal by treatment. In contrast, for solitary pancreas transplants (PAK and PTA), serum creatinine cannot be used as a marker of pancreas rejection, hyperglycemia is a late manifestation of rejection, and exocrine markers must be used. Although serum amylase and lipase may elevate during a rejection episode, this does not occur in all cases, but for bladder-drained grafts, a decrease in urine amylase eventually always accompanies rejection (100% sensitive, even though it is not specific) and nearly always precedes hyperglycemia so that a rejection episode is more likely to be diagnosed in a bladder-drained graft and lead to treatment and reversal.

Approximately one quarter of enteric-drained pancreas grafts reported to UNOS were done with a Roux-en-Y loop; in the past, the outcomes were not improved by this procedural addition,[45] and that is still the case.[55]

Another variation in surgical technique is portal drainage of the venous effluent for enteric-drained grafts.[30,86] It establishes normal physiology and a theoretic metabolic advantage versus systemic venous drainage, and some groups have reported that portal venous enteric-drainage grafts are less prone to rejection than systemic venous enteric-drainage grafts,[87,88] although others have not.[89] The latest Registry analysis shows that portal venous drainage was used for one fifth of enteric-drainage transplantations, but there were no significant differences in pancreas graft survival versus systemic venous enteric-drainage transplantations in any of the categories: at 1 year, 84% ($n$ = 718) versus 86% ($n$ = 2896) for SPK, 79% ($n$ = 130) versus 79% ($n$ = 651) for PAK, and 78% ($n$ = 51) versus 80% ($n$ = 305) for PTA cases.

Regarding immunosuppression, according to the latest Registry analysis, anti–T-cell agents were used for induction therapy for more than 80% of the 2005 to 2009 U.S. pancreas recipients in each category.[55] The most frequently used regimen for maintenance immunosuppression (more than two thirds of the recipients in each category) was tacrolimus and mycophenolate mofetil in combination, with or without prednisone. In recipients of primary deceased donor pancreas grafts given anti–T-cell agents for induction and tacrolimus and mycophenolate mofetil for maintenance immunosuppression (Fig. 47-10), the 1-year graft survival rates in the SPK, PAK, and PTA categories were 86% ($n$ = 2737), 81% ($n$ = 544), and 86% ($n$ = 271), respectively. A sirolimus-based regimen was used as a maintenance immunosuppressive drug

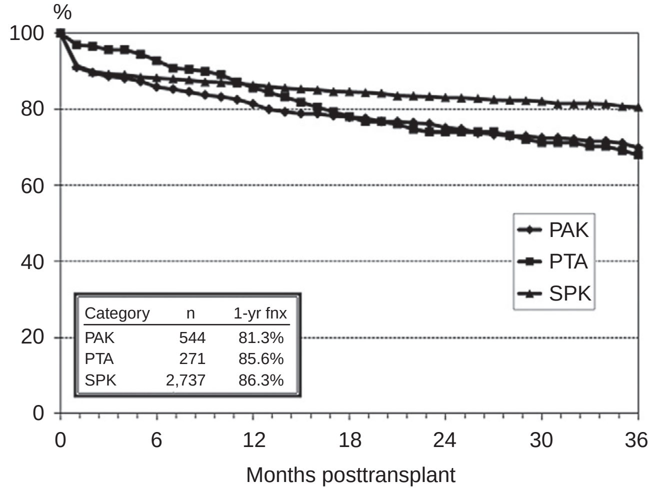

**FIGURE 47-10** Pancreas graft functional survival rates (insulin independence) for 2005 to 2009 U.S. deceased donor primary transplantations by category in diabetic recipients given anti–T-cell agents for induction and tacrolimus (TAC) and mycophenolate mofetil (MMF) for maintenance immunosuppression. Fxn, function; PAK, pancreas after kidney transplantation; PTA, pancreas transplantation alone; SPK, simultaneous pancreas and kidney transplantation.

in more than 13% of recipients in each category (Fig. 47-11), with excellent outcomes: The 1-year pancreas graft survival rates in the SPK, PAK, and PTA categories were 90% ($n$ = 407), 89% ($n$ = 94), and 89% ($n$ = 84), respectively. In contrast, the remaining recipients given alternative immunosuppressive regimens had distinctly lower pancreas graft survival rates in each category: at 1 year, 74% in SPK ($n$ = 153), 61% in PAK ($n$ = 71), and 29% in PTA ($n$ = 35) cases. A center effect may play a role in the outcomes of the Registry analysis according to immunosuppressive regimens.

Regarding the logistics of pancreas transplantation, the recent Registry data[55] showed a significant increase in technical

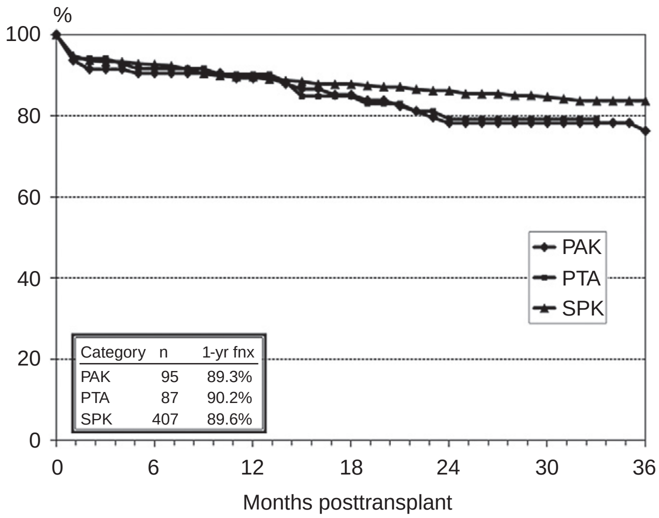

**FIGURE 47-11** Pancreas graft functional survival rates (insulin independence) for 2005 to 2009 U.S. deceased donor primary transplantations by category in diabetic recipients given sirolimus-based maintenance immunosuppression. Fxn, function; PAK, pancreas after kidney transplantation; PTA, pancreas transplantation alone; SPK, simultaneous pancreas and kidney transplantation.

failure rates and a decrease in graft survival rates with increasing preservation time. The relative risk (RR) to lose the graft doubled for SPK grafts with a preservation time greater than 24 hours compared with a preservation time of 12 to 24 hours. Shorter SPK preservation time showed a decreased risk of one third. HLA matching had virtually no impact on SPK graft survival rates, but matching at least at the class I loci had a beneficial effect in the PAK and the PTA categories.

Regarding pancreas recipient age, the recent Registry analysis of the 2005 to 2009 cases showed an effect on outcome mainly in solitary recipients, with rejection more likely in younger patients. In the SPK category, only 3 patients were younger than 15 years of age, and 312 recipients (7%) were between 15 and 29 years of age. In PAK, 5% ($n = 60$) were between the age of 15 and 29 years of age, and 15% ($n = 75$) in PTA. The relative risk for graft loss was not significantly increased for younger SPK recipients ($P = 0.21$) but clearly higher for PAK recipients (RR = 1.75, $P = 0.003$) and PTA recipients (RR = 1.99, $P = 0.009$) compared with recipients 30 to 45 years of age. Thus the young nonuremic diabetic is highly immunocompetent and more prone to reject a pancreas graft, consistent with an earlier analysis of outcomes in U.S. pediatric pancreas transplantation recipients from 1988 to 1999.[90] In that analysis, of slightly more than 8000 pancreas transplantations, only 49 were in recipients younger than 21 years of age (<1%), 34 in the SPK, 2 in the PAK, and 13 in the PTA category; all were deceased donor pancreas transplantations, except for two PTA segmental grafts from living donors. Less than half of the pediatric pancreas recipients were younger than 19. In the PTA recipients, the 1-year graft survival rate was only 15%, with all but one loss being from rejection in less than 1 year. The Registry data do not include the indications for a PTA in the pediatric recipients, but presumably they had extremely labile diabetes, justifying placement on immunosuppression in an attempt to gain control. In the pediatric SPK recipients, however, the 1-year patient, pancreas, and kidney graft survival rates were 96%, 78%, and 71%, respectively, which were outcomes comparable to those of adult SPK recipients for the entire period. Of the pediatric SPK recipients, most had a renal disease other than diabetic nephropathy.

Thus pancreas transplantations in the pediatric age group are uncommon, and most are in diabetic children who also have renal failure and thus need a kidney transplantation, obligating them to immunosuppression. At least in this group, the outcomes are such that it seems reasonable to recommend the addition of the pancreas so that the child can become insulin independent as well as dialysis free for the price of immunosuppression.[13] For nonuremic diabetic children with extreme lability, in whom a successful pancreas transplantation would be appropriate treatment, the antirejection strategies need to be optimized to improve the graft survival rates versus what has been achieved in the past.

With respect to outcome measures other than insulin independence, prevention and reversal of secondary complications, improvement in quality of life, extension of life span, and reduction of health care costs per quality-adjusted life-year have all been positively demonstrated in type 1 diabetic pancreas transplant recipients.[91–97] In patients with labile diabetes and hypoglycemic unawareness, a pancreas transplantation can resolve an otherwise intractable and life-threatening course.[98–100]

Whether a pancreas transplantation has an effect on survival probabilities for the diabetic population selected for the procedure is controversial. Two separate analyses of U.S. data from UNOS and the Organ Procurement Transplant Network (OPTN) for pancreas transplantation candidates and recipients between 1995 and 2000 compared the survival probabilities for patients who remained on the waiting list with those receiving a transplant by category.[103,104] In the first analysis,[103] SPK recipients had a significantly higher probability of survival than those remaining on the waiting list for the procedure, but, for solitary (PAK or PTA) recipients, just the opposite was the case. In the second analysis,[104] the higher survival probability for SPK recipients was confirmed, and, in addition, the overall survival probabilities of solitary pancreas transplant recipients compared with those waiting, and even after 1 year, were favorable for transplantation. In the second analysis, patients who listed at multiple centers were identified and were counted only once from the time of first listing, corrections were made for patients who changed categories, and longer follow-up was available. Thus pancreas transplantation does not entail a higher risk than staying on exogenous insulin for those on the waiting list and may improve survival probabilities for solitary as well as SPK recipients.[105]

In regard to secondary complications of diabetes,[106] numerous studies show a beneficial effect on neuropathy,[94,107–113] retinopathy[114–118] and nephropathy[92,119–122] as well as on cardiovascular disease,[123–128] and quality of life.[129,130] In regard to nephropathy, specifically in PTA recipients, even though the diabetic lesions in the native kidneys can improve,[131] this can be offset by the nephrotoxicity of the calcineurin inhibitors given for immunosuppression.[132]

It should be noted that pancreas retransplantation can be done if the first graft fails, with only slightly lower graft survival rates than for primary transplants.[66,67,133,134] Indeed, even third transplants can do well.[134]

Also of note, pancreas allografts are often procured by one center and transplanted at another, and there are studies showing no difference in outcomes compared with locally procured organs.[135]

Surgical complications of pancreas transplantation are numerous and are the subject of an extensive review recently published.[136] The most frequent complication leading to graft loss is venous or arterial thrombosis (5% to 10%). Anastomotic leaks are also common, but if diagnosed early, graft salvage is possible.

# Islet Transplantation

Human islet transplantation, the less invasive islet beta cell replacement alternative to transplantation of the vascularized pancreas, has been investigated for more than 3 decades[137–140] after the first clinical islet allograft was performed in 1974.[141] Since then, nearly 1000 islet allotransplantations have been performed worldwide.[142,143]

Islet autotransplantations have had a relatively high success rate in preventing diabetes after total pancreatectomy for more than 2 decades; so, they are briefly described before reviewing the current status of islet allografts for type 1 as well as for surgical diabetes.

## ISLET AUTOTRANSPLANTATIONS AFTER PANCREATECTOMY FOR BENIGN DISEASE

Islet autotransplantations to prevent diabetes after a total pancreatectomy for benign disease, primarily painful chronic pancreatitis, have been successful since the first case was performed in the 1970s[144,145] but depend on the number of islets transplanted.[146–151] Children with chronic pancreatitis and intractable pain who require pancreatectomy for relief of the pain and resolution of narcotic dependence nearly always have some beta cell function preserved by an islet autotransplantation, and they are either nondiabetic (more than a third) or can maintain euglycemia with once-daily long-acting insulin or near euglycemia with standard basal-bolus insulin.[152–155] Total pancreatectomy is highly successful in relieving the pain of chronic pancreatitis in both adults and children, particularly if done early before years of narcotic dependence.[148,150,153] The islet yield is also better if the pancreatectomy is not delayed, because the number of islets isolated correlates with the degree of pancreatic damage in both adults[156] and children.[157]

The surgical technique of pylorus-sparing total pancreatectomy and duodenectomy is shown in Figure 47-12. The procedure can be staged, but when the body and tail of the pancreas are removed, they should always be processed for islet isolation for an intraportal autotransplant (Fig. 47-13, *A*).

If a distal pancreatectomy is the primary procedure and a Whipple (completion) pancreatectomy becomes necessary, diabetes will have been prophylactically prevented by the initial islet autograft. If a Whipple procedure was the primary procedure, but pain persists and a distal (body and tail) completion pancreatectomy is required, it should be done in an institution capable of isolating islets from the excised gland for an autotransplantation.[158]

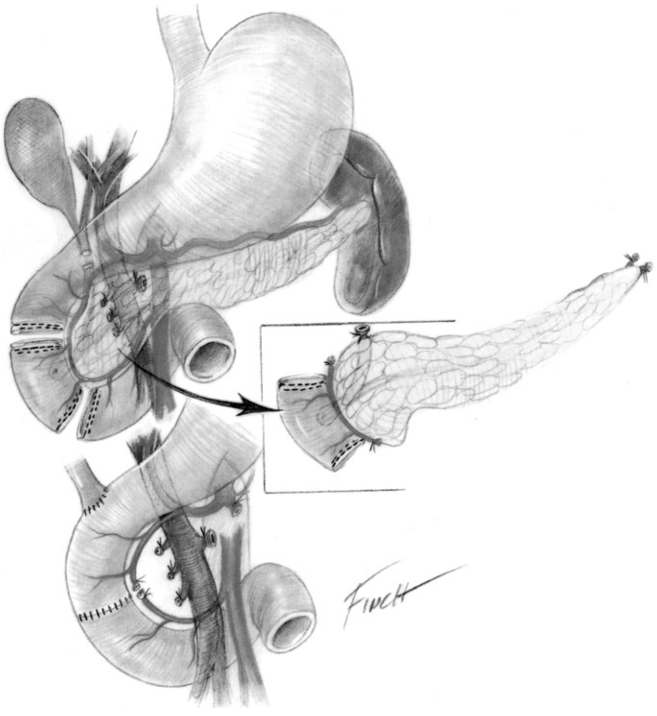

**FIGURE 47-12** Pylorus-sparing total pancreatectomy and partial duodenectomy technique for patients with chronic pancreatitis undergoing islet autotransplantations. The bile duct is transected and reimplanted into the duodenum, shown here proximal to a duodenoduodenostomy or duodenojejunostomy, but, more commonly, it is placed distal to the enteric anastomosis, with the site depending on the individual anatomy. When possible, only the second portion of the duodenum is resected, and an end-to-end duodenoduodenostomy is created; but if viability is not maintained, the entire distal duodenum must be resected and an end-to-end or end-to-side duodenojejunostomy performed. The short gastric vessels are preserved, as well as the gastroepiploic artery if possible, and the spleen is not removed if its viability is maintained. ## ISLET ALLOTRANSPLANTATIONS

Islet allotransplantations have been performed for the treatment of surgical and type 1 diabetes. As with autotransplantations, islet allotransplantations are usually done with embolization of the islets to the liver via the portal vein, where at least some islets will survive by nutrient diffusion until revascularization occurs (Fig. 47-13, *B*). A drawback of islet allotransplantations, as compared with pancreas transplantations, is the reduced beta cell mass; much attention has been given to compensating for the attrition that occurs. Islet allografts in patients with surgical diabetes have been associated with a very high success rate,[159,160] possibly because of the avoidance of diabetogenic steroids and the lack of an autoimmunity.

Islet allograft transplantations in patients with autoimmune type 1 diabetes have initially been performed simultaneously with a kidney transplant or in patients with established kidney transplants.[142] Insulin independence in this recipient group, even on an anecdotal basis, was not achieved until the early 1990s.[161–165]

Islet allografts have also been performed in patients in whom type 1 diabetes (T1D) is complicated by hypoglycemia unawareness and defective hormonal glucose counter-regulation resulting in recurrent episodes of severe hypoglycemia.[166] Today, the majority of human islet allografts are performed in this recipient group.[143] Acute complications are frequent in the 12.5% of T1D patients who have become aware of hypoglycemia 20 years after diabetes onset.[167] Iatrogenic hypoglycemia is the most limiting factor in the glycemic management of T1D;[168] it causes recurrent physical and psychological morbidity, including coma, seizures, and significant social embarrassment, and 7% to 10% of all deaths in patients with T1D are the result of hypoglycemia.[169,170] Hypoglycemia-related problems have not abated during the more than 18 years since they were first highlighted by the landmark report of the DCCT in 1993.[168,171] New glucose monitoring technologies are being developed; however, continuous glucose monitoring did not lower the rate of severe hypoglycemia in patients with T1D.[173,174]

A major milestone was reached in 2000 when Dr. Shapiro and colleagues at the University of Alberta in Edmonton achieved diabetes reversal in seven of seven recipients by using islets from more than one donor pancreas and by using corticosteroid-free, less diabetogenic immunosuppression.[175] Since then, several groups around the world have reported restoration of insulin independence after human islet allotransplantation in type 1 diabetic recipients.[11,176–194]

Furthermore, remarkable additional progress has been made in the past decade toward developing islet transplantation into a vital treatment option for T1D. First, new protocols

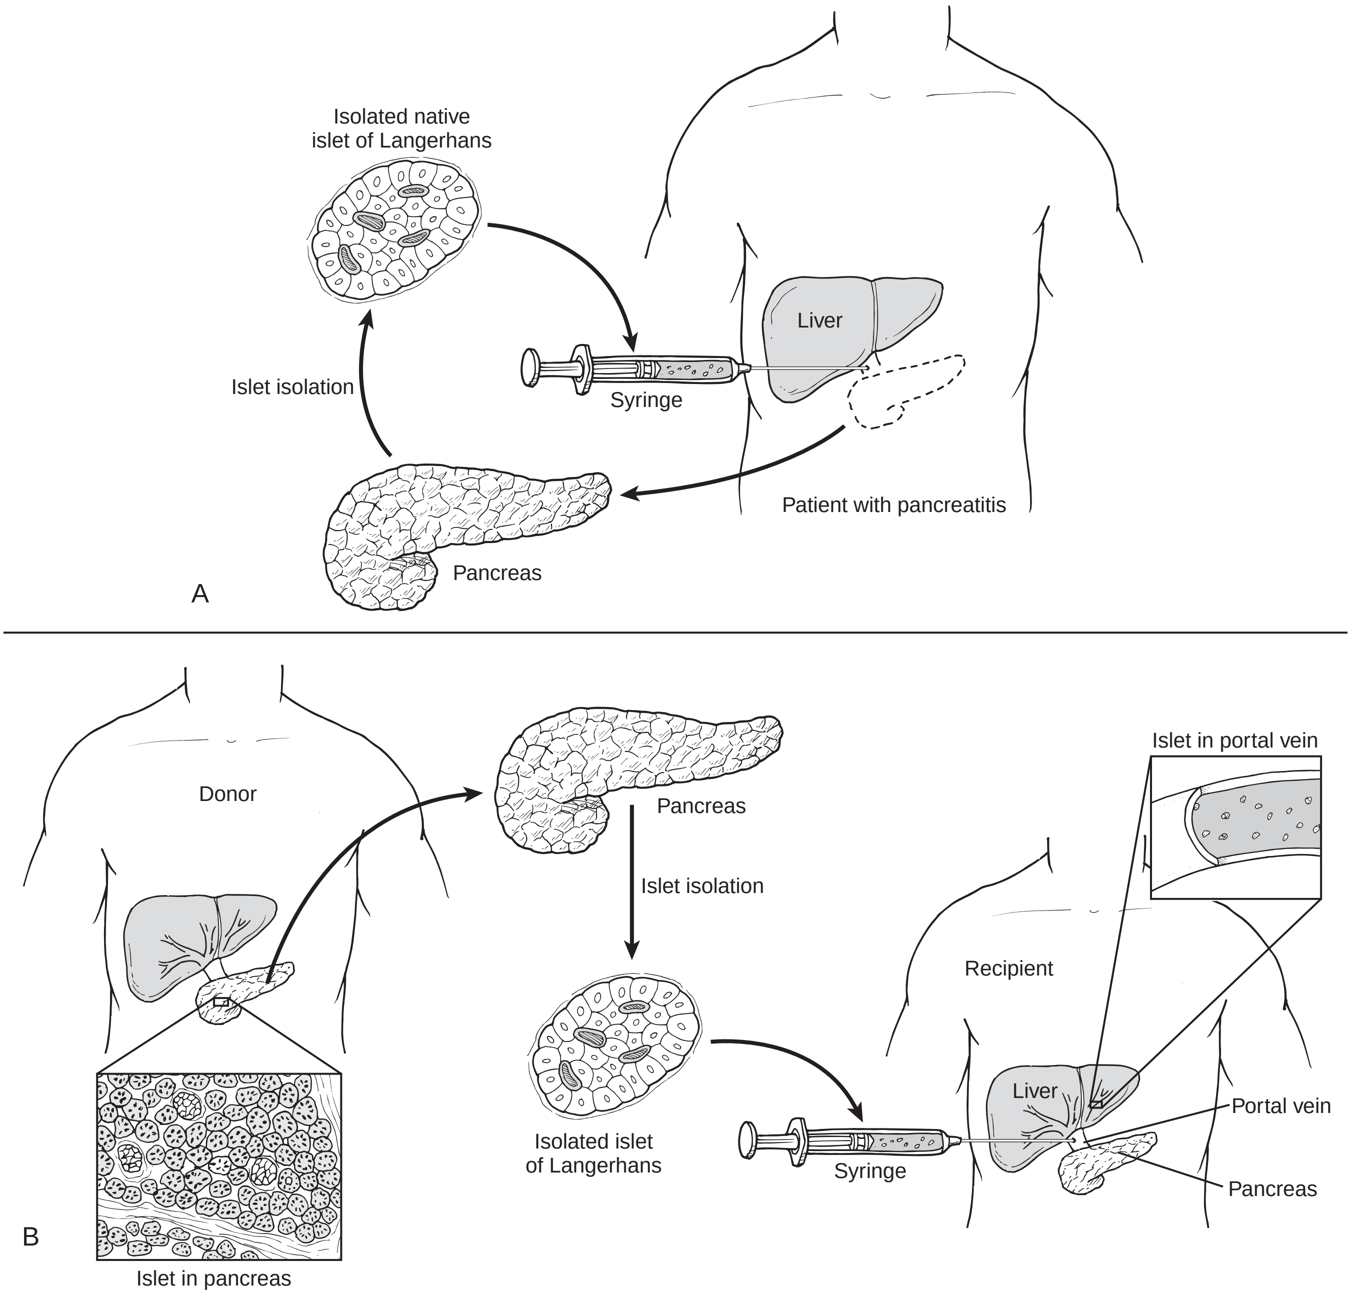

**FIGURE 47-13** Islet transplantation using the portal vein for embolization to the liver where revascularization will occur, either as an autograft of islets isolated from the excised specimen after pancreatectomy for benign disease **(A)** or as an allograft of cells isolated from a donor for treatment of a patient with type 1 diabetes **(B)**.

succeeded in achieving insulin independence with islets from a single donor pancreas.[179,180,187–191] Many of these protocols include adjunctive peritransplant anti-inflammatory and/or cytoprotective therapy, likely facilitating improved islet engraftment. Second, recent data indicate that islet allograft survival in T1D can be sustained with calcineurin inhibitor–free protocols.[188–190] Two immunosuppressive regimens, based on the costimulation blocker belatacept or the antileukocyte functional antigen-1 antibody efalizumab, were effective, well tolerated, and involved the first calcineurin inhibitor/steroid-sparing islet protocols resulting in long-term insulin independence. Although efalizumab is no longer available for clinical use, these early results demonstrate that calcineurin inhibitor–free regimens may be an effective alternative to improve graft function and longevity while minimizing renal and islet beta cell toxicity. Third, Berney and colleagues reported on the first type 1 diabetic patient who remained insulin independent for more than 10 years after islet allotransplantation.[195] Preliminary data now suggest that long-term insulin independence (>5 years) can be achieved in 50% of recipients given T-cell–depleting induction immunotherapy, matching insulin independence rates of solitary pancreas transplantation.[196] Early studies examining long-term islet function suggested a rapid loss of insulin independence beyond 1 year in many patients.[183,197] One possible factor contributing to islet loss is recurrent beta cell autoimmunity.[198,199]

Anti-CD3 antibodies and T-cell–depleting therapies, including anti-Thymoglobulin, have proved promising agents for minimizing autoimmunity in murine models of autoimmune diabetes and in clinical trials for new-onset T1D.[200–204] A recent analysis of University of Minnesota data and data reported to the Collaborative Islet Transplant Registry indicated that patients receiving an induction immunosuppression regimen that includes T-cell–depleting agents, either anti-CD3 antibody alone or either antithymocyte globulin (ATG) or alemtuzumab plus short-term TNF-α inhibition, for alloislet transplantation are more than twice as likely to maintain long-term insulin independence for at least 5 years post-transplant.[196] Three-year and 5-year insulin independence rates in these recipients are comparable with rates previously only attainable in recipients of pancreas transplants alone. Fourth, numerous reports have confirmed that human islet transplants are remarkably effective in protecting recipients with full and even partial islet graft function from severe hypoglycemia.[166,205,206] Finally, a prospective clinical trial demonstrated reduced progression of diabetic microvascular complications after islet transplantation compared with intensive medical therapy.[207] These data extend previous reports by the Milan group[208,209] and highlight the immense potential of cell-based diabetes therapy.

The unlimited and on-demand availability of xenogeneic pig islets would boost access to islet beta cell replacement. The quality of islet products from healthy, young, and living donor pigs would be predictably high and not compromised, as with human islet products, by comorbidity, brain death, age, and cold ischemia. The actual risks of infectious disease transmission from designated pathogen-free (DPF) source pigs are lower compared with risks associated with the use of deceased human donor organs.[210] Finally, genetic modification of source pigs would present opportunities for minimizing recipient immunosuppression not available to recipients of human islet allografts.[211] Thus exploiting the unique possibilities associated with porcine islet products would increase the availability and benefit-risk ratio of islet replacement therapies when compared with human islet products. The impact of such medical products on addressing unmet clinical needs in diabetes would be profound.

During the past few years, prolonged diabetes reversal exceeding 6 months has been demonstrated after porcine islet xenotransplantation in immunosuppressed nonhuman primates (NHPs) and for up to 6 months in nonimmunosuppressed NHPs.[212] Porcine C-peptide has been positive in the plasma of these recipients, and their fasting and, in some studies, also their non-fasting blood glucose levels have been in the normoglycemic to near-normoglycemic range. Perhaps most intriguing is that success has been achieved by five independent groups involving the use of various tissue sources (adult, neonatal, and embryonic pig islet tissue; wild-type and transgenic), implantation sites (portal vein, omental pouch, subcutaneous space), immunosuppressive protocols (with and without anti-CD154 monoclonal antibodies or encapsulation, avoiding immunosuppression), and animal models (streptozotocin-induced and surgical diabetes; in cynomolgus and rhesus monkeys).[213–216] Collectively, the demonstration of prolonged functional islet xenograft survival in nonhuman primates with several distinct xenotransplantation strategies suggests that porcine islet products could potentially be developed into a more widely available cellular therapeutic for T1D.

Although a transition from pancreas to islet transplantations as the dominant form of beta cell replacement therapy may occur during the next few years, pancreas transplantations will not disappear entirely. Patients with high pretransplantation insulin requirements, in whom diabetes reversal with islet transplantations is less likely, would best be served with a vascularized pancreas transplant, at least as long as other more unlimited sources of beta cells, such as porcine islets, are not available for clinical therapy. Furthermore, diabetic patients with exocrine deficiency would best be served by an enteric-drained pancreas transplant. In addition, in patients who have very high insulin requirements or insulin resistance (type 2 diabetes), an intact organ may be needed to obtain a sufficient islet mass to restore insulin independence from a single donor in the presence of insulin resistance.

Tissue availability will be the limiting factor in determining the magnitude of the impact of beta cell replacement therapy. Six thousand deceased donors are available each year in the United States, but it is estimated that only half have a pancreas suitable for transplantation. Thus the maximal number of pancreas transplantations that could be done in the United States is 12,000 per year, assuming that each deceased pancreas could be split for use in two recipients,[217] and that living donors would be used for segmental pancreas transplantations[61] to the extent that they have been for kidney transplantations (currently about 6000 per year in the United States). This scenario has not yet materialized, but the potential is there to transplant at a rate approaching half of the annual incidence of new-onset cases of type 1 diabetes (30,000/year in the United States). The numbers could be increased further if enough islets could be isolated from one donor for transplantations into more than two recipients. Although the efficacy of islet transplantation protocols will continue to improve, and the procedural and immunosuppressive risks now associated with islet transplantations will continue to diminish, islet transplantations will not be the ultimate approach to diabetes care. Just as pancreas transplantations set the stage for islet transplantations, the real value of islet transplantations will be to create and build momentum for the development of xenogeneic and stem/precursor cell–derived islet beta cell therapy[218] that will then make cell replacement therapy routine and commonplace in diabetes care.

Pancreas transplantations, and eventually islet transplantations, should be in the armamentarium of every transplantation center for the treatment of diabetic patients. Likewise, every endocrinologist should consider beta cell replacement in the treatment of patients in whom type 1 diabetes is complicated by hypoglycemia-associated autonomic failure[219] and/or progressive microvascular complications. Continued clinical research on pancreas and islet transplantations is needed to identify the most appropriate recipient population, the optimal timing in the course of diabetes, and the most suitable donor tissue and transplantation protocol for a given patient. Both pancreas and islet transplants need to be made as economical as possible.[220] Studies such as those done in pancreas-kidney transplant recipients, showing the efficiency in the treatment of complicated diabetes,[221] are needed in islet recipients as well. Currently, beta cell replacement has a well-defined clinical role for adult patients with

incapacitating hypoglycemic unawareness and is also appropriate in children and adults who otherwise need immunosuppression, such as for a kidney transplantation. As antirejection strategies become safer and with fewer side effects, the indications for pediatric beta cell replacement therapy can be liberalized.

CHAPTER 48

# Liver Transplantation

Bob H. Saggi, Douglas G. Farmer,
and Ronald W. Busuttil

The treatment of liver disease in children with transplantation has its roots in the origin of liver transplantation itself, with the initial cases performed by Thomas E. Starzl on two children in 1963 and 1968.[1] Although the initial results were disappointing, during the ensuing 2 decades, liver transplantation developed into the standard therapy for decompensated cirrhosis, certain malignancies of the liver and biliary tract, acute liver failure, and many metabolic derangements. The National Institutes of Health Development Conference designated it as such in 1983, and the National Organ Transplantation Act created a nationally regulated system of organ allocation in 1987. The United Network for Organ Sharing (UNOS) was subsequently created and currently regulates the field through a peer review process. In 2009, 6320 liver transplantation procedures were performed in the United States, and of these, 572 were in the pediatric population.[2] This number of transplantation procedures has remained relatively stable since the late 1990s, although an increasing number of "partial" liver grafts from cadaveric and living donors are now being used. Pediatric liver transplantation offers unique challenges because of size, perhaps enhanced immune responsiveness, and the paucity of donor organs. Although nearly 65% of pediatric liver transplantation recipients are less than 6 years of age, only 25% of the pediatric cadaveric donor population comes from this same age group (Fig. 48-1).[2] As a consequence, achieving success in this arena requires technical perfection, both from the standpoint of obtaining a suitable graft and performing a meticulous transplantation operation. With reduction in transplantation waiting time and with improvements in immunosuppression, surgical technique, and long-term post-transplantation care, survival has markedly improved and now exceeds 90% at 1 year and 80% at 5 years, with many children surviving into adolescence and adulthood with a good quality of life.[3,4] In this chapter, we review the major indications for liver transplantation in children, the basic pathophysiology and clinical presentation of liver failure, operative strategies with emphasis on the unique surgical options available to children, postoperative management with emphasis on management of surgical complications, and outcome analysis.

## Indications and Pretransplant Care

### INDICATIONS FOR LIVER TRANSPLANTATION

Liver transplantation is currently indicated for children with decompensated cirrhosis because of cholestatic and noncholestatic causes, acute hepatic failure, some metabolic liver diseases, select tumors, and a variety of miscellaneous indications (Fig. 48-2). The general indication for liver transplantation in children is liver disease that limits long-term survival or quality of life, or markedly impairs normal growth and development. Cirrhosis alone is not an indication for transplantation, because many patients can be medically managed for a prolonged period prior to decompensation. In acute liver failure, the development of clear symptomatology, such as refractory coagulopathy, acidosis, and encephalopathy that correlate with a poor prognosis for spontaneous recovery of liver function, is an indication for transplantation. Otherwise, medical support in those with a better prognosis is provided until liver function returns to normal.[5,6] Finally, metabolic inborn errors of metabolism are a unique and not uncommon indication for transplantation in children, making up 9% of transplantation in children compared with approximately 2% in adults. Parenteral nutrition–associated liver disease accounts for 8% of liver transplantations, and less than 1% of adults are transplanted for this reason. Most of these transplantations are combined with an intestinal graft (Chapter 49).

With long-standing cirrhosis, the development of a constellation of symptoms and signs that represent decompensation of hepatocellular function or portal hypertension herald a need for transplantation. These include progressive jaundice, coagulopathy, protein-calorie malnutrition and growth retardation, impaired cognitive development, encephalopathy, hypersplenism, variceal hemorrhage, and advanced or refractory ascites. The majority of patients undergoing transplantation in this population are deeply jaundiced because of secondary or primary biliary cirrhosis from long-standing intrahepatic and/or extrahepatic biliary obstruction. On physical examination, these patients often have muscle wasting, an enlarged spleen, a hard palpable liver, abdominal distention

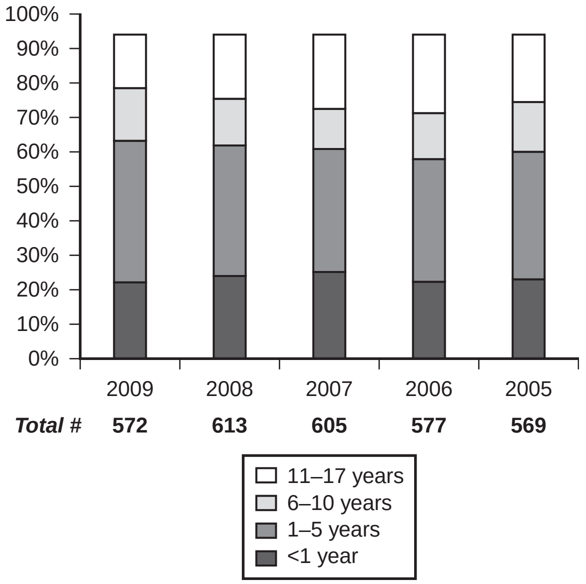

FIGURE 48-1 Distribution of pediatric liver transplantations by age. Data obtained from www.unos.org.

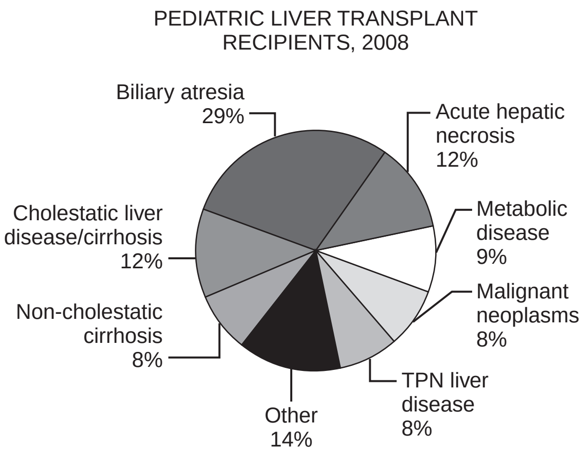

FIGURE 48-2 Indications for pediatric liver transplantation. Data obtained from www.unos.org, based on 2008 transplantations. TPN, total parenteral nutrition.

from ascites, and peripheral edema. With decompensation, long-term survival without liver transplantation is limited, and referral for transplantation must be made prior to decompensation.[3,7–9]

## CHOLESTATIC LIVER DISORDERS

The most common indications for liver transplantation are the cholestatic liver disorders, with the most common being biliary atresia (BA). This group accounts for roughly 40% of the transplantation performed on children in 2008, and BA accounts for 70% of this cholestatic group (see Fig. 48-2).[2] The management of BA rests on early diagnosis, using surgical exploration with biopsy as the central confirmatory test in most cases. The diagnostic workup is detailed in Chapter 105. Portoenterostomy (PE) is the preferred treatment if diagnosis precedes the development of cirrhosis, usually before 3 months of age, though long-term results from PE are optimal if it is done prior to 8 weeks.[10] This procedure is essential for slowing, and, in some cases, arresting, the progression of liver disease to cirrhosis and portal hypertension. Unfortunately, despite effective biliary drainage, more than 70% of patients will go on to develop decompensated cirrhosis by the age of 5 years and require transplantation.[10,11] However, in many cases, PE allows reasonable growth so that transplantation is forestalled until the child is older and larger. Primary PE performed late in the course of BA and reexploration for a failing biliary drainage procedure are both usually unsuccessful and only complicate transplantation outcomes. Instead, once a PE has failed, patients should be evaluated for transplantation. Liver transplantation is indicated when the diagnosis is made beyond 3 months of age, when decompensated cirrhosis is clearly present at any age, or after a PE has failed. Patients with BA should be managed by a pediatric hepatologist experienced in transplantation to ensure early referral for transplantation. This should occur prior to severe liver decompensation when signs are obvious on physical examination, especially with an advanced presentation at a late stage (Fig. 48-3).

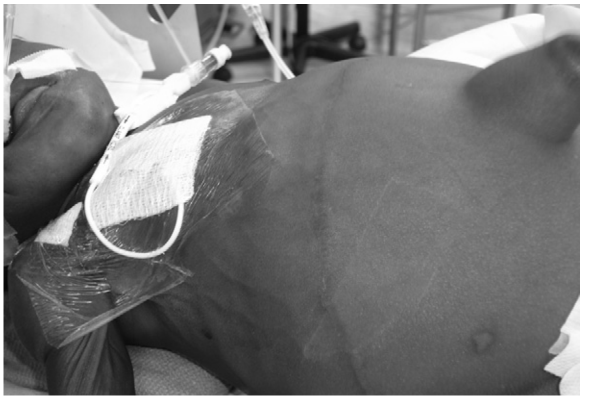

FIGURE 48-3 Decompensated cirrhosis after a Kasai portoenterostomy. This 6-month-old, 5-kg child presented for liver transplant with the advanced findings of hepatosplenomegaly, extensive abdominal wall venous collaterals, tense ascites, jaundice, and profound malnutrition.

Other uncommon etiologies of cholestatic liver injury and cirrhosis include familial paucity of intrahepatic bile ducts, which exists in a syndromic (Alagille syndrome) and nonsyndromic form, familial cholestatic syndromes, primary or secondary sclerosing cholangitis, and uncorrectable choledochal cyst disease, including Caroli disease. The cystic diseases have a component of uncorrectable extrahepatic obstruction while the others are the result of malformation or destruction of intrahepatic bile ducts and/or arterial systems. All these share in common a variable and unpredictable progression to advanced fibrosis, cirrhosis, and portal hypertension. These patients typically present with progressive jaundice at an older age than patients with BA. Although their management does not entail a PE, the indications for transplantation in these patients follow the same rationale as that for BA.

## NONCHOLESTATIC CIRRHOSIS

Noncholestatic cirrhosis is an uncommon indication for liver replacement in children, accounting for less than 10% of all procedures performed in 2008 (see Fig. 48-2).[2] These children usually present later in life than the cholestatic disorders.

Etiologies of cirrhosis and decompensated cirrhosis in these patients include chronic autoimmune hepatitis, neonatal hepatitis, chronic viral (B or C) hepatitis, and cryptogenic cirrhosis.

### ACUTE LIVER FAILURE

Fulminant hepatic failure is usually defined as the onset of encephalopathy within 28 days after the onset of jaundice in a patient with acute liver failure without evidence of chronic liver disease. The hallmarks of acute liver failure include profound coagulopathy, acidosis, hypoglycemia, and progressive hyperbilirubinemia. Acute liver failure patients can develop acute renal failure, systemic inflammatory response with multiorgan failure syndrome, or cerebral edema progressing to herniation. Early referral is essential to avoid progression to a condition that contraindicates transplantation. A variety of criteria to determine the need for transplantation have been devised in European centers, where these patients are managed in a highly structured and centralized manner.[12] The most common established etiology in children is viral hepatitis, followed by acetaminophen and other drug toxicities and Wilson disease. However, in nearly two thirds, an etiology cannot be identified. Liver transplantation is the only acceptable therapy in patients who meet the criteria of fulminant hepatic failure, and early referral of all patients with acute liver failure is essential.[5,6]

### METABOLIC LIVER DISEASE

These disorders have in common an enzyme deficiency or some other defect in hepatocellular function. This impairment can result in progressive fibrosis or cirrhosis (e.g., cystic fibrosis, chronic Wilson disease, and neonatal iron storage disease), with a typical presentation of decompensated cirrhosis. In other cases, the liver is structurally normal, but harmful byproducts of metabolism accumulate to cause neurologic injury (e.g., Crigler-Najjar syndrome, ornithine transcarbamylase deficiency, and acute Wilson disease), cardiovascular disease (e.g., familial hypercholesterolemia), or renal injury (familial hyperoxaluria). Some disorders are associated with the development of malignancies (e.g., tyrosinemia), and transplantation should be considered preemptively. Transplant evaluation of all patients with known metabolic disorders of the liver involves a thorough evaluation of extrahepatic function. This will ensure transplantation of only those patients who can benefit from liver transplantation and prevents progression of extrahepatic disease. In some patients, simultaneous or sequential or dual organ transplantation may be necessary (e.g., lung, kidney, heart).

### TUMORS

The most common liver malignancy in children is hepatoblastoma.[13,14] Although sporadic cases have been reported, hepatocellular carcinoma (HCC) is primarily seen in children with viral hepatitis, tyrosinemia, some of the glycogen storage diseases, or in association with cirrhosis from other causes. Primary liver malignancies in pediatric patients are managed by surgical resection unless tumor size and/or location preclude resection. The benefit of neoadjuvant and/or adjuvant chemotherapy and radiation for hepatoblastoma has been well documented.[15–17] In HCC, multimodal therapy can be used to prevent further cancer progression or perhaps to improve the outcome of highly selected patients with advanced HCC. Both may benefit from preoperative transarterial chemoembolization and/or radiofrequency ablation.[18] If the lesion is unresectable, transplantation can be considered after excluding extrahepatic disease.[15,17] With multimodal therapy to include liver transplantation, the long-term survival with hepatoblastoma now exceeds 50%, while outcomes from HCC are in excess of 70%.[15,17,19] The major controversy that exists is whether transplantation should be attempted for large hepatoblastomas primarily or as a salvage after recurrence following resection, and whether focal lung metastases contraindicate transplantation if they can be resected The most common benign tumor of the liver is hemangioendothelioma, and although the vast majority regress with growth and medical therapy, occasionally, progression of heart failure or mass effect warrants transplantation.[13,19]

### MISCELLANEOUS CONDITIONS

These conditions include diagnoses such as Budd-Chiari syndrome, trauma, biliary cirrhosis secondary to intestinal failure, and long-term total parenteral nutrition (TPN) use. The latter is detailed in Chapter 49.

## Organ Allocation and Pretransplant Care

Patients who have evidence of decompensated cirrhosis are candidates for liver transplantation. However, the small size of the pediatric patient combined with a nationwide shortage of organs relative to wait-listed patients makes achieving transplantation in a timely fashion problematic. In 2008, there were 613 pediatric liver transplantations performed. In that same year, there were 773 pediatric-aged cadaveric liver donors. The problem with a discrepancy between donors and recipients is primarily a problem in the less-than-6-year age category, where there were 423 liver recipients but only 274 donors.[2] Another problem is, of course, timing: When a pediatric donor is available, there is not necessarily a size-matched pediatric recipient available. This creates a relative shortage of organs that necessitates a system to allocate these scarce organs to those who will derive the most benefit. Since 2002, the Pediatric End-Stage Liver Disease (PELD) score was implemented to allocate organs based on this "sickest first" paradigm.[9] The PELD score consists of five variables: international normalized ratio (INR), total bilirubin, serum albumin, growth retardation ($\geq$2 standard deviations below the median height or weight for age), and young age ($<$1 or 1 to 2 years). Status I-A is used to designate patients with fulminant hepatic failure, primary graft nonfunction after transplantation, early hepatic artery thrombosis, and miscellaneous acute conditions. Unlike adults, pediatric patients with decompensated cirrhosis requiring intensive care unit (ICU) stay for accepted reasons, and occasional exceptions can be listed as status I-B. This is because their mortality is high despite an often minimal change in PELD score with a decompensation requiring ICU stay. In an effort to ameliorate the shortage of potential organs, the livers of all donors 18 years of age and younger are preferentially allocated to pediatric recipients before being offered to adults.

Also, in 2006, organ allocation policy was changed so that rather than allocating livers from donors less than age 18 years locally, they are allocated at a regional level to children to increase the probability of use of the organ in pediatric patients and to facilitate liver splitting. These changes in organ allocation combined with the widespread use of split-liver transplantation (see later) has markedly reduced waiting times and positively impacted wait list mortality.[3,20]

# Donor Procurement and Hepatobiliary Anatomy

## HEPATOBILIARY ANATOMY

The performance of a donor hepatectomy or transplant operation requires a thorough understanding of foregut anatomy. In addition, a very detailed understanding of this anatomy is essential to the field of segmental liver transplantation and has impacted hepatobiliary surgery. The blood supply to the liver is based on a highly variable arterial and portal system. Venous drainage is through the right, mid-, and left hepatic veins that join the inferior vena cava, which traverses the dorsal surface of the liver (the retrohepatic cava). The liver is composed of the major right and left lobes that are separated by external landmarks and further subdivided into the right anterior and posterior sectors and left medial and lateral sectors. This nomenclature is still used to describe major anatomic liver resections. However, through the elegant anatomic techniques of the pioneering surgical anatomist Claude Couinaud, hepatic anatomy was found to be much more intricate (Fig. 48-4). The "Couinaud nomenclature" describes nine hepatic segments based on portal vein branching in relationship to the transverse plane (a cross-sectional plane located at "midpoints" of the hepatic veins) and the longitudinal planes of the individual hepatic veins (see Fig. 48-4). Each of the segments is supplied by an independent portal and hepatic arterial branch and drained by an independent biliary radicle. The biliary tree is second only to the arterial system in its variability. The hepatic venous drainage is intersegmental.

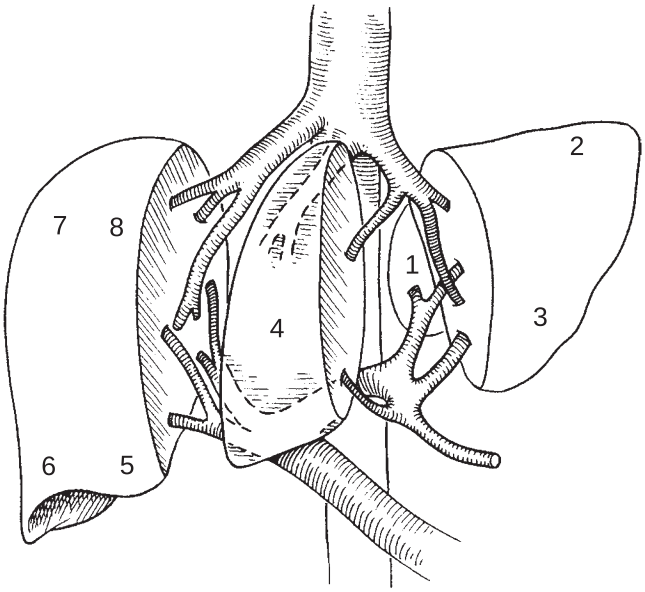

FIGURE 48-4 Segmental liver anatomy. The division of the liver into independently vascularized and drained segments is based on the parallel bifurcation of the portal vein and hepatic artery.

# Donor Operation

The use of organs from cadaveric donors in pediatric liver transplantation involves selecting an appropriate quality and size-matched donor, organizing an experienced transplantation harvest team, and performing a precise technical operation that recognizes arterial anatomical variants and allows for multiorgan procurement. The advent of segmental liver transplantation has expanded the acceptable donor age to approximately 40 years. Preharvest donor management should focus on maintenance of hemodynamic stability with adequate but not excessive volume loading, the minimization of vasopressors, optimization of oxygenation without excessive use of positive end-expiratory pressure (PEEP), and correction of hypernatremia that results from diabetes insipidus. In the stable donor, once these goals are achieved, the procurement operation can be performed. In the properly selected unstable donor, unnecessary delays are to be avoided, because expedient hypothermic perfusion and cold storage only help minimize the ongoing organ ischemia.

The donor operation begins with midline laparotomy and median sternotomy for wide exposure (Fig. 48-5). The abdominal great vessels are exposed by a medial visceral rotation of the right colon and small intestine, and the aorta and inferior mesenteric vein are cannulated. The liver quality is assessed, and the biliary tree is flushed via the gallbladder. After full systemic heparinization, the supraceliac aorta is cross-clamped, and the intrapericardial inferior vena cava is incised to exsanguinate the donor. Then cold-organ perfusion is begun through the previously placed cannulas, and the abdominal cavity is immersed in ice to attempt achieving a liver core temperature of 4°C. University of Wisconsin (UW) solution has been used as the standard solution in the United States since 1987 when it was developed by Belzer and Southhard. This solution extended the limit of preservation to as long as 12 to 18 hours, after which the incidence of primary

FIGURE 48-5 Cadaveric organ procurement. A wide exposure with median sternotomy extending to midline laparotomy is made for multiorgan procurement. This harvest resulted in the procurement of six organ grafts from a single recipient, benefiting six different recipients.

graft failure increases substantially. However, the acceptable preservation time depends on numerous donor and recipient variables and should still be minimized when possible. This is particularly the case with reduced-size or split-liver transplantation. The UW solution is a hyperkalemic, hyperosmolar solution that prevents cell swelling, maintains stable transmembrane electrical gradients upon reperfusion, by preventing efflux of intracellular potassium during storage, and contains a variety of oxygen free radical scavengers. Many centers are now using a histidine-tryptophan-ketoglutarate solution because of its lower potassium content and viscosity.[21] Once procured, the harvest team typically transports the liver graft to the transplantation center and prepares it for engraftment for a separate recipient team.

## Segmental Liver Transplantation: Living Donor, Reduced Size, and Split

The shortage of pediatric organs coupled with a significant wait-list death rate has driven the development of alternative organ sources. Three alternatives to use of a whole organ graft are available to these patients: living donor, reduced-size and split-liver grafts.[7,20,22,23] Living donor transplantation was developed as an alternative to scarce whole organ grafts and typically uses a segment 2 and 3 (left-lateral sector, LLS) graft. Because of the small but real risk of safety in a healthy donor, reduced-size transplantation was simultaneously developed as an alternative and involves resecting the LLS graft prior to or after cold-organ perfusion and discarding the remaining liver. Obviously, this benefits the pediatric recipient but wastes an organ that could be used by an adult recipient. Splitting the whole organ into a right trisegment and LLS graft to use in an adult and pediatric recipient, respectively, was first reported by Pichlmayr in Hanover in 1988. This can be done either prior to cold organ perfusion (in-situ technique) (Fig. 48-6) or after cold-organ perfusion and removal of the liver from the donor (ex-vivo technique).[22] This provides a suitable graft for the pediatric population without worsening the already severe organ shortage in the adult population. Although the initial results were discouraging, with increased experience, the survival rates of patients and grafts are nearly equal to whole organ and living donor transplantation, though the risk of vascular and biliary complications is somewhat higher.[27,23–25] At the University of California in Los Angeles (UCLA), we are only performing living donor transplantations when a whole or split graft is not available in a timely fashion or for special indications. There has been a marked reduction in transplant wait time since the routine use of segmental grafts with this strategy.[3,20,23]

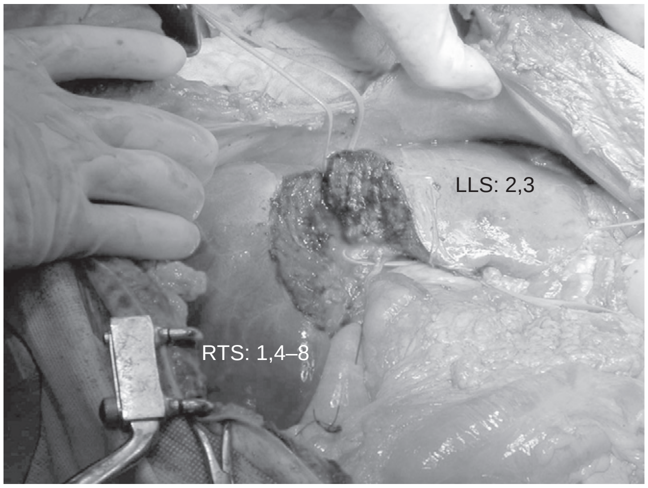

**FIGURE 48-6** Cadaveric in-situ split-liver procedure. The liver is separated just to the left of the umbilical fissure into a right trisegment (RTS) graft and a left-lateral segment (LLS) graft.

## Liver Transplant Operation

The performance of the whole organ cadaveric liver transplant procedure has changed little during the last 2 decades. Although there are tremendous individual and institutional differences in the subtleties and how certain techniques are used or not used, the basic steps in the procedure remain the same. What follows is a description of how the procedure is generally performed at UCLA today and has been applied in more than 3000 cases.[26] The procedure can be roughly divided into four major phases, each with its own anatomic and physiologic challenges: hepatectomy phase, anhepatic phase with engraftment, reperfusion with arterialization, and biliary reconstruction. Perhaps the most challenging step during liver transplantation is the hepatectomy. Coagulopathy, portal hypertension, and poor hepatic and renal function create a surgical environment wherein continuous bleeding is possible. During this phase, the anesthesiologist plays a key role in maintaining volume by rapid transfusion, correcting coagulopathy and fibrinolysis, and maintaining body temperature. The goal of this phase is to devascularize the liver by ligating and dividing the hepatic artery and portal vein as well as to mobilize the suprahepatic and infrahepatic vena cava to enable removal. These goals are achieved while leaving in the recipient adequate lengths of each vessel for later implantation of the donor graft. In the majority of pediatric liver transplant operations, the retrohepatic vena cava is retained as the liver is dissected off the vena cava by dividing the tributaries from the right and caudate lobes, and often only partial occlusion of the vena cava is necessary. Meticulous but expedient surgical technique is essential during the hepatectomy to ensure optimal patient outcome. During the anhepatic phase, the anesthesiologist must support certain aspects of hepatic function to prevent or treat acidosis, hypothermia, coagulopathy, and occasionally fibrinolysis. In addition, they must ensure adequate circulating volume and maintain hemodynamic stability. In children, venovenous bypass is rarely used.

While the patient is anhepatic, the liver graft is taken out of hypothermic storage and engrafted. This begins with the suprahepatic caval, followed by the infrahepatic caval and the portal anastomoses. If the retrohepatic cava was retained, the “piggyback” technique is used, in which the suprahepatic cava of the graft is sewn to the cloacae created from the confluence of the recipient hepatic veins, and the donor infrahepatic cava is ligated (Fig. 48-7). Prior to reperfusion, the liver is flushed with a cold colloid and albumin solution through the donor portal vein to lessen the potential reperfusion-associated complications.

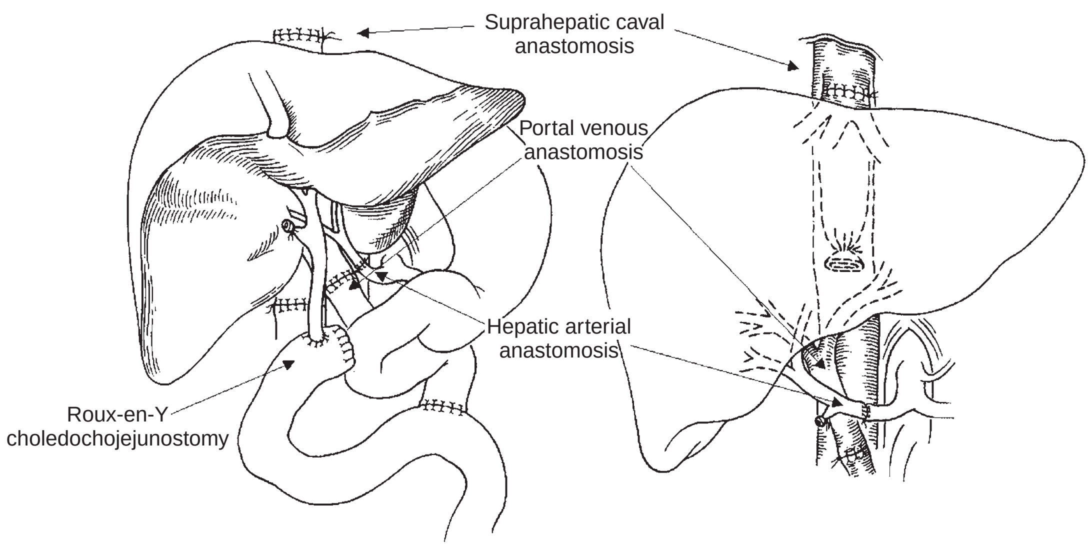

**FIGURE 48-7** Whole organ engraftment. Both the standard orthotopic and "piggyback" techniques are depicted.

Reperfusion is then undertaken in a controlled manner. Communication between the surgical and anesthesia teams is essential to allow the anesthesiologist time to institute preparative and preventive measures. Reperfusion is undertaken by first removing the suprahepatic vena cava clamp, then the infrahepatic vena cava clamp and, lastly, the portal venous clamp. As blood is reintroduced into the liver allograft and allowed to drain into the right atria, many serious and life-threatening complications can develop. The major challenges encountered by the anesthesiologist at this point are life-threatening hyperkalemia, acidosis, arrhythmias, and hemodynamic instability with or without surgical or coagulopathic bleeding. Factors that contribute are the return of cold, acidotic, and hyperkalemic blood directly into the right atrium. It is at this point that maintenance of physiologic stability by the surgeon and anesthesiologist in the preceding phases, the preoperative state of the recipient, and the intrinsic quality of the graft converge to determine early graft function as well as the course of the remainder of the operation. Without a doubt, this is one of the most hazardous portions of the liver transplant process.

The hepatic arterial anastomosis is then performed. In general, arterial inflow is obtained from one of the branches of the celiac trunk. However, in some instances, inflow from these vessels is not adequate, thus necessitating the use of aortic conduits. A conduit can be placed either on the supraceliac or infrarenal aorta. In some cases, when the arteries are of very small caliber (<3 mm), the arterial anastomosis is performed prior to reperfusion. The biliary tree is then reconstructed by choledochocholedochostomy or by Roux-en-Y choledochojejunostomy, the latter being more common in small children and used exclusively in partial liver grafts because of the size of the donor duct (Fig. 48-8). After ensuring sufficient hemostasis, drains are placed and the abdominal cavity is closed. The patient is then transferred directly to the ICU. Segmental transplantation, using split, reduced-size, or living donor grafts, involves variations in the manner in which the anastomoses are performed, but the general steps are the same (see Fig. 48-8).

# Post-transplant Care

## EARLY POSTOPERATIVE CARE

The early and long-term postoperative care of the liver transplant recipient is almost as important as the performance of the operation in ensuring optimal outcomes. The immediate postoperative care is aimed at assessing graft function, providing supportive care for the recipient, and early detection of complications. Graft function can be assessed in many ways. Physiologic and clinical assessment can be done almost immediately with a warm, arousable, hemostatic, and hemodynamically stable patient whose liver is making "golden-brown" bile (in the infrequent case where a biliary drainage tube is placed),

characteristics that are the hallmarks of a functional graft. Graft function is then confirmed biochemically by evidence of synthetic and metabolic function (e.g., correcting prothrombin time, reversal of acidosis). The degree of preservation injury, as measured by liver enzyme levels, does not linearly correlate with graft function, but grafts with severe injury are more likely to exhibit delayed function or nonfunction. Failure of a graft without vascular compromise (primary nonfunction [PNF]) is treated by retransplantation in almost all cases, with outcome directly related to the time to retransplantation. The incidence of PNF in pediatric patients is 5% to 10%.[7,8,23,24,27]

# Technical Complications

Technical complications can be divided into vascular, biliary, and general surgical complications. In the early postoperative period, infectious and general surgical complications of liver transplantation today are similar to those that occur after any major abdominal operation. However, the incidence of fungal infection is higher, and the incidence of bowel perforation in pediatric recipients is as high as 19% in some series. Also, early exploration or computed tomography (CT) imaging should be considered when sepsis is suspected and no other etiology can be found.

### VASCULAR COMPLICATIONS

Major vascular complications include hepatic artery thrombosis (HAT), portal vein thrombosis, and caval thrombosis or stenosis. Intravenous low-dose unfractionated heparin with or without low-molecular-weight dextran is routinely used for prophylaxis against vascular thromboses. Duplex ultrasonography and computerized tomographic or conventional angiography are accepted means of diagnosis. HAT is the most common complication, and its incidence varies from 5% to 18% depending on patient age and type of graft.[7,8,23,24,27,28] Early vascular complications are usually technical in nature, while immunologic and infectious (e.g., cytomegalovirus [CMV]) etiologies have been ascribed to those occurring months after transplantation. HAT occurring in the first week is commonly associated with graft nonfunction and biliary necrosis or leak, while those occurring later do not necessarily affect graft function immediately, but usually produce biliary complications. These include intrahepatic biliary abscesses, biliary anastomotic stricture, and sclerosing cholangitis with sepsis, all of which lead to significant morbidity. If diagnosed early, some patients can be managed by thrombectomy and surgical revision. However, most early HATs require urgent retransplantation. Late HATs with preserved graft function can be managed by radiologic interventional techniques and retransplanted remote from initial transplantation. Thrombosis of the portal vein occurs in 2% to 4% of pediatric liver transplantations and is usually associated with loss of the graft. Prompt retransplantation is required for patient salvage. Late portal vein thrombosis usually presents with recurrent variceal bleeding or ascites and can be managed medically, endoscopically, or surgically with shunting or retransplantation. Vena caval or hepatic vein thrombosis or stenosis occurs in 3% to 6% of pediatric patients and presents with variceal bleeding and/or ascites and is usually best managed with balloon dilation in interventional radiology[7,8,23,24,27,28]

### BILIARY COMPLICATIONS

Biliary complications that are not associated with HAT occur in 3% to 20% of patients depending on the type of graft and whether a choledochojejunostomy was used. These usually result from technical factors, but occasionally warm ischemia or immunologic and infectious factors can be implicated (e.g., CMV). Diagnosis is by cholangiography and treatment can be by endoscopic or radiologic intervention or by surgical revision.[7,23–25,27]

# Immunosuppressive Therapy and Rejection

Immunosuppression for liver transplantation in the modern era rests on a class of drugs known as calcineurin inhibitors (CNI), the prototype being cyclosporine (Table 48-1). Cyclosporine, especially its microemulsion formulation, which allows better bioavailability and more consistent therapeutic levels, revolutionized organ transplantation by reducing the incidence of rejection in all solid organs. The second-generation CNI, tacrolimus, was first used clinically in 1990. The greater potency of tacrolimus allowed for a further reduction in the early incidence of rejection following liver transplantation, while also allowing the earlier weaning of steroid therapy. Also, the incidence of chronic rejection has significantly decreased with the use of tacrolimus, which can also effectively treat episodes of acute rejection. Currently, most liver transplant centers use a tacrolimus-based regimen combined with steroid therapy with or without adjunctive agents. Cyclosporine and tacrolimus share certain acute and long-term side effects while having some that are unique to the agent. The most important of these is nephrotoxicity, which occurs in an acute variety from vasoconstriction of the afferent renal arterioles and is reversible, as well as a more chronic variety marked by tubular atrophy, interstitial fibrosis, and glomerulosclerosis. The latter is variably reversible depending on the degree of disease. To minimize acute toxicity and to allow lower early CNI levels, especially with pretransplant renal insufficiency, a purine antimetabolite, mycophenolate mofetil, is sometimes used as an adjunctive agent (see Table 48-1). The newest class of immunosuppressants is the inhibitors of mammalian target of rapamycin, the prototype being sirolimus. This agent has been used sparingly in pediatric liver transplantation, and only preliminary data exist. Although this drug has no nephrotoxicity, it has other long-term sequelae, such as hypercholesterolemia. No perfect immunosuppression (i.e., one with minimal side effects) has been developed yet.

Acute rejection (AR) is common in pediatric liver transplantation, with the peak incidence being within the first 6 months, during which 30% to 50% of patients experience at least one episode.[7,8,23,27] It is less common after the first post-transplant year, occurring in 10% or less of patients. AR is suspected with elevated aspartate or alanine transaminase levels or by elevated alkaline phosphatase levels and gamma-glutamyl transferase levels. AR is an alloantigen specific, T-cell–mediated inflammatory process that targets

**TABLE 48-1**
**Modern Immunosuppressants Used in Liver Transplantation**

| *Name* | *Mechanism of Action* | *Principal Use* | *Common Toxicities* |
|---|---|---|---|
| Calcineurin inhibitors (CNI) cyclosporine tacrolimus | Exact and complete mechanism unknown; inhibits IL-2 and other cytokine gene transcription, thus preventing T-helper cell expansion | Induction and maintenance of immunosuppression long term; tacrolimus is the only agent approved for monotherapy, while cyclosporine must generally be used with another agent long term | Shared: nephrotoxicity, hypertension, hyperglycemia, neurotoxicity (seizures, myoclonus, essential tremors) Cyclosporine: hirsutism, gingival hyperplasia, more diabetes Tacrolimus: diarrhea, anorexia, more neurotoxicity, more hypertension |
| Glucocorticoids methylprednisolone prednisone | Diffuse action on immune system by its anti-inflammatory properties, especially inhibition of IL-1 | Induction of immunosuppression and maintenance; may be weaned off long term in some patients | Hyperlipidemia, osteopenia, hypertension, diabetes, impaired wound healing, growth retardation, Cushingoid features, striae, acne |
| Mycophenolate mofetil | Purine antimetabolite, semiselective for salvage pathway present primarily used in lymphocytes | Used as an adjunctive agent to reduce the dose of CNI or steroid | Myelosuppression, diarrhea, anorexia, nausea, vomiting, GI mucosal ulceration |
| Mammalian target of rapamycin inhibitors rapamycin | Inhibits cell cycle progression in stimulated cells, thus preventing clonal expansion of stimulated B and T cells | Unclear, use in pediatric patients preliminary; may be useful in minimizing CNI dose when toxicity exists or in refractory AR or chronic allograft rejection | Hyperlipidemia, impaired wound healing, pneumonitis, oral ulceration |
| OKT3 monoclonal antibody | Clonal deletion of (CD3+) T cells | Severe or refractory acute allograft rejection | SIRS and other infusional reactions, increased risk of viral infections and PTLD |
| Antilymphocyte globulin (Thymoglobulin) | Exact and complete mechanism unknown, but produces central and peripheral deletion of lymphoid cells | Severe or refractory acute allograft rejection | Increased risk of viral infections and PTLD, lower incidence of infusional reactions than OKT3, thrombocytopenia |
| IL-2 receptor antagonists basiliximab daclizumab | Competitive inhibition of IL-2 receptors | Induction of immunosuppression as an adjunct to CNI; used to minimize other immunosuppression (CNI, steroids) | Increased risk of viral infections, possible PTLD, rare infusional reactions |

AR, acute rejection; GI, gastrointestinal; IL-1, IL-2, interleukin-1, interleukin-2; PTLD, post-transplant lymphoproliferative disorder; SIRS, systemic inflammatory response syndrome.

vascular endothelium and biliary epithelium but not hepatocytes. This is based on the greater expression of donor human leukocyte antigens on the former cell types. The histologic hallmark of AR is a mixed cell inflammatory infiltrate (polymorphonuclear cells, lymphocytes, and eosinophils) in the portal triad, with evidence of inflammation of the endothelium and/or biliary epithelial injury. Rejection can be graded as mild, moderate, and severe depending on the proportion of involved portal triads, the degree of infiltrate and injury, and the presence of central vein endothelial inflammation, which is a sign of severe AR. Treatment of AR is centered on a high-dose methylprednisone bolus, but cases unresponsive to this may require use of antibody therapy (OKT3, antithymocyte globulin [ATG], see Table 48-1). Mild AR can often be treated by simply increasing the tacrolimus level, though steroid bolus should be considered if there is not a prompt response. AR does not influence long-term graft survival in adults or children, unless it occurs in multiple or steroid refractory episodes, or if it occurs beyond the first year post-transplant.[4,7,29] AR accounts for less than 3% of overall patient and graft loss. However, treatment for AR is an important risk factor for the development of cytomegalovirus and Epstein-Barr viral infections in children. The latter is a risk factor for the development of post-transplant lymphoproliferative disorder. Therefore a balance between adequate immunosuppression to prevent AR and over-immunosuppression to avoid toxicity is necessary. Currently, long-term morbidity from immunosuppressive drug therapy is the major challenge facing long-term survival and quality of life in the pediatric population.

Chronic rejection is a common cause of late graft loss in children, because disease recurrence is uncommon. It is not felt to be entirely alloantigen driven, and may be due to a number of factors that share final common pathway of graft injury. Its hallmark is the intrahepatic loss of bile ducts and has been termed "vanishing bile duct syndrome" in the past because of this histologic finding on biopsy. This diagnosis is suspected if progressive jaundice and rising levels of alkaline phosphatase occur. Currently, there is no prophylactic or therapeutic agent for chronic rejection, though progression of graft fibrosis may be forestalled by sirolimus, based on animal and preliminary clinical data.[30] Although maintenance immune suppression is often enhanced, the only definitive treatment when decompensated graft failure occurs is retransplantation.

# Infectious Complications

Post-transplant infections are the most common cause of morbidity and mortality after liver transplantation (Table 48-2). The highest incidence of bacterial and fungal infections is in the first month after transplantation. Fungal infections occurring months to years after transplantation are unusual and are more commonly the atypical or endemic organisms, such as *Cryptococcus* spp., *Mucormycosis* spp., *Blastomycosis* spp., or *Coccidiomycosis* spp. Viral infections are the most common infections after the early post-transplant period. Cytomegalovirus (CMV) and Epstein-Barr virus (EBV) infections account for the vast majority of opportunistic viral infections. Overall

**TABLE 48-2**
**Infectious Complications after Liver Transplantation**

| *Organism* | *Presentation* | *Diagnosis* | *Antimicrobials* |
|---|---|---|---|
| Cytomegalovirus (CMV) | Infection results from reactivation of virus; blood transfusion; infected transplanted organ<br>Mild viral, "flulike" syndrome<br>Invasive tissue infection (retinitis, pneumonitis, myocarditis, enterocolitis, hepatitis, CNS) | Quantitative CMV-DNA PCR<br>pp65 antigen<br>Tissue cultures<br>Blood or fluid cultures<br>Biopsy with immunostains | Prophylaxis: IV ganciclovir, oral valganciclovir<br>Therapy: IV ganciclovir with or without CMV immunoglobulin |
| Epstein-Barr virus (EBV) | Spectrum: infectious mononucleosis to lymphoproliferative disease to lymphoma to EBV-associated soft tissue tumors<br>Occurs with EBV and immunosuppression, 10%-15% infant liver transplantation<br>GI tract, neck, thorax, CNS | Quantitative EBV-DNA PCR<br>Blood smear<br>Biopsy with immunostains<br>CT scans of suspected sites | Prophylaxis: IV ganciclovir, oral valganciclovir<br>Therapy: Acyclovir, reduction or withdrawal of immunosuppression; possible use of systemic chemotherapy for lymphoproliferative disorders or lymphoma |
| Herpes simplex virus (HSV) | Skin lesions, GI tract disseminated herpes—fever, fatigue, abnormal liver functions, hepatitis, pneumonia | HSV-1 and HSV-2 antibodies<br>Biopsy with viral cultures | Acyclovir |
| Pneumocystis | Atypical pneumonia, can progress to life-threatening pneumonitis | BAL, lung biopsy | Prophylaxis: low-dose oral sulfamethoxazole/trimethoprim, Dapsone, or pentamidine<br>Therapy: high-dose IV sulfamethoxazole/trimethoprim |
| *Candida* | Local mucous membrane, invasive tissue infection, fungemia | Blood, fluid, and tissue cultures, fundoscopic exam | Prophylaxis: fluconazole, possibly lipid formulation of amphotericin B in very-high-risk patients<br>Therapy: fluconazole (for sensitive candidal species) or lipid formulation of amphotericin B, caspofungin, or voriconazole (insensitive *Candida* or *Aspergillus*) |
| *Aspergillus* | Entry via upper or lower respiratory tract with metastatic spread (CNS, intra-abdominal, solid-organ) | Blood, fluid, and tissue cultures, BAL, CT scans | |
| Bacteria | Gram negative: enterobacteria, *E. coli, Pseudomonas*<br>Gram positive: *Enterococcus, Staphylococcus* | Blood, fluid and tissue cultures, BAL, CT scans, surgical exploration | Varies |

BAL, bronchoalveolar lavage; CNS, central nervous system; CT, computed tomography; GI, gastrointestinal; IV, intravenous; PCR, polymerase chain reaction.

reduction and more selective immunosuppression and prophylaxis with ganciclovir have reduced the incidence and morbidity of these infections. The other agents responsible for infectious morbidity, their presentation, diagnosis, and treatment are included in Table 48-2. Of particular importance in children is the prophylaxis and effective treatment of EBV. This is associated with the development of numerous malignant consequences. The most common of these is a diffuse proliferation of lymphoid tissue known as post-transplant lymphoproliferative disorder (PTLD). PTLD can present as a mononucleosis-like syndrome with diffuse lymphadenopathy or as lymphoma involving any organ. A variety of other tumors are also associated with EBV infections.[29] The general therapy for PTLD is reduction or elimination of immunosuppression, and, occasionally, surgical intervention and/or chemotherapy. The complete discussion of these disorders is beyond the scope of this chapter but is extensively covered elsewhere.[29]

# Outcome and the Future

Numerous factors are known to impact patient and graft survival in this population of liver transplant patients.* Overall, survival has improved with 1-year and 5-year patient survival exceeding 90% and 80%, respectively, in patients less than 18 years of age.[3,4] Age, nutritional status, urgency of transplantation, the indication for transplantation, and presence of renal dysfunction are all major factors that determine the outcome in any individual patient. Although early data suggested that patients with BA have worse outcomes because of their often-malnourished state, young age, and previous surgical intervention, more recent data suggest that this difference is not significant.[11,31] Patients with metabolic disease do exceedingly well, because they often are older, do not have liver failure and its sequelae, and have not previously undergone abdominal operation. Finally, transplantation for malignancy in children is associated with survival that is substantially less than that of transplantation for other indications but much better than the natural history of the disease. Numerous large series exist in the literature detailing the improvement in outcome with experience.[4,7,8]

Although outcomes have improved, many issues still remain to be resolved. The first and foremost is the organ shortage. The number of listed patients is increasing, while the number of suitable donors (even with segmental liver transplantation and improved organ allocation policies) has plateaued. Strategies aimed at expanding the donor pool and allocating organs to those patients that not only have the greatest survival benefit compared with pretransplant survival, but also the greatest chance of optimal post-transplant outcome are essential. National policies aimed at effectively identifying donors for splitting and development of local, regional, and national sharing of split grafts still await refinement. Finally, the development of gene therapy or optimization of hepatocyte transplantation as alternatives

* References 3, 4, 7, 8, 23, 24, 27, 31.

to transplantation for metabolic diseases may alleviate some of the organ shortage.

Another important challenge for the liver transplant community is the perfection of immunosuppression. Currently, all immunosuppressants have long-term side effects that result in impaired growth and development, infectious morbidity, malignancies, and numerous medical complications such as renal failure. The development of drug therapy that minimizes or eliminates these is essential. Furthermore, a better understanding of the immunology of peripheral T-cell tolerance and chronic rejection is essential. Although the last decade saw improvements in many technical and immunosuppressive aspects of liver transplantation, improvements in survival and quality of life in the next decade will rest firmly on a better understanding of our immune system on a cellular and molecular level.

CHAPTER 49

# Pediatric Intestinal Transplantation

Yann Révillon and Christophe Chardot

Intestinal failure (IF) is characterized by the inability of the gastrointestinal tract to provide sufficient digestion and absorption capacities to cover the nutritional requirements for maintenance in adults and for growth in children.[1] The first-line treatment for IF is parenteral nutrition (PN). In patients with life-threatening complications of PN, intestinal transplantation (IT)—isolated or combined with the liver and/or other organs—provides children with a second chance for survival. Since the early days of IT in the 1980s (treatment with cyclosporine-based immunosuppressive regimens), significant progress has been made in the medical and surgical management of children requiring IT, with short-term results (1-year patient survival) now approaching those of liver transplantation.

## Indications for Intestinal Transplantation

The causes of intestinal failure in children can be divided into five groups[2] (Fig. 49-1): (1) short bowel, mainly resulting from gastroschisis, midgut volvulus, necrotizing enterocolitis, and intestinal atresia; (2) motility disorders: long-segment Hirschsprung disease and chronic intestinal pseudo-obstruction; (3) epithelial disorders with intractable diarrhea, such as microvillous inclusion disease and tufting enteropathy; (4) children with a failed intestinal transplant; and (5) miscellaneous, including tumors.

Parenteral nutrition, including home PN, is the first-line treatment for children with intestinal failure and allows satisfactory growth and acceptable (although not normal) quality of life in most patients.[1,3] However, life-threatening complications of PN may occur, primarily line sepsis, loss of venous access resulting from thrombosis, and liver disease leading to cirrhosis. In such cases, intestinal transplantation may be the only lifesaving alternative. Depending on the underlying disease and the complications of PN, transplantation of additional organs may be required: liver in patients with cirrhosis, stomach and duodenopancreas in patients with extended motility disorders, and kidney(s) in patients with renal failure.[4]

The management of children with intestinal failure requires a multidisciplinary approach and is a continuous process that may last the whole life of the child. In most patients, the disease starts in the neonatal period and requires initial surgery. The possibility that the child may need other operations in the future should be considered at each surgical intervention. Adequate parenteral nutrition and prevention of line infections have paramount importance for the long-term prognosis of children with intestinal failure.[3,5] If long-term dependence on PN is expected, early contact with a team specializing in the management of children with intestinal failure is recommended before the onset of PN-related complications, to optimize the overall management of the child: adaptation of long-term PN and prevention of its complications, education of parents about home PN, and anticipation and preparation of further steps of the medicosurgical management, which may include nontransplant surgery or transplantation. This early contact with the intestinal failure team is recommended for every child whose requirements for PN are anticipated to be more than 50% at 3 months after initiating PN.[6] In a retrospective study, including 302 children followed for home PN in our center between 1980 and 1999, the median duration of home PN was 1.3 years. By January 2000, 54% had been weaned from PN, 26% were still receiving PN, 16% had died, and 4% had undergone intestinal transplantation. Patient survival rates at 5, 10, and 15 years were 89%, 81%, and 72%, respectively. Nine percent of children with primary digestive disease died versus 38% of children with nonprimary digestive disease.[3] In a multicenter prospective European study, including 688 adults and 166 children on home PN, the candidacy rate for transplantation was estimated at 16% in adults and 34% in children, and it varied greatly among home PN centers.[7,8] The 5-year survival rate on home PN was 87% in noncandidates for transplantation, 73% in candidates with home PN failure, 84% in those with high risk of death attributable to the underlying disease, 100% in those with IF with high morbidity or low acceptance of PN, and 54% in IT recipients ($P < 0.001$). Nontransplant surgery may have a place in the rehabilitation program of such children, especially bowel lengthening procedures in those with a short bowel and limited hepatic or vascular complications.[9,10]

The appropriate timing of intestinal transplantation sometimes is not easy to determine, because it is difficult to predict the ability of the native intestine to adapt, as well as the course of PN-related complications. On the one hand, intestinal adaptation may allow digestive autonomy in some patients with

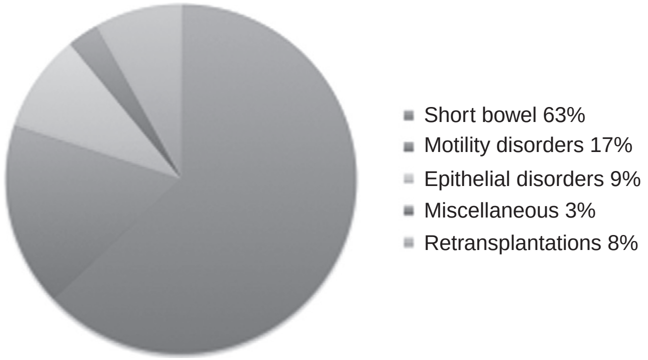

**FIGURE 49-1** Indications for intestinal transplantation. From the Intestine Transplant Registry 2003 report[2]: 606 grafts (223 isolated bowel, 306 liver and intestine, 77 multivisceral) in 563 children (age $\leq$ 18 years).

a short bowel,[9] and PN-associated liver disease may regress after optimization of PN, especially regarding the quality of lipid intake.[11–13] On the other hand, transplantation results are better in children who are in good general condition, as opposed to children with end-stage disease.[2] However, early referral to a specialized center for intestinal failure does not necessarily result in finding an indication for transplantation. In a series of 118 patients referred to our center for transplantation assessment, 10 could be weaned off PN, 12 patients were unsuitable for transplantation, 65 patients were listed for transplantation, and 31 remained potential candidates.

The two following examples of children treated by our team illustrate how the same condition (short bowel syndrome) may require very different therapies, based on the specifics of the patient.

*Yasmine* was born in 1971. In 1981, she presented with a midgut volvulus and complete necrosis of the small bowel and right colon. She underwent a duodenocolic anastomosis, and she has been on PN since then. Because of loss of venous access, an arteriovenous fistula was created in 1983. Today, she eats normally and receives home PN 5 nights per week. She has three bowel movements per day. Her general condition is good. She sometimes complains of anal burns or abdominal distension. She has an ovarian cyst and renal stones. She works in business, was married in 2002, and gave birth to two children. She enjoys dancing, skiing, and diving. She does not wish to receive an intestinal transplant.

*Virginie* was born in 1988, and underwent an extensive intestinal resection at birth after midgut volvulus. Because of complications of PN, she underwent intestinal transplantation, in 1989, with cyclosporine-based immunosuppression. Today, she eats normally and is off PN, with normal intestinal biopsies. Her weight and height are normal. She has mild intellectual retardation and does not work. Her renal function is moderately impaired. She is the world's longest survivor (22 years) with a functional intestinal graft. However, it is still impossible to predict whether this situation will last for a normal lifespan.

## Assessment and Preparation for Intestinal Transplantation

Potential candidates for IT usually have a complex medical history and may have undergone several prior operations. A detailed workup is needed to precisely evaluate (1) the level of IF and its potential reversibility; (2) the history of PN and central-line complications—number of catheters, number of episodes of line sepsis, and bacteria involved (antibiotic resistance profiles); (3) thrombotic complications and current cartography of patent vascular access; (4) intestinal failure–associated liver disease (IFALD)—liver fibrosis or cirrhosis, jaundice, ascites, portal hypertension (esophageal and/or gastric and/or peristomal varices, thrombocytopenia), liver insufficiency; (5) surgical status of the abdomen—previous operations, length and function of remaining bowel, stomas; (6) function of other organs, especially heart, lungs (pulmonary shunts or pulmonary hypertension), and kidneys; (7) neurologic development and potential neurologic impairment; (8) serologic status and immunizations; (9) immunologic status (anti-HLA antibodies); and (10) sociofamilial and psychological assessment and ability of the family to manage the child before and after transplantation. The indications for transplantation as well as all of these issues and alternate therapies are discussed in a multidisciplinary meeting. Whatever the proposal for treatment, the child will require careful follow-up, with further reassessments, because the indication for transplantation and the type of graft needed may change with time.

The general condition of the child has a strong impact on the results of transplant surgery; therefore careful preparation is required, focusing especially on (1) optimization of PN to improve nutritional status and reduce its toxicity; (2) prevention and treatment of infections (optimization of central venous-line management) and immunizations; (3) treatment of the complications of liver disease, primarily ascites and portal hypertension (sclerosis or ligation of esophageal varices, transjugular intrahepatic portosystemic shunt). Education of the child and family about transplantation is done simultaneously.

## Transplantation Surgery

The donor is usually a deceased donor, although a few living-related donations have been reported for isolated small bowel transplants.[14] The volume of the graft must correlate with the abdominal cavity of the recipient; this depends on (1) the donor to recipient weight ratio, (2) the native organs removed and the type of graft implanted, and (3) whether the abdominal cavity is small (IT for short bowel) or distended (IT for intestinal motility disorders with chronic intestinal distention).

A wide variety of grafts can be implanted, from isolated small bowel to multivisceral grafts, including stomach, pancreas and duodenum, small bowel, right colon, liver, and kidneys (Fig. 49-2). These grafts can be classified as

1. Isolated intestinal transplantation: small bowel $\pm$ right colon. This type of graft is generally indicated for IF with normal motility of the stomach and duodenum, and without significant liver disease. The native stomach, duodenum, pancreas, spleen, and liver are preserved. The superior mesenteric artery of the graft is connected to the recipient infrarenal aorta, and the mesentericoportal axis of the graft is joined to the native infrarenal vena cava. The proximal jejunum of the graft is connected to the native jejunum.

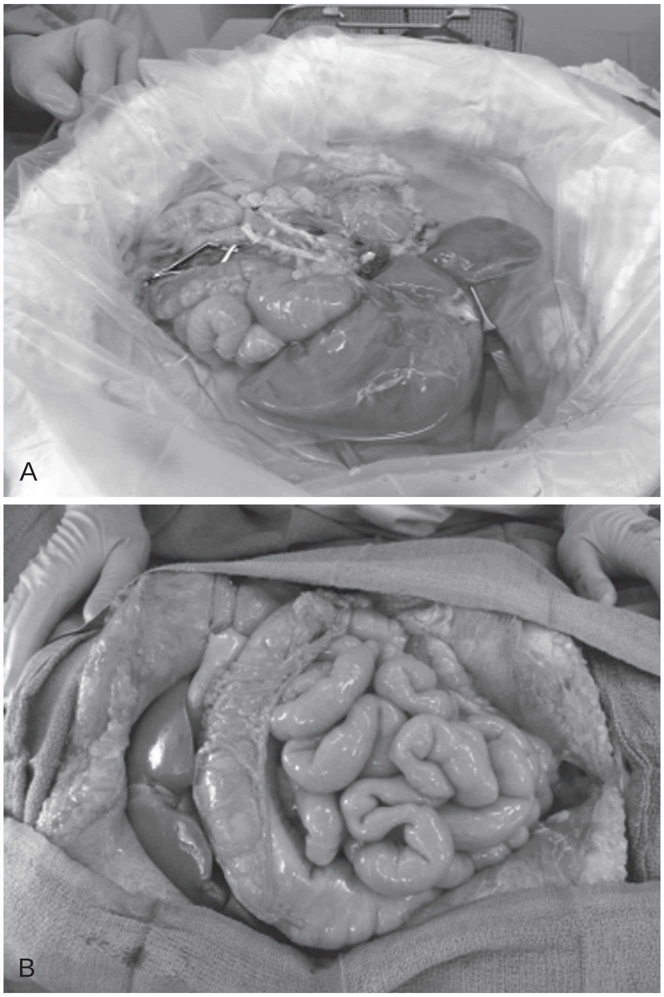

**FIGURE 49-2** **A,** Multivisceral transplantation: the graft before implantation. The graft includes stomach, pancreas, duodenum, small bowel, right colon, liver, and two kidneys. **B,** Multivisceral transplantation: the graft after implantation and reperfusion.

2. Modified multivisceral transplantation: stomach, pancreas and duodenum, small bowel ± right colon. This type of graft is indicated for IF with impaired motility of the native stomach and duodenum (i.e., pan-intestinal Hirschsprung disease and chronic intestinal pseudo-obstruction), without significant liver disease. The upper part of the native stomach, duodenum, pancreas, spleen, and liver are preserved. The arterial axis of the graft (including celiac trunk and superior mesenteric artery) is connected to the recipient infrarenal aorta, and the mesentericoportal axis of the graft is joined to the recipient infrarenal vena cava. The native and transplanted hemistomachs are connected, the native first portion of duodenum is closed, and the native jejunum is connected to the transplanted jejunum as a Roux loop.
3. Combined liver and intestinal transplantation: liver, pancreas and duodenum, small bowel, ± right colon. This type of graft is indicated for IF with normal motility of the stomach and duodenum, and with significant liver disease. The native liver is removed, and a portocaval anastomosis is fashioned between the native portal vein and vena cava. The native stomach, duodenum, pancreas, and spleen are preserved. The arterial axis of the graft (including celiac trunk and superior mesenteric artery) is connected to the recipient infrarenal aorta, and the suprahepatic vena cava of the graft is connected to the native suprahepatic vena cava in a "piggyback" fashion. The first portion of the duodenum of the graft is closed, and the graft jejunum is connected to the native jejunum as a Roux loop.
4. Multivisceral transplantation: liver, stomach, duodenum and pancreas, small bowel, ± right colon, ± kidneys. This type of graft is indicated for (1) IF with impaired motility of the stomach and duodenum (pan-intestinal Hirschsprung disease and chronic intestinal pseudo-obstruction), with significant liver disease; (2) when en-bloc ablation of native organs (liver, pancreas, duodenum, and intestine) is needed,[4] either due to previous surgeries and portal hypertension, making selective dissection of native abdominal organs impossible, or (rarely) because of a tumor. All abdominal organs anterior to the aorta and vena cava are removed. The arterial axis of the graft (including celiac trunk and superior mesenteric artery) is connected to the recipient aorta, and the suprahepatic vena cava of the graft is connected to the native suprahepatic vena cava in a "piggyback" fashion. The native lower esophagus is connected to the transplanted stomach.

In all cases, a distal ileostomy is performed to provide easy access to the graft for intestinal biopsies. When the right colon is transplanted, its distal end is either anastomosed to the remaining native rectum (patients with short gut or mucosal diseases) or a temporary distal colostomy is created (Hirschsprung disease). Cholecystectomy and gastrostomy (for continuous enteral feeding) are generally performed if not done previously.

Abdominal wall closure is an issue after intestinal transplantation, because of the size discrepancy between the graft and the abdominal cavity of the recipient and post-reperfusion edema of the graft. Reduction of the liver and/or intestinal graft is possible.[15,16] Staged abdominal closure, using a temporary Silastic sheet and a vacuum dressing, avoids abdominal compartment syndrome. The final abdominal closure is usually possible after 5 to 7 days (Fig. 49-3).

# Postoperative Care

The intestinal transit generally resumes quickly after surgery, and enteral feeding is progressively introduced 2 to 7 days after the operation. Transit time is accelerated because of the graft's denervation, and if dysfunction of the graft (mainly rejection or infection) has been ruled out, antimotility agents, such as loperamide or codeine, can be used to slow down the intestinal motility. In an uncomplicated postoperative course, full enteral feeding can be achieved 1 month after the operation.

Various surgical complications may occur (obstructions, peritonitis, fistulas, and pancreatitis), and may be difficult to detect under steroid therapy. Vascular monitoring of the graft relies on observation of the color of the stoma and, if the graft includes the liver, repeated ultrasonography (US) of the liver.

The intestine is highly immunogenic, and IT requires high-level immunosuppression. As understanding of the mechanisms of rejection progresses and new immunosuppressive

**FIGURE 49-3** **A,** Intestinal transplantation, end of operation. The edema of the graft after reperfusion prevents primary abdominal closure. A Silastic silo is performed. **B,** Staged abdominal closure. The Silastic silo is covered with a vacuum dressing. The silo is progressively tightened over the next days at the bedside, as edema progressively resolves and graft reintegrates the abdomen. **C,** Final abdominal closure. After 5 to 7 days, the edema of the graft has diminished, and final abdominal closure can be achieved; the musculoaponeurotic layer can be closed either completely or with a wound prosthesis (for instance, a GORE-TEX sheet).

drugs become available, immunosuppressive protocols evolve. The current standard immunosuppressive regimen is a combination of tacrolimus, steroids, and basiliximab or daclizumab (anti–IL-2 receptor antibodies). Monitoring of intestinal rejection is based on stoma output, protein concentration in the stools, and repeated intestinal biopsies through the stoma. Other markers, such as stool calprotectin or serum citrulline, have also been used. In case of biopsy-proven rejection, first-line treatment relies on high-dose steroid pulses. Second-line treatments are available but expose the child to complications of overimmunosuppression, primarily opportunistic infections, and post-transplant lymphoproliferative disease (PTLD). In case of uncontrolled rejection, removal of the transplanted intestine may be needed. Recently, humoral rejection has increasingly been studied: Donor-specific anti-HLA antibodies are monitored, and high levels can be treated by high-dose intravenous (IV) immunoglobulins, rituximab (anti-CD20 antibody), and plasmapheresis.

Because of the high level of immunosuppression, opportunistic infections are a constant threat after IT. Various infectious agents can be involved, the most common being cytomegalovirus (CMV) and Epstein Barr virus (EBV). CMV can cause severe graft enteritis and trigger rejection. EBV can trigger lymphoproliferation. Monitoring of the viral loads is currently determined by polymerase chain reaction (PCR), which guides the prophylactic or curative treatments.

Post-transplant lymphoproliferative disease is nowadays detected at earlier stages. First-line treatment relies on reduction of immunosuppression and rituximab.

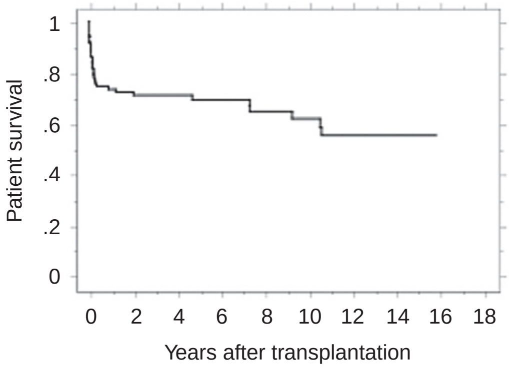
Drug toxicity is an issue after IT, because these children receive many drugs, some of them at high doses. Impairment of renal function, hypertension, and seizures are the most common side effects, which are usually reversible after dose reduction or a switch to alternate therapies.

Progressively, all treatments are decreased or withdrawn. Stoma closure can be considered when the child has been stable, without rejection, under maintenance immunosuppression for several months.

## Results of Intestinal Transplantation

Short-term results of intestinal transplantation have improved with increasing experience.[2] In the United States, current 1-year patient and graft survival is 89% and 79%, respectively, for isolated bowel recipients, and 72% and 69%, respectively, for liver-intestine recipients. However, medium-term results remain unsatisfactory; by 10 years, patient and graft survival falls to 46% and 29%, respectively, for isolated bowel recipients, and 42% and 39%, respectively, for liver-intestine recipients.[17,18] According to the International Intestine Transplant Registry (1985 to 2003 data: 989 grafts in 923 patients),[2] causes of death were sepsis (46.0%), multiorgan failure (2.5%), graft thrombosis (3.2%), graft rejection (11.2%), post-transplant lymphomas (6.2%), respiratory causes (6.6%), technical reasons (6.2%), and other causes (17.3%).

Our team in Paris performed 97 transplants in 90 children, between November 1994 and April 2011, using tacrolimus-based immunosuppression: isolated bowel in 55; stomach, pancreas, duodenum, and bowel (modified multivisceral) in 1; combined liver and bowel in 39; liver, stomach, pancreas,



| 90 patients | 1-year | 5-year | 10-year | 15-year |
|---|---|---|---|---|
| Patient survival | 73.0% | 61.8% | 48.6% | 43.7% |
| Standard error | 4.5% | 5.2% | 6% | 6.3% |
| Number of patients reaching considered follow-up | 66 | 43 | 21 | 2 |

**FIGURE 49-4** Patient survival after intestinal transplantation in the tacrolimus era. Paris series from November 1994 to March 2011: 90 patients.

duodenum, and bowel in 1; liver, stomach, pancreas, duodenum, bowel, and two kidneys in 1 (see Fig. 49-2). In 63 of 97 transplants (65%), the graft included the right colon. One-year, 5-year, 10-year, and 15-year patient survival rates are 73.0%, 61.8%, 48.6%, and 43.7%, respectively, and 1-year, 5-year, 10-year, and 15-year graft survival rates are 59.5%, 45.0%, 33.6%, and 31.2%, respectively (Figs. 49-4 and 49-5). Early mortality is higher, but long-term graft survival is better after combined liver and intestine transplantation compared with isolated intestinal transplantation. This is probably due to the protective effect of the liver against intestinal rejection.[19,20]

In a study of 31 children treated by our group, and who are alive with their graft 2 to 18 years after transplantation,[21] all were weaned from PN after transplantation, and 26 of 31 (84%) remained PN-free at last follow-up. Enteral nutrition was still required for 14 of 31 (45%) patients 2 years after transplantation. All children had high dietary energy intakes. The degree of steatorrhoea was fairly constant, with fat and energy absorption rates of 84% to 89%. After transplantation, two thirds of children had normal growth, whereas in one third, growth remained delayed, concomitant to a delayed puberty. Endoscopy and histology analyses were normal in asymptomatic patients. Five intestinal grafts (16%) were removed 2.5 to 8 years after transplantation for acute or chronic rejection. Late complications also include impairment of renal function and malignancies.

| Standard error | 5% | 5.3% | 5.7% | 5.8% |
| Number of grafts reaching considered follow-up | 53 | 31 | 14 | 2 |

**FIGURE 49-5** Graft survival after intestinal transplantation in the tacrolimus era. Paris series from November 1994 to July 2010: 97 grafts.

Results of intestinal transplantation have improved in the recent decades,[2,18] because of better preparation of patients and timing of transplantation, progress in surgical techniques, availability of new immunosuppressive drugs and improved immunosuppressive regimens, and better monitoring and treatments of postoperative complications. The scarcity of grafts remains an important issue, and patients still succumb while waiting for a graft. With expected improvements in the outcomes (especially in the long term), intestinal transplantation may move from a lifesaving procedure to an improving quality-of-life procedure,[22] which may also have economic advantages compared with PN.

# Conclusion

Home PN remains the first-line treatment of intestinal failure. Intestinal transplantation and its technical variants are indicated only in case of life-threatening complications of PN. Intestinal failure requires a multidisciplinary approach in specialized centers. Early assessment of the child in such a center, before the onset of complications of PN, is recommended. This does not mean early transplantation, but adequate planning of medicosurgical strategies to provide the child with the best chances of survival and an optimal quality of life.

## *Acknowledgments*

The authors, Yann Révillon and Christophe Chardot, who are part of the surgical team, wish to thank the following pediatric multidisciplinary team members*:

1. Current team members treating intestinal failure and performing transplantations:

CHAPTER 50

# Heart Transplantation

Stephanie M. P. Fuller and Thomas L. Spray

Thoracic organ transplantation has been successfully performed in pediatric patients since the mid-1980s and now serves as an important option in the treatment of both congenital and end-stage heart and lung disease in children. Approximately 400 pediatric heart transplantations are performed annually in the United States, or roughly 16% of all pediatric solid organ transplantations.[1] Despite the clinical success of heart and lung transplantation in children, limited donor availability has prevented broader application of this therapy. Infants awaiting heart transplantation face the highest wait-list mortality among all children and adults listed for a heart transplantation in the United States, with one in four infants dying before a donor heart can be identified.[2] Complications, such as acute and chronic rejection, graft coronary artery disease (CAD), and bronchiolitis obliterans, as well as the infectious and neoplastic complications of current methods of immunosuppression, threaten cardiac transplant longevity. This chapter focuses on the clinical aspects of heart transplantation in infants and children, including indications, preoperative evaluation, operative techniques, postoperative management, complications, and outcomes.

## Historical Notes

Kantrowitz and colleagues[2a] performed the first pediatric heart transplant in 1967 when they transplanted the heart of an infant with anencephaly into a 3-week-old infant with tricuspid atresia. The next year, Cooley[2b] transplanted the heart and lungs of a newborn with anencephaly into a 3-month-old with an atrioventricular septal defect and pulmonary hypertension. Although neither of the infants survived for more than a few hours because of allograft rejection, these pioneering procedures emphasized the technical feasibility of thoracic organ transplantation in children. It was only in 1980 with the introduction of cyclosporine as an immunosuppressive agent that meaningful clinical success became possible. In November 1985, Bailey performed the first successful cardiac transplantation on a 4-day-old neonate with hypoplastic left heart syndrome (HLHS) at Loma Linda.[3,4] During the last 2 decades, outcomes have been improved by technical advances, better immunosuppression, including reduced steroid use and the advent of induction therapy, a decreased incidence of rejection, increased attention to viral prophylaxis, and aggressive treatment of post-transplant lymphoma and other post-transplant complications.

## Indications

As published by the Registry for the International Society for Heart and Lung Transplantation in the Thirteenth Official Pediatric Report in 2010, the number of pediatric heart transplantations has remained relatively constant during the last 10 years (Fig. 50-1).[5] The most common indications for cardiac transplantation in the pediatric population remain congenital cardiac disease and cardiomyopathy, as demonstrated in Figures 50-2 and 50-3. Congenital heart disease is seen more commonly in infants, whereas cardiomyopathy is more prevalent in older children. As expected, the incidence of retransplantation increases with increasing patient age.

When examining the congenital heart disease population, the most common anomaly treated by transplantation is hypoplastic left heart syndrome (HLHS), a group of defects characterized by aortic or mitral atresia/stenosis with a diminutive left ventricle. Initial poor results with a staged palliative approach to HLHS led some centers to consider orthotopic heart transplantation as the primary treatment of this anomaly. Long transplantation waiting lists have led other institutions to advocate a stage I palliation (Norwood or Sano procedure) to help stabilize the patient and then list the patient for transplantation.[6] However, with improvement in early survival from the Norwood procedure followed by a Fontan repair, the majority of cardiac centers have abandoned primary transplantation as initial therapy for HLHS. Transplantation is an option now reserved for patients with unusually high risk, including aortic atresia with a diminutive ascending aorta and severe tricuspid or atrioventricular valve regurgitation.[7]

Other forms of congenital heart disease that have been treated by cardiac transplantation during infancy include an unbalanced atrioventricular canal, single ventricle, the Ebstein

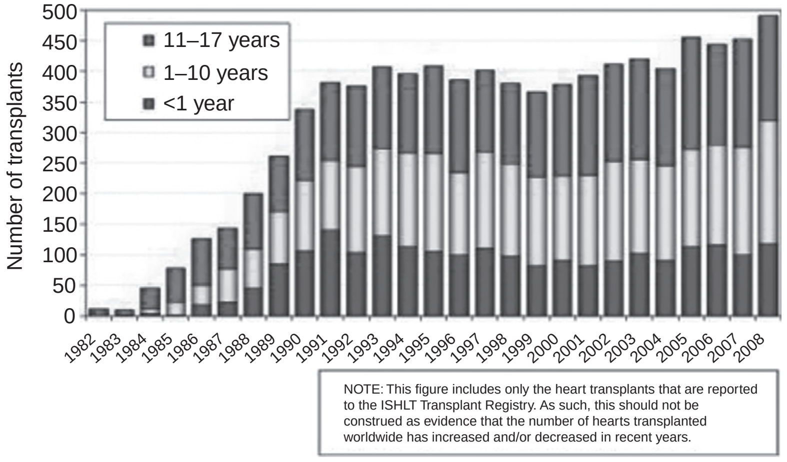

**FIGURE 50-1** Age distribution of heart recipients by year of transplantation. (From Kirk K, Edwards LB, Kucheryavaya AY, et al: The Registry of the International Society for Heart and Lung Transplantation: Thirteenth official pediatric heart transplantation report—2010. J Heart Lung Transplant 2010;29:1119-1128.)

anomaly, L-transposition of the great arteries, and pulmonary atresia with an intact ventricular septum (Table 50-1).[8,9] Even the most complex forms of congenital heart disease, such as heterotaxy syndromes with anomalies of systemic and venous drainage, are amenable to cardiac transplantation with suitable reconstruction.[10] Other pediatric candidates include infants with congenital heart disease who have undergone previous corrective or palliative procedures, yet who exhibit residual or progressive cardiac dysfunction manifested by left ventricular failure that ultimately requires transplantation. Postoperative cardiac dysfunction is often related to atrioventricular or semilunar valvar insufficiency that eventually results in dilated cardiomyopathy. In some cases, ventricular function may be preserved, but the indication for transplantation is for hemodynamic compromise secondary to anatomic abnormalities not amenable to surgical intervention, intractable arrhythmias, or complications that arise following the Fontan operation, such as protein-losing enteropathy. Of note, multiple previous palliative procedures do not preclude successful transplantation.[11] In the current era, despite the need for repeat sternotomy, the tendency toward diffuse coagulopathy and potentially prolonged ischemic times, patients undergoing transplantation for congenital heart disease experience no actuarial difference in survival compared with those patients undergoing transplantation for cardiomyopathy who undergo first-time sternotomy and dissection of mediastinal structures.[8,12]

Cardiomyopathy is the other most common indication for heart transplantation in infancy and childhood. Most pediatric heart transplantations outside infancy are performed for dilated, idiopathic cardiomyopathy. Other causes of cardiomyopathy include viral, familial, and hypertrophic. Despite the diverse causes of cardiomyopathy, several variables have been associated with poor outcome, including a very high left ventricular end-diastolic pressure, a left ventricular ejection fraction less than 20%, ventricular arrhythmia, and a family

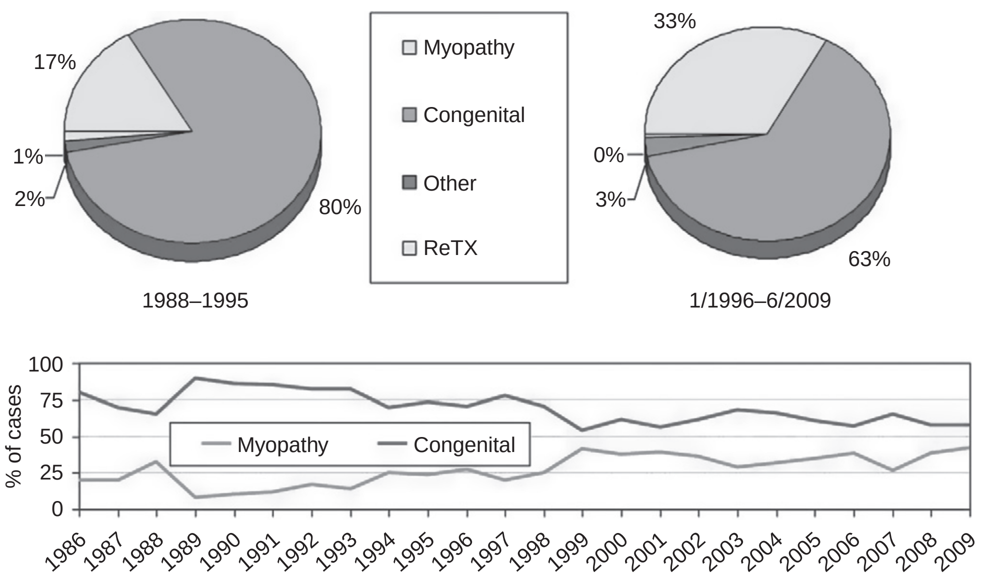

**FIGURE 50-2** Infant heart recipient diagnosis according to year of transplantation. ReTx, retransplant. history of cardiomyopathy.[13,14] Cardiomyopathy attributable to inflammation or arrhythmia tends to have a more favorable outcome, and these patients should be supported as long as possible before transplantation to allow for the possibility of spontaneous recovery. Other less common indications for cardiac transplantation are doxorubicin-induced cardiotoxicity from chemotherapy for malignancy and obstructive cardiac tumors, such as fibromas and rhabdomyomas that are not amenable to surgical resection.

Regardless of the diagnosis, there are several clinical indications for heart transplantation in children, many of which have been borrowed from the adult population. These include the need for ongoing intravenous inotropic support or mechanical circulatory support. Transplantation is indicated in those patients who experience a progressive deterioration of ventricular function despite optimal medical care or those with life-threatening arrhythmias unresponsive to medical treatment, ablation, or automatic implantable defibrillator. Progressive pulmonary hypertension secondary to systemic ventricular failure is an indication for cardiac transplantation, whereas pulmonary hypertension may otherwise be an indication for lung transplantation. Growth failure secondary to severe heart failure and unacceptably poor quality of life are considered indications as well as certain high-risk conditions following the Fontan procedure, such as protein-losing enteropathy and plastic bronchitis.[15]

# Preoperative Evaluation

The pretransplant evaluation is a multidisciplinary screening process that serves as the key to successful organ transplantation (Table 50-2). Potential recipients go through a thorough

physical and psychosocial evaluation with careful examination of the cardiac, pulmonary, neurologic, renal, infectious, and socioeconomic systems. The presence of an adequate family support system is of paramount importance to survival postoperatively. Parents must demonstrate the ability and resources to comply with the complex medical regimens required and to cope with the potential for long or frequent hospitalizations even years after transplantation. As part of this multidisciplinary evaluation, patients undergo screening laboratory tests, including a viral serology panel (e.g., human immunodeficiency virus [HIV], cytomegalovirus [CMV], human Epstein-Barr virus [EBV], hepatitis).

Cardiac evaluation is performed mainly by echocardiography and cardiac catheterization in which the anatomy of the systemic and pulmonary venous connections of the heart and lungs are precisely identified. Important hemodynamic data, including systemic cardiac output and pulmonary vascular resistance (PVR), both indexed to the patient's body area, are obtained at cardiac catheterization and used to screen candidates. These numbers become significant, because the major contraindication to transplantation is fixed pulmonary hypertension unresponsive to pulmonary vasodilators. Patients with elevated PVR (>4 to 6 Wood units) are tested with pulmonary vasodilators, including sodium nitroprusside, oxygen ($FiO_2$ 100%), and inhaled nitric oxide, to establish whether the pulmonary vascular bed is reactive. In general, the presence of a fixed PVR in excess of 6 to 8 Wood units is a contraindication to orthotopic heart transplantation, because the donor heart is unable to tolerate right-sided dilation caused by high pulmonary vascular resistance. Patients who demonstrate improvement with vasodilators may undergo transplantation with a survival rate comparable to that in patients with normal resistance.[11] Although patients with fixed pulmonary hypertension have successfully undergone transplantation, they have a much higher mortality rate, usually because of postoperative right ventricular failure. Other contraindications to cardiac transplantation include multiple noncardiac congenital anomalies, active malignancy, infection, severe metabolic disease (i.e., diabetes mellitus), multiple organ failure, multiple congenital anomalies, and the lack of an adequate family support system, in addition to socioeconomic factors that lead to noncompliance with drug regimen and follow-up care (Table 50-3).

| | Recurrent medical noncompliance |

BMI, body mass index.

Children suffering from cardiomyopathy and manifesting symptoms of chronic congestive heart failure that limit activity or uncontrollable arrhythmias are often referred for transplantation, particularly if they are unresponsive to medications. The timing for transplantation, especially for those children with hypertrophic cardiomyopathy, is less clear because some patients may improve with medication and conservative therapy. As previously stated, the mortality for idiopathic dilated cardiomyopathy in children is highest in the first year after diagnosis and is mainly determined by the degree of left ventricular failure.

Children listed for heart transplantation should be closely monitored until their transplantation, either as outpatients, if their condition permits, or while hospitalized. Good nutritional status should be maintained, and supplementation, such as tube feedings or total parenteral nutrition, is used as needed. A close watch for infectious complications is important, and any subtle indications of infection should be thoroughly investigated. Major infections require patients to have their transplantation status put on hold until they are treated adequately. Anticongestive therapy should be optimized with digoxin, diuretics, and afterload reduction with captopril or other angiotensin-converting enzyme inhibitors. If heart failure worsens, hospitalization may be required for inotropic support with dobutamine or phosphodiesterase inhibitors such as milrinone. Long-term therapy may require the placement of an intravenous access device such as a Broviac catheter.

The use of mechanical support as a bridge to cardiac transplantation in critically ill children had been limited mostly to those with postcardiotomy ventricular failure. In general, the results have been poor, although several studies show survival rates ranging from 45% to 73% when extracorporeal membrane oxygenation (ECMO) is used as a bridge to cardiac transplantation.[16,17] ECMO is restricted to short-term use. Additional limitations are the inability to ambulate and undergo effective physical therapy while on ECMO, as well as the damage to circulating red blood cells and platelets requiring persistent transfusion. In the current era, children have excellent survival with the use of long-term ventricular assist devices (VADS) as a bridge to transplantation. Although adult systems can be used in adolescent patients, the Berlin Heart VAD (Berlin Heart AG, Berlin, Germany) is a pulsatile, paracorporeal VAD that is suitable in neonates and infants for both single and biventricular support. The North American experience from 2000 to February 2007 details approximately 80 patients supported for more than 200 days, with the smallest patient being 3.0 kg. Overall, approximately 55% of the patients have undergone transplantation, 13% were weaned, and 25% died during device support.[18]

A neonate referred for cardiac transplantation requires several other unique considerations. Infants with complex congenital heart disease, such as HLHS, are commonly confined to a neonatal intensive care unit and are usually maintained on a continuous infusion of prostaglandin $E_1$ to prevent closure of the ductus arteriosus if there is ductal-dependent physiology. Implantation of expansile stents in the ductus may allow for discontinuation of prostaglandin therapy while waiting. Initial palliative procedures, such as the Norwood procedure for HLHS or a Blalock-Taussig shunt for lesions with ductal-dependent pulmonary blood flow, can be performed in the face of a prolonged wait for a

donor. Balloon atrial septostomy, with or without stenting to improve mixing of saturated and desaturated blood and to decompress the left atrium, can be helpful if there is a restrictive patent foramen ovale. Other important issues are the maintenance of adequate nutritional support, avoidance of renal and metabolic complications, and prompt and thorough treatment of any infectious complications, especially line sepsis, in these fragile infants. Common neonatal problems, such as seizures, necrotizing enterocolitis, and intraventricular hemorrhage are also seen. At the minimum, 10% to 20% of infants die while awaiting a donor heart.

In all cases, important consideration is given toward pretransplantation recipient human leukocyte antigen (HLA) sensitization. Circulating antidonor antibodies may result in either cellular or humoral rejection culminating in early graft failure.[19] The presence of HLA antibodies is reported as a panel reactive antibody (PRA), and a panel percentage of greater than 10% is considered elevated. Patients prone to developing anti-HLA antibodies include those who have received blood and platelet transfusions during prior surgeries, postgravid adolescent girls, children who have undergone implantation of cryopreserved tissue valves or allograft conduits, and patients with previous organ transplants. Strategies for reduction in PRA include the use of intravenous immunoglobulin as well as agents that may inhibit antibody production by B cells. Candidates who are high risk are managed with pretransplantation plasmapheresis that is continued postoperatively, resulting in good short-term outcomes. However, long-term outcomes are unknown. The United Network for Organ Sharing determines organ allocation and, in 2002, revised their classification for pediatric patients awaiting heart transplantation. Status 1A applies to patients requiring ventilatory or mechanical circulatory support (i.e., left ventricular assist device, ECMO, or a balloon pump) or multiple- or high-dose inotropes, infants younger than 6 months with pulmonary pressure greater than 50% of systemic levels, or any patient with a life expectancy of less than 14 days without a heart transplantation. Status 1B applies to patients requiring single-dose inotropic support or infants younger than 6 months who have significant failure to thrive (less than the 5th percentile for weight or height or loss of 1.5 standard deviations [SD] of expected growth). All other patients with less acuity are classified as status 2. A patient's status may change depending on changes in clinical condition, or the patient may be placed on hold (status 7) because of an infectious, malignant, or other complication and then reactivated.

## Donor Evaluation and Organ Procurement

The criteria for an ideal organ donor are as follows: meets requirements for brain death, consent from next of kin, ABO compatibility in older children, weight compatibility (1 to 3 times that of the recipient), normal echocardiogram, age younger than 35 years, and normal heart by visual inspection at the time of harvest. A history of cardiopulmonary resuscitation is not an absolute contraindication to cardiac donation for pediatric recipients. All potential donors are evaluated carefully for the cause of death, including the presence of chest trauma, need for cardiopulmonary resuscitation, and cardiac function before death. For neonates, most donors have suffered sudden infant death syndrome or birth asphyxia, whereas older donors are victims of violence and car accidents.

The shortage of suitable organ donors, especially for neonatal recipients, has led to many attempts at expanding the donor pool. Hearts from donors with moderately impaired ventricular function by echocardiography (left ventricular shortening fraction greater than 25% without major wall motion abnormalities) have been successfully transplanted into infant recipients.[10] Donor-to-recipient weight ratios of up to 4:1 have been used in infants. Tamisier and colleagues demonstrated that the higher the PVR, the larger the donor heart needed for successful transplantation and that hearts with PVR values thought to be in excess of normal can also be used.[20] Although ideal donor ischemia time is from 2 to 4 hours, ischemic times have been successfully extended beyond 9 hours. Deviations from the "ideal" donor criteria should be individualized, and even though the use of a marginal donor for a dying infant maintained on ECMO may be justified, use of the same heart for a child who is stable as an outpatient might not.

ABO-incompatible transplantation has been introduced as a method to decrease recipient waiting time and associated waiting list mortality.[19] Because neonates do not have the ability to produce antibodies to T-cell antigens, including major blood group antigens, ABO incompatibility becomes a negligible complication. ABO-incompatible transplantation has been infrequently used in the United States, and the age at which it is no longer feasible is still not clearly defined. Despite ABO-incompatible listing, it has not yielded lower wait-list mortality under the current UNOS allocation algorithm.[21]

Good donor management is a vital part of successful organ transplantation. The main goals are maintenance of normothermia, euvolemia, and adequate tissue perfusion and prevention of infection. Often, donors with poor cardiac function on initial evaluation will respond to volume loading and low-dose inotropic support with a significant improvement in function after heart retrieval, usually as part of a multiorgan retrieval procedure. Similar to recipients, all donors are screened for agents that might cause serious infection in an immunocompromised host, such as CMV, EBV, HIV, hepatitis, and *Toxoplasma*. The presence of antibodies is not a contraindication to transplantation but helps guide post-transplant therapy.

The four major goals in procurement of a donor heart are to (1) work effectively with the other teams to ensure the optimal condition of each recovered organ, (2) evaluate the hemodynamic status of the patient and the gross function of the heart by inspection, (3) use an effective cardioplegia and venting procedure that maximizes preservation of the heart, and (4) expertly remove the heart and adjoining vascular connections to ensure optimal anatomy for implantation. Procurement is performed through a median sternotomy. Donor blood is obtained for viral titers and retrospective HLA typing. The initial dissection involves separating the aorta from the main pulmonary artery to allow cross-clamping. Careful inspection of the heart is performed, and the patient is systemically heparinized. Procurement commences when the aorta is cross-clamped. Cardioplegia solution is infused through the aortic root, and the heart is vented through the right atrial

appendage or superior or inferior vena cava for the right side and through the superior pulmonary vein or left atrial appendage for the left side. The superior vena cava is dissected free of its pericardial attachments up to the innominate vein, and the azygous vein is ligated and divided. The pericardial reflections around the right superior pulmonary vein and the inferior vena cava are sharply divided. The cardiectomy begins with inferior vena cava transection at the pericardial reflection. The main pulmonary artery is divided and then the posterior pericardial attachments and the superior vena cava. Last, the aorta is transected at the level of the innominate artery or more distally if the aorta is needed for the recipient. The donor heart is immersed in cold (4° C), sterile saline and then triple-bagged in a sterile manner for transport. In general, the cold ischemia time should be limited to a maximum of 4 to 5 hours.

## Recipient Preparation and Techniques of Implantation

The standard technique for orthotopic heart transplantation was first described by Lower and Shumway in 1960 and consists of biatrial anastomoses, thus avoiding individual caval and pulmonary vein connections (Fig. 50-4).[22] Currently, however, the majority of cardiac transplant centers now use the bicaval technique, because it preserves atrial morphology and kinesis and is simpler when reconstruction after previous congenital heart repair is necessary. Once adequate hemodynamic monitoring is in place and the recipient is properly anesthetized, a median sternotomy is performed and the heart is suspended in a pericardial cradle. If previous sternotomies have been performed, appropriate precautions should be taken, including exposing the groins in the sterile field for access for femoral bypass. Once in the chest, the main pulmonary artery is dissected off the aorta past the bifurcation, and the pericardial reflection is mobilized off the aortic arch. Normally, aortic and bicaval cannulation is used.

In the case of a neonatal recipient with HLHS, the aortic arch vessels are mobilized proximally and controlled with snares, and the descending thoracic aorta is dissected to a level 2 to 3 cm below the insertion of the ductus arteriosus. The right and left pulmonary arteries are mobilized and controlled with snares in preparation for cardiopulmonary bypass. After heparinization, the main pulmonary artery is cannulated for arterial inflow, and a single venous cannula is placed in the right atrium, because circulatory arrest will be used. Immediately on instituting cardiopulmonary bypass, the pulmonary arteries are snared tight and the body perfused though a patent ductus arteriosus. The recipient is cooled to 18° C for circulatory arrest.

Once the donor organ is available in the operating room and the patient has been adequately cooled, circulatory arrest is established, the arch vessels are snared tightly, and the patient is exsanguinated into the venous reservoir. The aorta is divided just above the valve and incised longitudinally along the lesser curve of the aortic arch to a level 1 to 2 cm below the ductal insertion site on the descending aorta. The ductus is ligated next to the pulmonary artery and divided, and then the main pulmonary artery is transected just below the bifurcation. The right atrial incision is started superiorly at the base of the appendage. This incision is then carried down into the coronary sinus and across the atrial septum into the left atrium. The superior aspect of the right atrial incision is next carried across the septum to open the roof of the left atrium. The lateral wall of he left atrium is incised above the left pulmonary veins with the left atrial appendage included with the specimen.

The donor organ is prepared on the back table in cold saline solution. The right atrium is incised from the inferior vena

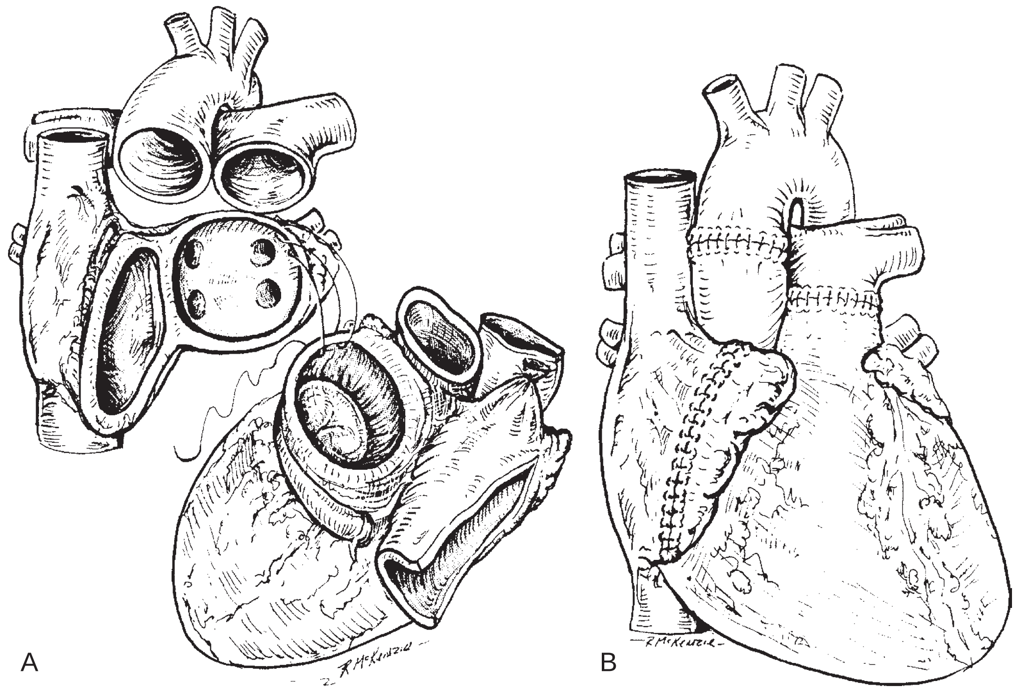

FIGURE 50-4 Standard heart transplantation using biatrial anastomosis. **A,** A recipient ventricular mass has been removed, and the left atrial anastomosis has been started. **B,** Final appearance after all anastomoses are completed.

cava laterally to the base of the appendage; the area of the sinoatrial node is avoided if atrial anastomoses rather than caval anastomoses are to be performed. The pulmonary vein confluence is excised off the back of the left atrium, leaving an opening comparable in size to the recipient left atrial cuff. The pulmonary artery is transected just below the bifurcation to provide a wide anastomosis. The aorta is trimmed, depending on the level required in the recipient. Care must be taken to check for and adequately close a patent foramen ovale, which is frequently present, especially in infant hearts. Failure to do so may result in significant postoperative right-to-left shunting in the face of pulmonary hypertension.

The implantation is begun by forming an anastomosis between the lateral wall of the left atrium from the level of the left atrial appendage inferiorly. A left ventricular vent is placed through the right superior pulmonary vein, and the left atrial anastomosis is completed by reconstructing the intra-atrial septum. The arch of the aorta is then reconstructed. The right atrial anastomosis is begun at the inferior vena cava orifice and then taken superiorly along the intra-atrial septum. The ascending aorta is then cannulated by a new purse-string suture, air is evacuated, and cardiopulmonary bypass is resumed. The snares are released from the head vessels and warming is commenced. The pulmonary anastomosis is then performed in an end-to-end fashion. If time permits, this step may be done during circulatory arrest in a drier field. After adequate warming, the patient is weaned from cardiopulmonary bypass and the cannulas removed (Fig. 50-5).[22] Right atrial, left atrial, and, occasionally, pulmonary artery pressure catheters are placed before discontinuing bypass and brought out through the skin below the incision.

In older children with cardiomyopathy or infants without aortic arch abnormalities, the recipient procedure is similar to that performed in adults. The ascending aorta is mobilized to the pericardial reflection and used for arterial cannulation. The child is cooled to 28° C to 34° C, because the implantation is performed under aortic cross-clamp rather than circulatory arrest. After the left atrial anastomosis has been completed, the right atrial connection can be sewn either directly or by using a bicaval technique if a previous cavopulmonary connection has been performed. This may decrease the incidence of tricuspid regurgitation in certain patients. The aortic anastomosis is then completed in an end-to-end fashion in the midascending aorta. The pulmonary artery anastomosis may or may not be performed during aortic cross-clamp, depending on how long the implant procedure takes.

Numerous other variations of the implantation procedure can be used, depending on the recipient anatomy. Modifications accounting for a persistent left superior vena cava, previous cavopulmonary shunt or Fontan procedure, corrected transposition of the great arteries, and situs inversus totalis have been described.

## Postoperative Management

The recipient is returned from the operating room to an isolation room in the intensive care unit. Mechanical ventilation is required initially but is weaned as rapidly as possible. Antibiotics are continued until all monitoring lines and chest tubes have been removed.

Some level of inotropic support is required in virtually all heart transplant recipients. Isoproterenol is often an ideal choice because of its pulmonary vasodilatory effects, as well as its inotropic and chronotropic effects, because many patients have a slower than optimal heart rate initially. This transient sinus node dysfunction is rarely permanent. Dobutamine and dopamine, especially at "renal doses," are also frequently used to augment ventricular contractility. Epinephrine and norepinephrine are usually reserved for poor graft function. Sodium nitroprusside infusion or phosphodiesterase inhibitors are used for afterload reduction in the early postoperative period. Right ventricular dysfunction secondary to pulmonary hypertension may respond to phosphodiesterase inhibitors, which are used for afterload reduction in the early postoperative period. Right ventricular dysfunction secondary to pulmonary hypertension may respond to phosphodiesterase inhibitors such as milrinone. Inhaled nitric oxide has been shown to be an effective selective pulmonary vasodilator with few systemic side effects and is useful in cardiac transplant recipients with pulmonary hypertension.

## Transplant Immunosuppression

A combination of immunosuppressive agents is used for the prevention and treatment of rejection. Standard triple-drug immunosuppression therapy consisting of prednisone, cyclosporine, and azathioprine has been successfully used in pediatric cardiac transplant recipients and remains the most common regimen.[23] In 2009, more than 70% of transplant recipients received induction immunotherapy. The induction and maintenance doses of medications used for immunosuppression at the Children's Hospital of Philadelphia are listed in Table 50-4. Because of the adverse effects of corticosteroids, withdrawal from prednisone is usually attempted 6 months after transplantation.[24] Up to 80% of recipients may be successfully weaned from steroids; only a quarter of these patients have an episode of rejection in the first 6 months.[25]

Most patients are maintained on an immunosuppressive regimen that is a combination of calcineurin inhibitor and cell-cycle inhibitor. Tacrolimus (formerly called FK-506) has been shown to be an effective immunosuppressive agent in children, and its use has increased over the last 5 years, with approximately 66% of all pediatric cardiac transplant patients receiving it for maintenance immunosuppression 1 year after transplantation in the place of cyclosporine. Overall, patients taking tacrolimus appear to have a lower incidence of rejection. Side effects of azathioprine therapy, such as bone marrow depression, have precipitated the use of mycophenolate mofetil (MMF) in its place. It is estimated that approximately 66% of patients use MMF as a cell-cycle inhibitor. It is well tolerated with few side effects and has been shown in large clinical trials to have benefits in survival and treated rejection episodes.[26]

An increasing number of centers use induction immunosuppression in pediatric cardiac recipients, with nearly 70% of patients now receiving a polyclonal anti–T-cell preparation, OKT3 (a murine monoclonal CD3 antibody), or an interleukin-2 receptor antibody immediately after transplantation. However, there have been no significant

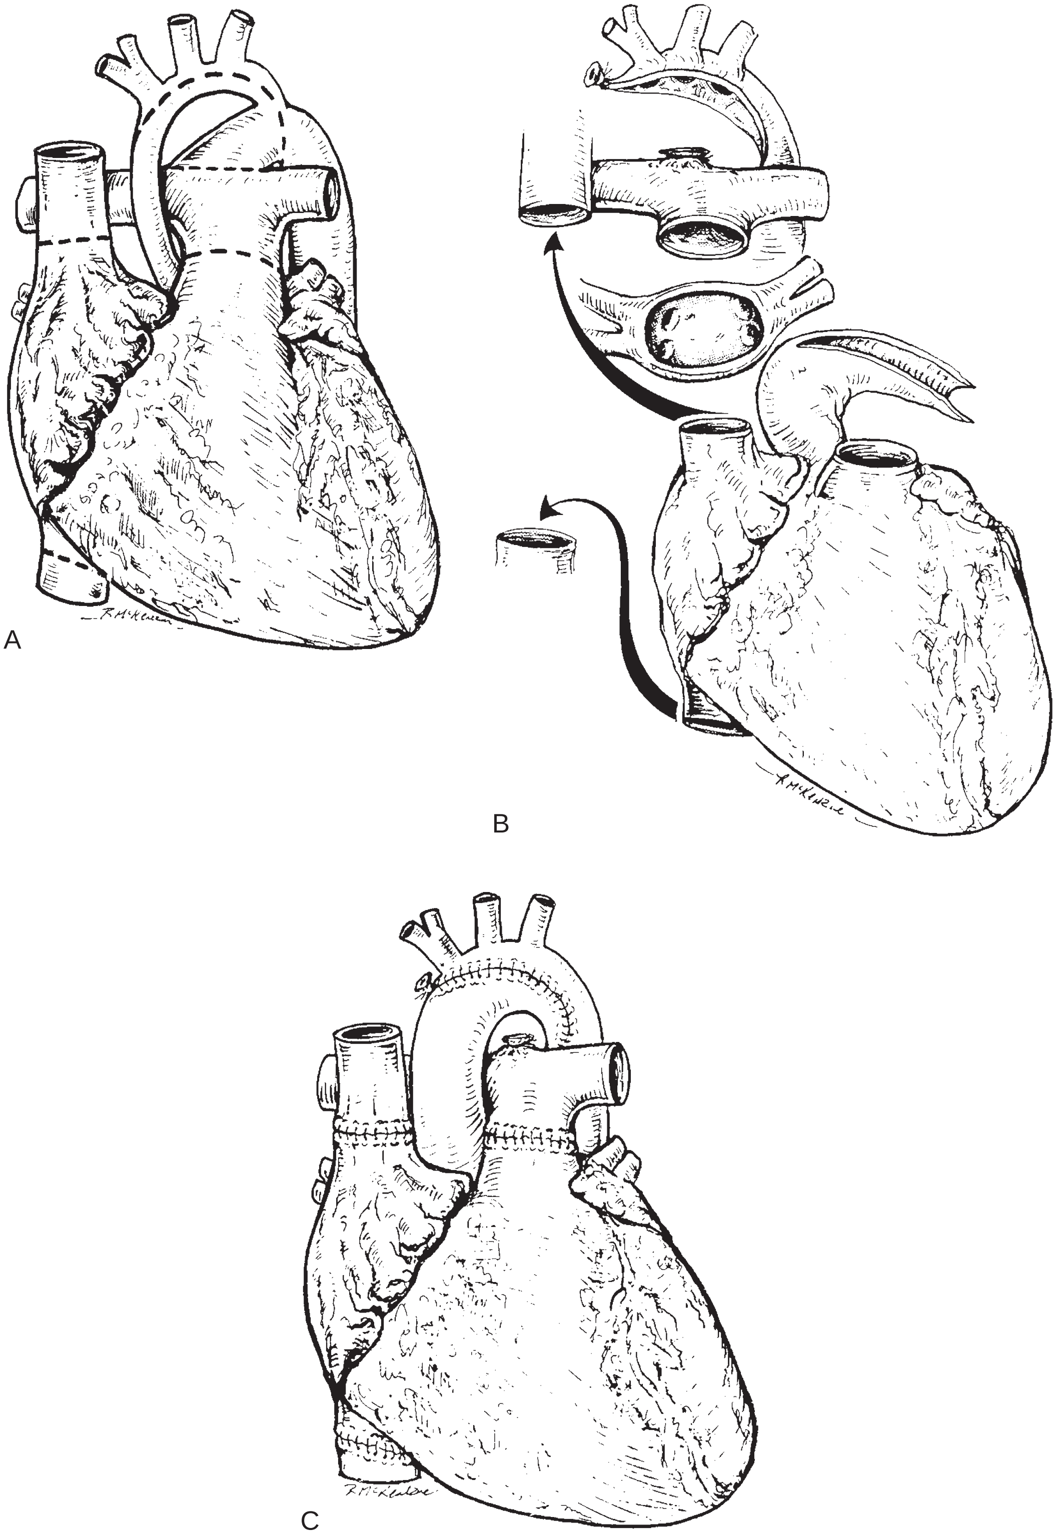

**FIGURE 50-5** Technique for transplantation in hypoplastic left heart syndrome (with the use of bicaval anastomosis). **A,** Recipient anatomy before cardiectomy. **B,** Appearance of the recipient after cardiectomy. Note that the aortic incision must be extended into the descending aorta beyond the level of the arterial duct. **C,** Final appearance after all anastomoses are completed.

differences in the average number of rejection episodes in patients treated for rejection regardless of the type of induction used. In addition, there is no significant difference in survival between the induction groups or between use of induction versus no induction. Induction therapy does not increase the risk of CMV disease or post-transplant lymphoproliferative disease.

Infectious prophylaxis includes oral nystatin for fungal prophylaxis and oral trimethoprim-sulfamethoxazole 3 times per week. Pentamidine inhalation treatment is an effective

alternative to trimethoprim-sulfamethoxazole for *Pneumocystis carinii* prophylaxis if bone marrow suppression is a problem. Routine CMV prophylaxis is used in cardiac transplant recipients at our institution.

## Early Complications

Acute rejection and infection are the most common early complications after cardiac transplantation. Nearly 60% to 75% of patients have at least one episode of rejection, and it should be expected that about a third will have an episode in the first 3 months and 50% within the first year after transplantation.[27] Some studies suggest that infants may be less prone to rejection than older children. Rejection surveillance is based on clinical evaluation, echocardiography, and endomyocardial biopsy. Clinical assessment includes observation of changes in a patient's activity or appetite. Atrial or ventricular ectopy, including tachycardia, is suspicious for rejection and mandates evaluation. Echocardiography is particularly useful in neonates, in whom biopsy is technically difficult and carries significant risk because of patient size. Echocardiographic evaluation is typically performed weekly for the first month and then monthly for the first year after transplantation. Echocardiography-guided transjugular endomyocardial biopsy has been shown to be an effective means of monitoring pediatric transplant recipients for rejection and remains the gold standard for detection of rejection.[28] An aggressive approach, consisting of routine endomyocardial biopsy weekly for the first month after transplantation, every second week for the second month, and then once monthly for the remainder of the first year, has been adopted at the Children's Hospital of Philadelphia for rejection surveillance. Subsequent biopsies are obtained twice annually or whenever rejection is clinically suspected. Most biopsies are performed on an outpatient basis. The international grading system for cardiac transplant rejection is shown in Table 50-5.

Episodes of acute rejection are usually treated with a 3-day course of intravenous methylprednisolone (10 mg/kg). OKT3 and antithymocyte globulin are reserved for an incomplete response or rejection refractory to steroids. Response is confirmed by follow-up biopsy 1 to 2 weeks after treatment.

J Heart Lung Transplant 1990;9:587-593; Stewart S, Winters GL, Fishbein MC, et al: Revision of the 1990 working formulation for the standardization of nomenclature in the diagnosis of heart rejection. J Heart Lung Transplant 2005;24:1710-1720.

Although infectious complications are common in cardiac transplant recipients, infection-related deaths do not appear to be. Bacterial infections are most frequent in the early post-transplant period, but can occur late after transplantation and usually respond to proper antibiotic therapy. Of viral infections, CMV appears to be the most common and is treated with intravenous ganciclovir. Viral respiratory infections usually occur at a frequency similar to that in normal children and appear to be well tolerated by the recipient.

Aside from rejection and infection, the immediate postoperative complications after heart transplantation are hypertension, seizures, renal dysfunction, and diabetes. Nearly 10% of infant heart transplant recipients require perioperative peritoneal dialysis. Among neonates, 10% to 15% require phenobarbital therapy for postoperative seizures.

## Late Complications

The primary late complications in pediatric cardiac transplant recipients are chronic rejection, post-transplant lymphoproliferative disease (PTLD), and transplantation CAD. Rejection may account for up to 40% of deaths after cardiac transplantation. Lymphoproliferative disease is associated with EBV infection and is currently treated by a reduction in immunosuppressants, acyclovir, and chemotherapy.[29]

The onset of transplant CAD has a prevalence of 10% to 15% and may be suggested by symptoms of congestive heart failure in recipients. Echocardiograms are performed routinely during follow-up visits of heart transplant recipients, and worsening ventricular function is a sign of graft CAD. A new onset of arrhythmias after transplantation, especially ventricular arrhythmias, may also be an indication of underlying CAD. Additionally, CAD may be found on routine follow-up catheterization or intracoronary ultrasonography, without any previous suggestion of disease. A number of causes have been implicated in the development of graft CAD, including chronic cellular rejection, hyperlipidemia, vascular rejection, and CMV infection. Unlike adult cardiac transplant recipients, CAD appears to develop in pediatric patients relatively early after transplantation, with one series demonstrating an incidence of 35% by 2 years after transplantation. A review of 815 pediatric transplant patients found nearly 8% to have significant CAD by angiogram or autopsy findings. The mean time after transplantation to diagnosis was 2.2 years, with one patient having significant CAD 2 months after transplantation. Only 20% of patients in whom graft CAD was diagnosed were still alive, and most of the deaths were sudden or unexpected. Retransplantation appears to be the only viable option for these patients, although the results in general are not encouraging, with 1- and 3-year survival rates of 71% and 47%, respectively, and CAD developing in the second grafts in 20% of retransplantation patients. However, the Loma Linda group has reported a significantly better retransplantation experience in infants who were first transplanted when younger than 6 months. In this group, a 10-year actuarial survival rate of 91% was observed after retransplantation. Potential medical treatment targeted at cholesterol and lipid-lowering therapies are currently under investigation.

## Results

The largest group of infant cardiac transplant recipients reported in the literature is from Loma Linda, where 233 heart transplantations in infants younger than 6 months have been performed. Nearly 65% were for HLHS, and the rest were for other complex congenital anomalies (29%) or cardiomyopathy or tumor (8%). The operative (30-day) survival rate was 89%, with the primary causes of mortality being primary graft failure, technical problems, pneumonia, or acute rejection. The overall 1-year survival rate was 84%, with a 5- and 10-year actuarial survival rate of 73% and 68%, respectively. In addition, patients undergoing transplantation when younger than 30 days had a significantly better outcome than did older infants, with an actuarial survival rate of 80% and 77% at 5 and 10 years, respectively, potentially related to improved immune tolerance in the younger subgroup.

Stanford University reported its series of 72 patients younger than 18 years who have undergone heart transplantation since 1977. Only 25% were younger than 1 year (mean of 9 years), and nearly two thirds had cardiomyopathy unrelated to congenital heart disease. The operative survival rate was 87.5%, with deaths mainly caused by pulmonary hypertension/right ventricular failure and acute rejection. There were 20 late deaths, 24% were due to rejection, and 17% were due to graft CAD. Actuarial survival rates at 1, 5, and 10 years were 75%, 60%, and 50%, respectively.

At St. Louis Children's Hospital, 45 heart transplants were performed from 1983 to 1993, more than half in infants with HLHS. The infant group had a survival rate (92%) similar to that of the Loma Linda series, whereas the pediatric group (older than 1 year) had an 80% early survival rate. Morales and colleagues published results of their experience spanning more 2 decades at Texas Children's Hospital and reported no change in mortality in survivors after the first post-transplant year.[30]

Results from the Registry of the International Society for Heart and Lung Transplantation reveal a perioperative mortality rate higher for infants than for older children (Fig. 50-6). Despite the much greater early mortality, however, the half-life of 18.3 years is longer than that of the childhood or adolescent survivors. For the childhood age group of 1 to 10 years, the half-life was 17.5 years versus 11.3 years for the adolescent age group, thus conferring the younger patients a significant survival advantage. If those patients who died within the first year after transplant were excluded, the median conditional survival was 21.4 years for those who underwent transplantation in the first year of life, 19.3 years for those aged between 1 and 10 years, and 15.2 years for older children (Fig. 50-7). Survival has been improving in relation to the era of transplantation, with the median survival increased

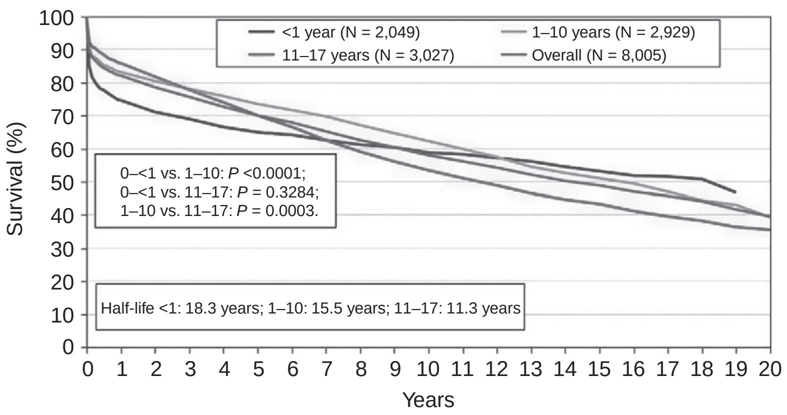

**FIGURE 50-6** Survival analysis for transplantations performed January 1982 to June 2008. (From Kirk K, Edwards LB, Kucheryavaya AY, et al: The Registry of the International Society for Heart and Lung Transplantation: Thirteenth official pediatric heart transplantation report—2010. from 9.5 years for the period 1982 to 1989, to 11.7 years for the period 1990 to 1994, to 14.3 years for the period 1995 to 1999 (Fig. 50-8). Averaged over 15 years, an infant recipient would have an approximate 2% per year risk of mortality, whereas for older children, it remains approximately 4%, again indicating a longer-term survival advantage for younger cardiac transplant recipients.

The most predictive risk factors for 1-year mortality in the pediatric population remain congenital heart disease, donor age, pulmonary artery systolic pressure greater than 35 mm Hg, and the need for mechanical ventilation and hospitalization while awaiting transplantation. Among the most significant risk factors for 5-year mortality are dialysis, congenital heart disease, and female gender (Fig. 50-9). Causes of death include CAD, acute rejection, lymphoma, graft failure, and infection. Retransplantations now account for 5% of all transplantation operations. Survival for retransplantation is decreased when the intertransplantation interval was less than 3 years and is relative to indication for primary transplantation (Fig. 50-10).[31,32]

Aside from survival, it has been demonstrated that transplanted hearts in children appear to grow normally, and the left ventricle increases muscle mass to maintain the normal left ventricular mass-to-volume ratio with time. Exercise testing in older children has shown peak heart rate and oxygen consumption to be consistently two thirds of that predicted in heart transplant recipients. Somatic growth appears to be normal in infants after heart transplantation, and neurologic development is generally preserved, although some neuro-

logic abnormalities may be seen in up to 20% of neonatal recipients on long-term follow-up.

## Conclusion

Despite further improvements in surgical technique, immunosuppression, perioperative management, and rejection surveillance, long-term results of pediatric heart transplantation have shown little change, with a 15-year survival rate of approximately 50%. Chronic rejection, graft CAD, and the long-term effects of steroids on growth continue to cloud the development of cardiac transplantation as the primary treatment of complex congenital heart disease. However, for many children with end-stage cardiomyopathy and structural heart disease not amenable to corrective surgery, transplantation is the only option. Future areas of research include the use of xenografts, ABO incompatibility, permanent mechanical support, and widening the bridge to transplantation with smaller and more adaptable assist devices.

CHAPTER 51

# Pediatric Lung Transplantation

Sanjiv K. Gandhi, Albert Faro,
and Charles B. Huddleston

The first reported attempt at lung transplantation occurred in 1963 and was performed by Dr. James Hardy at the University of Mississippi Medical Center.[1] The patient did not survive the hospitalization, dying 18 days after the transplant. There were a number of additional attempts at this during the next few years, with most failures related to poor healing of the airway anastomosis. Approximately 20 years after Dr. Hardy's ill-fated effort, the first truly successful lung transplant was performed in Toronto, Canada, by a team led by Dr. Joel Cooper. This patient had a single-lung transplant for pulmonary fibrosis and survived for more than 6 years, ultimately dying of renal failure.[2] During the subsequent years, and particularly in the late 1990s, pediatric lung transplantation has emerged as a viable treatment option for children with end-stage pulmonary parenchymal and vascular diseases. However, the number of children undergoing transplantations throughout the world since 1989 remains relatively small, representing only 4% of all lung transplantations performed.[3] In this chapter, pediatric lung transplantation is described as an isolated procedure, and heart-lung transplantation is not included.

## Organ Allocation

In 2005, a new system to allocate lungs to recipients was established across the United States. Previously, lungs were allocated based on the amount of time the recipient had accrued on the waiting list (first come, first served). In an attempt to make distribution of lungs more equitable, a lung allocation score (LAS) was devised and implemented.[4] This score attempts to prioritize organs to patients on the list most in need of the organ (the sickest) as well as to those most likely to do well post-transplantation. This score is used in children 12 years and older. For those younger than 12 years, the old system still remains in effect at present.

## Indications

Isolated lung transplantation is applicable to any child with life-threatening and progressive disability because of pulmonary parenchymal or vascular disease. In general, this treatment modality is indicated for increasing the duration of life and for improvement in the quality of life. The current long-term survival after lung transplantation is approximately 50% at 5 years. Thus the selection of patients for transplantation and the timing of the procedure are critically important. One would like to be able to predict when a child would be within 2 years of dying without any form of medical treatment. Obviously, this may be very difficult. The major diagnostic groups for pediatric lung transplantation are cystic fibrosis (CF), interstitial lung disease with pulmonary fibrosis, primary pulmonary hypertension, pulmonary hypertension associated with congenital heart disease, retransplantation, and a "miscellaneous" category (Table 51-1). Chronic obstructive lung disease, the most common indication for transplantation in adults, is remarkably absent from this list.[3]

### CYSTIC FIBROSIS

This disease, the most common lethal hereditary disease in North America, comprises the largest diagnostic group of children younger than age 18 years who undergo lung transplantation. Although the median survival now exceeds 38 years, one eighth of the deaths from CF in 2008 still occurred in the pediatric age group. Without question, the most common cause of death is respiratory related. About 250 to 300 transplantations are performed annually in the United States for CF, and, although this number is growing slowly each year, donor availability still remains a major limiting factor.[5]

As with other diagnostic groups, timing of transplantation in the course of a chronic disease is a crucial issue. Kerem, in the early 1990s, demonstrated that a 1-second forced expiratory volume ($FEV_1$) less than 30% of predicted, a $PaO_2$ less than 55 mm Hg, and/or a $PCO_2$ greater than 50 mm Hg were associated with a survival beyond 2 years of less than 50%.[6] The impact of these factors is magnified in the pediatric age group, particularly in girls. However, more recent studies on the natural history of CF patients, once they have severely compromised lung function, show that an isolated measure of the $FEV_1$ alone may not be sufficiently predictive. The rate of

**TABLE 51-1**

| Primary pulmonary hypertension |
| Eisenmenger syndrome |
| Bronchiolitis obliterans |
| Retransplantation |
| Other |

decline in the $FEV_1$ may be a more accurate determinant of survival.[7,8] Other factors that may serve as relative indicators in deciding to proceed toward transplantation include the need for continuous supplemental oxygen, increased frequency of hospitalizations, and diminished weight for height (below the 80th percentile).[6] More recently, Liou and colleagues validated a formula that included microbiological data, body mass index measures, and presence of diabetes, in addition to lung function and gender, as important determinants in prognosticating 5-year survival.[9] The presence of antibiotic-resistant organisms in the sputum is a relative contraindication to lung transplantation. The synergistic effectiveness of antibiotic combinations is not useful in treating pulmonary exacerbations and is no longer readily available. Chronic infection with *Burkholderia cenocepacia,* pretransplantation, is associated with a particularly poor post-transplantation prognosis and therefore is of particular concern.[10,11] Portal hypertension with hepatic cirrhosis occurs in 5% to 10% of patients with CF. These children are at risk for variceal bleeding as well as derangements of synthetic function. In general, if the synthetic function is preserved, decompression of the portal venous system with percutaneous procedures will lower the risk to a level satisfactory for lung transplantation.[12] However, when there is also synthetic dysfunction of the liver, combined liver-lung transplantation may be the only appropriate option.[13,14] Diabetes mellitus is generally not considered a contraindication to transplantation unless there is evidence of vasculopathy, bearing in mind that control of serum glucose will be more difficult after transplantation.[15] As many as 10% to 15% of CF lung transplantation candidates will have had prior thoracotomies for either pneumothorax or pulmonary resection. Most centers do not consider this a contraindication to transplantation, although the resultant adhesions from these prior operations do increase the difficulty and the risk of bleeding.[16] Mechanical ventilation or presence of a tracheostomy are not in and of themselves contraindications to transplantation, but the overall medical condition of patients requiring this level of support must be carefully considered.[17]

## PULMONARY VASCULAR DISEASE

This rather broad classification of patients includes those with primary pulmonary hypertension (PPH) and those with pulmonary hypertension associated with congenital heart disease (PH/CHD). The latter category includes patients with Eisenmenger syndrome but is not limited to this. These patients die of either progressive right-sided heart failure, arrhythmias, or a lethal episode of hemoptysis. It is difficult to predict when a patient might have a fatal arrhythmia or episode of hemoptysis. However, most patients with pulmonary vascular disease will die of progressive right-sided heart failure over a protracted period of time.[18] In the past several years, a number of somewhat selective pulmonary vasodilators have become available for use in these patients. These include intravenous prostacyclin,[19] prostacyclin analogues iloprost (inhaled)[20] and betaprost (oral),[21] and bosentan,[22] an endothelin receptor antagonist. These drugs have enabled patients to delay the need for transplantation for years. In fact, the number of patients undergoing transplantation for pulmonary vascular disease has significantly dropped in recent years. The timing of transplantation for patients with pulmonary vascular disease is influenced significantly by the response to medical therapy and the underlying cause of the pulmonary vascular disease. Although primary pulmonary hypertension and Eisenmenger syndrome result in identical histologic changes in the pulmonary vascular bed, the latter of these two is associated with a much more favorable long-term prognosis. A retrospective analysis by Hopkins of 100 adults with severe pulmonary hypertension resulting from either Eisenmenger syndrome or PPH revealed that, in the former group, actuarial survival without transplantation was 97% at 1 year, 89% at 2 years, and 77% at 3 years. In contrast, survival was 77%, 69%, and 35% during the same respective time intervals in the PPH cohort.[23] It is presumed that the intracardiac defect allows the right ventricle to “decompress” via the defect when the afterload in the pulmonary vascular bed becomes prohibitively high. On the basis of this and other observations, atrial septostomy performed in the cardiac catheterization suite has been demonstrated to provide clinical benefit in patients with PPH.[24] Results from a multicenter study of patients with PPH performed before the advent of long-term intravenous prostacyclin therapy demonstrated a median survival from time of diagnosis of 2.8 years. In that study, a formula was developed incorporating hemodynamic variables to assist in predicting the 2-year mortality,[18] and it was recommended that patients should be listed when this figure is less than or equal to 50%. Studies regarding natural history in adults have been applied to children, but it is unclear whether this disease behaves the same in a younger population. Clabby and co-workers reviewed 50 patients from many centers to provide a means of estimating survival in children with PPH.[25] There was a direct correlation of mortality with the product of the mean right atrial pressure and the pulmonary vascular resistance.[25] With progress in the medical therapy of PPH to identify selective pulmonary vasodilators as well as the underlying mechanisms of this disease, these formulas predicting survival may be obsolete. The durability of medical therapy is unclear. How this therapy might be applied to secondary pulmonary hypertension, such as Eisenmenger syndrome, is speculative.

The two main issues in considering patients with Eisenmenger syndrome or PH/CHD for lung transplantation are the timing of listing and the complexity of the cardiac lesion to be repaired. As noted earlier, it is clear that, once the diagnosis is made, these patients can live much longer than those with PPH.[23] The mode of death in these patients is by progressive heart failure, pulmonary hemorrhage, stroke, or sudden death, presumably due to arrhythmias.[25] Patients should be listed when symptoms develop, when there has been a single pulmonary hemorrhage, or perhaps arbitrarily when they reach their late 30s. Most patients with PH/CHD have an atrial septal defect, ventricular septal defect, or patent ductus arteriosus. All of these require relatively simple cardiac repairs. However, there

are patients with unrepaired atrioventricular canal defects, transposition of the great arteries, and truncus arteriosus who would require more complex procedures. An alternative for these patients would be heart-lung transplantation. The likelihood of obtaining a donor heart-lung block for anyone more than 40 kg is low because of the distribution policy for thoracic donor organs. In addition, the long-term survival after heart-lung transplantation is particularly poor (approximately 40% at 5 years post-transplantation).[3] These two issues must be factored into the decision as to whether one should perform the higher-risk procedure of lung transplantation in combination with repair of a complex cardiac lesion or heart-lung transplantation. Some patients with congenital heart disease who have undergone repair may not experience the expected decline in pulmonary vascular resistance after appropriate correction. Occasionally the repair has been performed relatively late in life, but there are children who have undergone timely repair and still present later with severe pulmonary hypertension. It is not clear how to classify these patients. In general, this is a less uniform group than either the patients with PPH or those with Eisenmenger syndrome. They seem to follow a clinical course similar to that seen in patients with PPH and should be treated in a similar fashion.[23]

Another diagnostic group with pulmonary vascular disease are patients with an inadequate pulmonary vascular bed. Examples of this include pulmonary atresia, ventricular septal defect and multiple aortopulmonary collaterals, and congenital diaphragmatic hernia, where there is primarily a general deficiency of pulmonary parenchyma. In the former group, complete correction (repair of the ventricular septal defect combined with reconstruction of the right ventricular outflow tract with a conduit to the unifocalized aortopulmonary collaterals) represents a high-risk but viable option for the majority of these patients. However, when the anatomy of the aortopulmonary collaterals is not amenable to unifocalization or when unifocalization has not produced satisfactory growth of the pulmonary vascular tree, the result is progressive cyanosis or progressive pulmonary hypertension or both. Lung transplantation with repair of the residual cardiac defect may be the only feasible option for survival. Children with congenital diaphragmatic hernias, despite having undergone a successful hernia repair, may still be left with inadequate pulmonary parenchyma and vascular bed to handle the full cardiac output. The resultant severe pulmonary hypertension is the usual cause of death in these infants and is an indication for transplantation. The problem here is that these infants often will require extracorporeal membrane oxygenation (ECMO) support during the perioperative period. This reduces the time that patients such as this can wait for a donor offer once listed for lung transplantation. It is possible that a single-lung transplant on the affected side would be sufficient in this circumstance. In this scenario, once the patient has grown, it may be possible to remove the transplanted lung altogether, leaving the patient with a presumably normal contralateral lung to maintain normal respiratory function. In reality, those patients with insufficient pulmonary reserve will have to be identified very early in the course for lung transplantation to be a realistic option. The mortality is quite high even when donor organs are identified.

In all the previous situations, isolated lung transplantation is appropriate only when left ventricular function is normal. Poor left ventricular function will result in elevated left ventricular end-diastolic pressure post-transplantation, which will add significantly to problems with pulmonary edema and early graft failure. Right ventricular function is frequently poor, particularly in the patient group with PPH. That should not be a deterrent to isolated lung transplantation, because the right ventricular function always returns to normal within a relatively short period of time.[26]

Although a prior thoracotomy is generally not a contraindication to lung transplantation in patients with pulmonary parenchymal disease, this is not true for those with pulmonary vascular disease, especially when secondary to congenital heart disease and associated with cyanosis. The adhesions that develop after a thoracotomy for palliation of cyanotic congenital heart disease are extremely vascular. Intercostal and internal mammary arteries will form direct connections through the pleura into the parenchyma of the lung in a compensatory attempt to enhance pulmonary blood flow. The bleeding that occurs during the recipient pneumonectomy portion of the transplantation procedure is often horrendous and life threatening.

## PULMONARY FIBROSIS

These patients account for 5% to 10% of pediatric patients undergoing lung transplantation.[3] Placed in this category are those patients with “usual” interstitial fibrosis, radiation-induced fibrosis, bronchopulmonary dysplasia, and pulmonary fibrosis secondary to chronic aspiration. The progression of these disease processes is quite variable. Generally, patients should be listed when normal activities are markedly limited and minor viral illnesses lead to significant deterioration. Most patients will be oxygen dependent and may well have evidence of coexistent pulmonary hypertension. For those in whom aspiration is the underlying problem, the source of the aspiration must be eliminated.

The prognosis of children with idiopathic pulmonary fibrosis is not altogether clear. This may be because there is not a “usual interstitial pulmonary fibrosis” disease in children; the underlying causes are frequently unique and unusual. Decisions regarding listing for transplantation are somewhat difficult because of this. Pulmonary fibrosis presenting during infancy was once believed to have a poor prognosis; however, some studies have demonstrated improved survival with high doses of corticosteroid therapy.[27] The prognosis for adults with total lung capacity less than 60% predicted is still poor; nearly all are dead within 2 years.[28] It is difficult to translate this information into the pediatric experience. Pulmonary hypertension frequently accompanies this disease as it progresses. These patients should be evaluated and listed for transplantation when they become symptomatic. If there is a favorable response to corticosteroids, they can be followed with standard (age $>$ 5 years) or infant (length $<$ 90 centimeters) pulmonary function tests. One problem with managing this disease is that patients with progression of their disease tend to remain on relatively high doses of corticosteroids and come to transplantation in a rather cushingoid state. This should not exclude them from transplantation.

## BRONCHIOLITIS OBLITERANS AND RETRANSPLANTATION

Bronchiolitis obliterans is not a specific disease but rather a histologic description characterized by the obstruction and destruction of the distal airways. It may occur as a

consequence of any severe lung injury, including viral pneumonia, graft-versus-host disease after bone marrow transplantation, autoimmune diseases, chemical injury, Stevens-Johnson syndrome, and others. Of course, it is a relatively common late complication of lung transplantation (see later). The underlying etiology is unknown. “Primary” bronchiolitis obliterans (not related to prior lung transplantation) is a perfectly legitimate indication for lung transplantation: It is a slowly progressive disease in virtually all cases with no known effective treatment. When this disorder occurs as a consequence of an isolated lung injury, transplantation is a fairly straightforward decision process. However, those patients with prior bone marrow transplantations (usually for leukemia) offer special considerations.[29] Although the standard definition of “cure” is remission of the malignancy for more than 5 years, most of these patients present within 2 or 3 years of treatment. Another problem is the deranged immune competency seen after bone marrow transplantation and how the immunosuppressant agents used after lung transplantation might further affect this. We have found that these patients have less acute rejection than most other lung transplantation recipients but may be more prone to opportunistic infections.[29] However, the number of patients transplanted in this setting is low. For patients who acquire bronchiolitis obliterans through other immunologic injuries, such as autoimmune disorders, there are concerns about the likelihood of recurrence in transplanted lungs. One would have to ascertain that the primary process has completely abated before transplantation.

Retransplantation for acute graft failure after transplantation has an extremely poor prognosis.[30] Retransplantation for bronchiolitis obliterans is a controversial issue. Bronchiolitis obliterans accounts for the majority of deaths occurring more than 90 days post-transplantation.[3] This figure is borne out in our pediatric series.[31] Although early mortality after retransplantation is higher than for “first-time” lung transplantations, those who do survive this early phase have long-term survival similar to the non-redo transplantations.[30] Risk factors for poor early outcome include nonambulatory status, short period of time since the first transplantation, transplantation at a center with limited experience, and dependence on mechanical ventilation. We have further noted that a low glomerular filtration rate is an independent risk factor. Because patients continue to die on the waiting list, one could argue that no patient should ever be retransplanted because this might deprive an otherwise lower-risk patient from receiving organs in a timely fashion. At present this issue is unresolved. One can only advise use of proper judgment in selecting only the best candidates when the issue of retransplantation arises.

### MISCELLANEOUS

A variety of diagnoses fall into this group. Congenitally based pulmonary parenchymal diseases constitute one of the more interesting broad categories. Typically, these full-term newborns present with severe respiratory distress and no obvious cause, such as meconium aspiration, sepsis, or persistent fetal circulation. The diagnoses falling into this category include surfactant protein B deficiency, other forms of pulmonary alveolar proteinosis, alveolar-capillary dysplasia, pulmonary dysmaturity, congenital interstitial pneumonitis, and others. These infants usually have severe respiratory failure and require a high level of ventilatory support. Often extracorporeal membrane oxygenation has been or is currently being used. An open-lung biopsy is often necessary to either make the diagnosis or to exclude other diagnoses. Surfactant protein (SP) B or C deficiency and the ABCA 3 mutation can now be diagnosed by looking for the specific genetic mutation in peripheral blood or cheek swabs and assaying tracheal effluent for the presence of this surfactant protein.[32] All children will survive less than 3 months even with aggressive therapy. Abnormalities in SP-C and ABCA3 can have more varied presentations. Additionally, because the surfactant proteins are expressed only in the lungs, extrapulmonary organ dysfunction is rare.[33] Until other therapies become available, lung transplantation is the only viable therapeutic option. In general, the waiting time for an organ offer is relatively short in infants. Therefore one might realistically believe that an infant with a 3-month life expectancy could undergo transplantation and survive. When an infant is on ECMO, every effort should be made to wean from it, using whatever means possible, including a high-frequency oscillating ventilator and/or nitric oxide. Although ECMO is not an absolute contraindication to transplantation, one should be very cautious in this setting because of the relatively high incidence of other organ dysfunction.

## Contraindications

Contraindications to transplantation in children are also based on experience obtained in adults (Table 51-2). Absolute contraindications include systemic disease with major extrapulmonary manifestations or severe dysfunction of other organ systems. Thus widespread malignancy, collagen vascular disease, human immunodeficiency virus infection, and severe neuromuscular disease are absolute contraindications. The acceptable degree of renal insufficiency is open to some interpretation. Given the nephrotoxicity of cyclosporine and tacrolimus, the drugs that form the basis of nearly all immunosuppressant regimens, a serum creatinine value greater than 2.0 mg/dL and a probable need for post-transplantation dialysis are clinical parameters that would mitigate strongly against proceeding with transplantation. A glomerular

| Inadequate psychosocial support system |
| Poor compliance |

filtration rate less than 50 mL/min has been associated with a poor outcome in some patients. Significantly deranged hepatic synthetic function precludes transplantation unless concomitant liver transplantation is also being undertaken. More complex issues include severe malnutrition, poorly controlled diabetes mellitus, osteopenia, vertebral compression fractures, and the need for mechanical ventilation. None of these factors in and of themselves serves as an absolute contraindication. Nonetheless, all such concerning aspects of the clinical presentation must be evaluated and carefully considered in the scope of the patient's overall state of health to assess the likelihood for successful recovery after transplantation. Chronic administration of corticosteroids before transplantation is considered to be undesirable, and, when possible, one should reduce the total daily dose or change to an every-other-day dosage schedule. Previously, corticosteroids were believed to have a significant negative impact on airway healing, particularly in the case of double-lung transplantation with a tracheal anastomosis. Bilateral sequential lung transplantation with bronchial anastomoses has obviated this problem to a large degree. Severe psychiatric disorder in either the patient or, in the case of a young child, the care provider, is a strong relative contraindication. Finally, a history of poor compliance with either a medical regimen or in keeping follow-up appointments is considered by most to be a strong relative contraindication to transplantation. Graft failure due to lack of proper care not only results in death to the recipient involved, but also results in either a delayed or denied transplantation for a more appropriate candidate.[34]

### SPECIAL CIRCUMSTANCES

Some infants born extremely prematurely survive the early days of their lives only to develop severe bronchopulmonary dysplasia with respiratory failure within the first year of life. The incidence of significant cerebral injury in this group is high; approximately 50% of those surviving have some disability.[35] We can only assume that the incidence is higher in those with severe residual lung disease requiring transplantation. It is often difficult to assess the neurologic status in these infants because of their small size and often the need for sedation and neuromuscular paralysis for maintenance of satisfactory ventilation. It is probably unwise to submit an infant born at less than 28 weeks' estimated gestational age to lung transplantation, unless there has been an opportunity for an accurate neurologic examination. Imaging studies may offer some reassurance but are inconclusive. Another unusual situation that arises where lung transplantation may be considered appropriate is the child with severe acute respiratory distress syndrome. Those children still in the acute phase of this illness often have other organ dysfunction, and their condition is too unstable for them to wait the obligatory time once listed for transplantation, given the current organ allocation system for children less than 12 years of age. Those who survive the early phase of acute respiratory distress syndrome and are left with fibrotic lungs and stable ventilatory requirements should be evaluated. Finally, occasionally a patient with a history of prior pneumonectomy will be referred for lung transplantation. After pneumonectomy in children, the mediastinum shifts to the affected side. This distorts the hilar structures to the point that bilateral or single lung transplantation is virtually impossible. When possible, a patient undergoing pneumonectomy who might require lung transplantation in the future should have a prosthetic spacer placed in that side of the chest to maintain normal mediastinal geometry.

## Donor Evaluation and Organ Procurement

Donor availability remains a major limitation to the applicability of transplantation for end-stage lung disease. Donors must be matched by ABO blood type compatibility and within a reasonable size range of the recipient. Height is used as the most accurate correlate to lung size. Height that falls within 15% to 20% of the recipient height is probably suitable. Extending this range upward is certainly feasible, because it is not difficult to reduce the size of the lungs by trimming off the edge or even using only the lower lobes. However, extending the lower limit should be done with great caution, because the transplanted lungs may not fill the chest and may be more prone to pulmonary edema. Donors are excluded in the presence of positive HIV serology, active hepatitis, history of asthma, tuberculosis, or other significant pulmonary disease. A history of limited cigarette smoking is probably acceptable if other parameters of the evaluation fall within the guidelines. In general, the upper limit of donor age is approximately 55 years. The chest radiograph should be free of infiltrates, and the arterial oxygen tension should be more than 300 mm Hg on an inspired oxygen fraction of 1.0 with an appropriate tidal volume and 5 cm $H_2O$ positive end-expiratory pressure. Mild pulmonary contusions and subsegmental atelectasis would not necessarily exclude a donor as long as these criteria are met. Flexible bronchoscopy should be performed to examine the airways for erythema suggestive of aspiration of gastric contents. In addition, this provides an opportunity to assess the nature and quantity of pulmonary secretions. The presence of purulent secretions that do not clear well with suctioning should exclude the donor even if the chest radiograph is clear and the oxygenation is adequate.

The surgical part of the procurement process is performed through a median sternotomy. Both pleural spaces are opened widely to allow visual inspection of the lungs and also the topical application of cold saline and slush. The trachea is dissected out between the superior vena cava and aorta. It may be helpful to develop the interatrial groove, also, to allow a more accurate division of the left atrial tissue that must be shared with the cardiac donor team in most situations. The principles of the procurement process beyond this are (1) anticoagulation with high-dose (300 units/kg) heparin; (2) bolus injection of prostaglandin $E_1$ (50 to 70 mcg/kg) directly into the main pulmonary artery; (3) decompressing the right side of the heart by incising the inferior vena cava; (4) decompressing the left side of the heart by amputating the left atrial appendage; (5) high-volume (50 mL/kg), low-pressure flush of cold (4° C) pulmonary preservation solution of choice; (6) topical application of cold saline and slush to the lungs; and (7) continued ventilation of the lungs with low volumes and low pressures using an $FiO_2$ of 0.4. When all the preservation solution has been administered, the lungs are excised en bloc. The trachea is divided while the lungs are held in gentle inflation (pressure of $\approx$ 20 cm $H_2O$) with the $FiO_2$ at 0.4. The lungs are then extracted, placed in a bag containing the preservation solution used for the flush, and then placed in cold storage for transport.

Much research has been devoted to finding the "ideal" preservation solution to extend potential ischemic times and avoid reperfusion injury.[36] A full discussion of this complex topic goes beyond the scope of this chapter. The most commonly used preservation solutions at this time are modified Euro-Collins solution, University of Wisconsin solution, Perfadex, and Celsior. None of these is clearly superior to the others, and all work reasonably well. However, none reliably allows for preservation times greater than 8 hours, and none completely avoids reperfusion injury.

# Technique of Transplantation

The surgical technique used for children is like that for adults, except that virtually all children will require cardiopulmonary bypass, whereas that is not always necessary in adults. Transplantation without cardiopulmonary bypass would require single-lung ventilation during the procedure. Maintaining single-lung ventilation in these small children is extremely difficult, because the airways are too small to accommodate double-lumen endobronchial tubes. Bilateral lung transplantation is performed for nearly all children because of concerns over the growth potential of the transplanted lungs. Trans-sternal bilateral anterior thoracotomy incision (the so-called "clamshell incision") through the fourth intercostal space provides excellent exposure of the heart and hilar regions. Though absorbable suture theoretically provides the greatest potential for growth, some surgeons use nonabsorbable suture material for the anastomoses.[37] We recommend a simple end-to-end rather than a telescoping anastomosis for the airway because of the high incidence of stenosis in the latter.[38,39] If the patient requires concomitant repair of an intracardiac lesion (e.g., with Eisenmenger syndrome), that is best performed after the recipient pneumonectomies and before implanting the donor lungs. Many of these patients have significant aortopulmonary collaterals resulting in significant pulmonary venous return to the heart while on cardiopulmonary bypass. After the recipient lungs have been removed, the absence of pulmonary venous return to the heart from bronchial arteries and other collateral vessels will allow for a bloodless operative field for the intracardiac repair. The subsequent period during which allograft implantation is performed provides sufficient time for cardiac reperfusion before weaning from cardiopulmonary bypass.

Living donor lobar transplantation and the use of cadaveric lobes, has become less commonplace as an alternative to standard cadaveric "whole lung" transplantation, since implementation of the LAS.[40] Although the upper lobes have been used, lower lobes seem better suited anatomically, with each lobe serving as an entire lung. When lobes come from a living donor, there is less bronchial and vascular tissue with which to work and thus longer cuffs of the bronchus, pulmonary artery, and pulmonary vein of the recipient will facilitate the procedure. A technique has been devised whereby a single left lung can be partitioned such that the upper lobe is used on the right and the lower lobe on the left.[41] The circumstances under which one might use this technique would be quite unusual—a single left lung from a large donor being made available to a desperately ill child. Nonetheless, it is another attempt at solving the ongoing problem of inadequate donor organ supply.

# Immunosuppression

Although the precise protocols differ from one center to another, most use the so-called triple-drug immunosuppression approach (Table 51-3). Combinations of these immunosuppressant drugs allow for a better overall effect with a relatively less toxic dose of any one agent. Drug regimens generally include cyclosporine or tacrolimus in combination with azathioprine or mycophenolate mofetil (MMF) and prednisone. Most pediatric lung transplantation centers now use tacrolimus because of the cosmetic advantages it offers versus cyclosporine and therefore perhaps improving adherence, especially among adolescent recipients. The use of induction cytolytic therapy using antithymocyte globulin is somewhat controversial because of the potential of infectious complications associated with their use. Basiliximab, a specific monoclonal antibody to interleukin 2, is an alternative to cytolytic agents to "induce" tolerance.[42] Rather than being cytolytic, these drugs work by blocking a critical pathway in the activation of lymphocytes involved in cellular rejection. The low infection rate using these monoclonal antibodies has stimulated the reemergence of induction therapy early after lung transplantation.[43] The initial target trough cyclosporine blood level is 300 to 400 ng/mL by whole blood monoclonal assay. When tacrolimus is used, that target trough level is 10 to 15 ng/mL. The initial corticosteroid dose is 0.5 mg/kg daily of prednisone or methylprednisolone. MMF is given at a dose of 600 mg/m$^2$ twice daily while azathioprine is given in a dose of 2.5 to 3.0 mg/kg daily. Acute rejection is treated with 3 consecutive days of intravenous methylprednisolone at a dose of 10 mg/kg/day. Rejection refractory to methylprednisolone is treated with antithymocyte globulin for 7 to 10 days. Recurrent (greater than three) bouts of acute rejection may also prompt a change of the baseline immunosuppression. Although the corticosteroid dose is gradually tapered with

**TABLE 51-3**
**Immunosuppressant Agents**

| *Class of Drug* | *Side Effects* |
|---|---|
| **Interleukin-2 Synthesis Inhibitors** | |
| Cyclosporine | Hypertension, seizures, nephrotoxicity, hirsutism, gingival hyperplasia |
| Tacrolimus | Hyperglycemia, seizures, nephrotoxic |
| **Lymphocyte Proliferation Inhibitors** | |
| Azathioprine | Leukopenia, nausea |
| Mycophenolate mofetil | Leukopenia, nausea, diarrhea, elevated liver enzymes |
| Sirolimus | Hypertriglyceridemia, delayed wound healing |
| Corticosteroids | Hypertension, hyperglycemia, cushingoid appearance |
| **Induction Agents** | |
| Antithymocyte globulin | Fever, chills, leukopenia, cytomegalovirus infections, post-transplantation lymphoproliferative disorder |
| OKT3 | Fever, chills, cytomegalovirus infections, post-transplantation lymphoproliferative disorder |
| Daclizumab, basiliximab | Nausea, diarrhea |

time, we do not believe it is appropriate to stop this drug altogether. The side effects of immunosuppressive drugs in children are similar to those seen in adults. Sirolimus (rapamycin) is chemically similar to tacrolimus but inhibits the proliferative response of lymphocytes to interleukin-2.[44] It does not share the nephrotoxic potential of tacrolimus. It is currently reserved for situations of failure of other immunosuppressant drugs. Some caution should be exercised in using sirolimus as initial immunosuppression early after transplantation because there has been evidence of impaired wound and airway healing resulting in serious complications.[45]

All patients receive prophylaxis against pneumocystis jiroveci pneumonia with either sulfamethoxazole-trimethoprim orally 3 times per week or when sulfa allergy or intolerance is present one may consider monthly treatment with aerosolized pentamidine or daily therapy with atovaquone. Prophylaxis against mucocutaneous *Candida* infections is also used.

# Post-transplantation Surveillance

Surveillance after transplantation is based on periodic spirometry and bronchoscopy with biopsies and bronchoalveolar lavage. Before discharge from the hospital, patients are provided with a home spirometer and are asked to perform spirometry at least once daily. A decrease in $FEV_1$ of greater than 10% from baseline is considered an indication for evaluation. All patients, regardless of size, undergo regularly scheduled surveillance bronchoscopy to diagnose lower respiratory infections, subclinical graft rejection, and airway anastomotic complications. Virtually all episodes of suspected rejection should be confirmed with transbronchial biopsies. The main challenge occurs in small infants in whom a mini-forceps is used through either the 2.8-mm or the 3.5-mm pediatric flexible fiberoptic bronchoscope. However, obtaining an adequate specimen with these forceps can be challenging. Recently a 4.0 mm bronchoscope with a 2.2-mm suction channel was introduced into clinical practice, thus allowing the use of adult-sized forceps for many young children. At our institution, bronchoscopy with biopsy is performed at 7 to 10 days and at 1, 2, 3, 6, 9, 12, and 18 months after transplantation as a surveillance procedure. Worsening pulmonary function, infiltrates on a chest radiograph, or deterioration in clinical status, such as fever or an oxygen requirement, also prompt bronchoscopy and biopsy. Bronchoalveolar lavage is performed at these procedures for quantitative bacterial, routine viral, and fungal cultures.

# Post-transplantation Complications

## AIRWAY ANASTOMOTIC COMPLICATIONS

Anastomotic complications can involve either the airway or the vascular anastomoses. Airway dehiscence was the major source of postoperative morbidity and mortality in the early days of lung transplantation when tracheal anastomoses were performed. Not until this problem was solved by using an omental wrap for the airway anastomosis could clinical lung transplantation progress.[46] Currently, dehiscence is rare in spite of the fact that most surgeons do not use the omental wrap any longer, but rather approximate donor and recipient peribronchial tissue over the anastomosis. Dehiscence of the airway may be either partial or total. Partial dehiscence can usually be treated expectantly but puts the airway at increased risk of late stenosis.[47] Complete dehiscence requires emergent therapy and is generally a lethal complication. Although reanastomosis should be attempted when possible, it is associated with a high rate of failure, and transplantation pneumonectomy is required. Smaller airway size in children prompted concerns about whether the incidence of bronchial anastomotic stenosis would be higher and also whether the anastomoses would grow. Current evidence suggests that the airways at the anastomoses grow and that the incidence of bronchial stenosis is not affected by age or size at the time of transplantation.[48,49] Bronchial stenosis is usually treated with dilatation initially with either progressively larger rigid bronchoscopes or with an angioplasty balloon. Balloon dilatation of a stricture may be preferable, because it is less likely than a rigid bronchoscope to injure the distal airway. Repeat bronchoscopy 10 to 14 days after initial dilatation of a bronchial stenosis is necessary to judge the overall effectiveness and to assess the likelihood of recurrence. Depending on the severity of the initial stricture or the rapidity with which it recurs, one might consider placing a stent. There are two basic types of stents applicable to this situation: Silastic and wire mesh. In general, wire mesh stents are easier to insert but much more difficult to remove, and Silastic stents are harder to place and easier to remove. Alternatives to stent placement include sleeve resection (of the bronchus or upper lobe) or retransplantation. Resection has been performed with good results in adults but would be a very difficult procedure in children.[50] Retransplantation should be reserved for situations in which the stricture extends beyond the bronchial bifurcation on either side and cannot be managed with either endobronchial techniques or local resection.

## VASCULAR ANASTOMOTIC COMPLICATIONS

Problems with either the arterial or venous anastomoses are rare. In most instances, a stenosis in either of these is secondary to excessive length on the donor pulmonary artery or left atrial cuff or torsion of either of these structures when performing the anastomosis. Stenosis in one of the pulmonary artery anastomoses may or may not be manifest by right ventricular hypertension. Because pulmonary artery catheters are not often placed in children, one should check the right ventricular pressure by direct puncture once off cardiopulmonary bypass. If elevated, the pressure distal to each anastomosis should be checked also by direct puncture. Unilateral mild to moderate pulmonary arterial anastomotic stenosis may not result in significant elevation of right ventricular pressure. A perfusion lung scan is routinely performed within 24 hours of the transplantation to screen for technical problems with the vascular anastomoses. Any significant discrepancy between right- and left-sided perfusion should be immediately evaluated with either direct visualization in the operating room or angiography. Stenosis in either or both pulmonary venous anastomoses is manifest by pulmonary hypertension, profuse pink frothy sputum, and diffuse infiltrates on a chest radiograph. These findings may also be present with a severe

reperfusion injury or diffuse alveolar damage. However, the pulmonary capillary wedge pressure is generally normal in the latter two instances and elevated with a stenosis in the pulmonary venous anastomosis. Transesophageal echocardiography is particularly helpful in the diagnosis of pulmonary venous anastomotic problems. Confirmation of the diagnosis usually requires direct measurement of the pulmonary venous and left atrial pressures, particularly in small children. Early correction is mandatory.

## BLEEDING

A number of factors place these patients at increased risk for bleeding after transplantation. Nearly all transplantations in children require prolonged cardiopulmonary bypass for recipient pneumonectomies and implantation of donor organs. Additionally, many of these patients have undergone prior thoracotomies or sternotomies. Patients with cyanotic heart disease and a prior thoracotomy have the greatest risk of serious bleeding, as mentioned earlier.

## PHRENIC NERVE INJURY

This complication occurs in about 20% of lung transplantations and is secondary to trauma because of stretch while retracting to expose the hilar regions; it is more common on the right side.[51] Recovery of diaphragmatic function within 6 months of transplantation is the general rule. The reason for the right side being injured more commonly probably relates to the proximity of the nerve to the pulmonary artery and the superior vena cava on that side. The superior vena cava (and thus the phrenic nerve) must be retracted to expose the proximal right pulmonary artery. Prior thoracotomy puts the nerve at greater risk for injury, because it may be obscured by adhesions.

## HOARSENESS

Vocal cord paralysis caused by recurrent laryngeal nerve injury has an incidence of approximately 10%. This diagnosis is made at the time of flexible fiberoptic bronchoscopy with direct examination of the cords. In most cases, anatomic asymmetry improves without directed therapy within 6 months of transplantation. The left vocal cord is nearly always the one involved, and the injury presumably occurs as a result of dissection of the left pulmonary artery in the region of the ligamentum arteriosum.

## GASTROINTESTINAL COMPLICATIONS

Many centers now routinely assess for the presence of gastroesophageal reflux because of its potential association with the development of bronchiolitis obliterans (BO).[52] Since instituting routine 24-hour pH probe monitoring at the 2-month post-transplantation evaluation, we have found that almost 70% of our patients have evidence of acid reflux. The etiology of this high incidence of gastroesophageal reflux is not clear but may be due to injury to the vagus nerves bilaterally in the process of performing the recipient pneumonectomies. Decreased intestinal motility is also a common problem in all age groups. Patients with CF are at risk for distal intestinal obstruction syndrome. This can be avoided by aggressively treating with osmotic cathartics after transplantation. Gastrografin enemas may be necessary if there is no response to oral cathartics.

## ATRIAL FLUTTER

Atrial arrhythmias are relatively common with significant episodes of atrial flutter occurring in 10% of pediatric lung transplantation recipients. Many require long-term treatment.[53] Investigation into this entity using a model of lung transplantation has shown that the suture lines for the left atrial anastomoses provide sufficient substrate for the maintenance of atrial flutter when initiated by programmed extrastimulus.[54]

## GRAFT COMPLICATIONS

Reperfusion injury manifesting as graft failure with diffuse infiltrates on chest radiography, frothy sputum, and poor oxygenation is the most common graft complication early after lung transplantation, occurring in 20% to 30% of transplantation recipients.[55] It is the most common cause of death within the first 30 days after transplantation.[3] The underlying cause is probably multifactorial, with both donor and recipient conditions contributing to this problem. The best preventive measures include careful evaluation and procurement of the donor organs as well as having a recipient free of active infection or other acute problems. A well-conducted transplantation procedure is also of utmost importance. The treatment of reperfusion injury is mostly supportive, although nitric oxide[56] and prostaglandin $E_1$[57] may be of some primary benefit.

Rejection is a common occurrence after lung transplantation, perhaps more so than in other solid organ transplantations (Fig. 51-1). The lung has a much larger endothelial surface than other organs. Because the major histocompatibility antigen expression on endothelial surfaces is the primary signal for local immune recognition, the lung would seem to be the least easily camouflaged organ in the body. In addition, the lung graft comes with its own parenchymal bronchial lymphocytes and macrophages. Gradually, these are replaced by the recipient lymphocytes and macrophages. This rather intense immunologic activity adds to the risk of rejection. Acute graft rejection early after transplantation presents in such a nonspecific fashion that each suspected episode should be documented with histologic evidence obtained by either transbronchial biopsy or open-lung biopsy. The great majority of episodes of acute rejection occur in the first 6 months after transplantation. Although the incidence of acute rejection in all children is about the same as that seen in adults, it appears that infants have a much lower incidence.[58,59] The precise reason for this is unclear but may have to do with the relative immaturity of the immunologic system in infants.

Antibody-mediated rejection (AMR) is now recognized as a serious and relatively common complication of lung transplantation. With the advent of better detection assays, one can now quantitate the amount of circulating donor-specific antibody in the recipient. However, it is also becoming increasingly clear that non–human leukocyte antigen (HLA) antibodies may also be responsible and that, in fact, autoantibodies to previously sequestered antigens may play a vital role

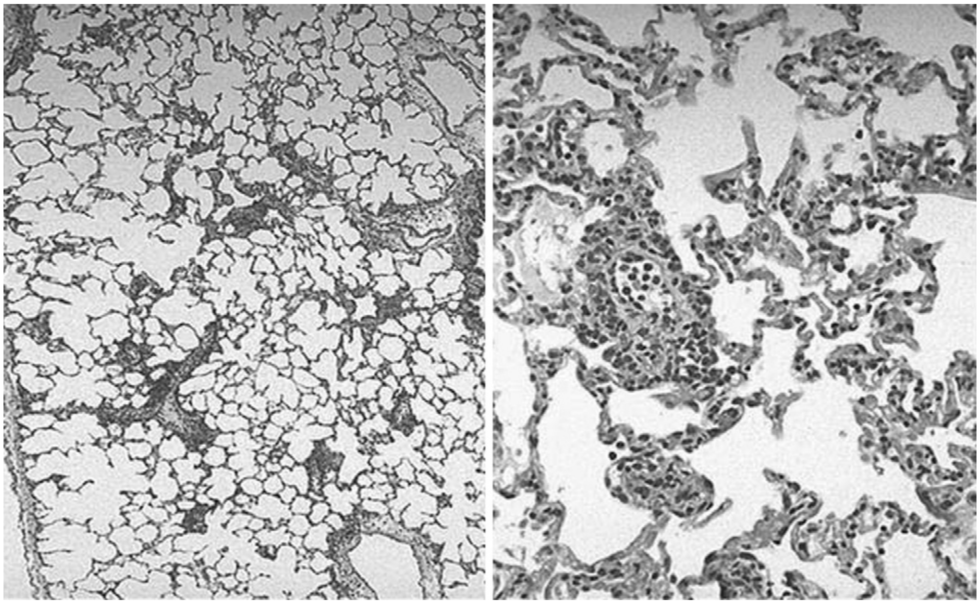

**FIGURE 51-1** Acute rejection. Multiple lymphocytes are present in a perivascular position involving many blood vessels, which can be seen better on higher power. This was interpreted as grade A2 acute rejection.

in the development of bronchiolitis obliterans. Increasing experience with C4d immunostaining of biopsy specimens and C4d and C3d immunofluorescence permit histologic confirmation of AMR. The exact frequency of this complication in lung transplantation recipients is not yet known. AMR has shown itself to be fairly refractory to therapy. We use a protocol that includes plasmapheresis, intravenous bortezomib, intravenous immunoglobulin (IVIG), and rituximab.

Bronchiolitis obliterans is viewed by most clinicians to be a manifestation of chronic rejection and occurs in nearly 50% of all long-term survivors.[60] The precise cause is unknown, although donor ischemic time, episodes of early acute rejection, and history of lymphocytic bronchitis have been identified as risk factors.[61,62] Bronchiolitis obliterans presents as a significant fall in $FEV_1$ without other obvious cause. The chest radiograph is generally clear, and the computed tomographic examination of the chest usually demonstrates evidence of air trapping with mosaicism and occasionally bronchiectasis. Ventilation/perfusion lung scanning may demonstrate air trapping with xenon retention. Bronchoscopy with transbronchial biopsy and bronchoalveolar lavage should be done as part of the evaluation to rule out other potential causes, such as acute rejection or infection, and to assess the degree of active lymphocytic infiltration of the airways. The histologic picture of bronchiolitis obliterans is one of dense scarring of the membranous and respiratory bronchioles (Fig. 51-2). It may be inferred by the absence of identifiable bronchioles on biopsy material. Diagnosis of bronchiolitis obliterans by histologic examination of transbronchial biopsy material may be very difficult, however, and many do not consider it necessary to establish the diagnosis. A staging system has been established based on the degree of decline of $FEV_1$ or forced expiratory flow $(FEF)_{25\text{-}75}$ from the peak value: post-transplantation stage 0p = 10% ($FEV_1$) or 25% ($FEF_{25\text{-}75}$), stage 1 = 20% to 35%, stage 2 = 35% to 50% decline, and stage 3 = more than 50% decline.[63] The usual treatment for bronchiolitis obliterans in the United States is to augment immunosuppression, usually beginning with antithymocyte globulin daily for 7 to 10 days; the clinical response has been variable. A change in the maintenance immunosuppression may also be appropriate. Antiproliferative agents may provide a more effective approach, but that has yet to be proved. Results from small studies suggest that azithromycin may be effective in stabilizing and perhaps even improving lung function.[64,65] Researchers at Duke University demonstrated that fundoplication in patients with BO and gastroesophageal reflux may potentially improve BO grade if performed early.[52] Total lymphoid irradiation and photopheresis are other modalities that have been proposed.[66] Patients not responding to these measures may be suitable candidates for retransplantation. As mentioned earlier, this is a somewhat controversial topic, because there is a shortage of donor organs, and the results with retransplantation overall are not quite as good as with first-time transplantations. However, if the candidates are ambulatory, not ventilator dependent, and at an experienced lung transplantation center, the survival results are not significantly different from first-time transplantations.[30]

Post-transplantation lymphoproliferative disease (PTLD) occurs in 10% to 19% of pediatric patients undergoing lung transplantation. PTLD occurs more frequently in association with a primary Epstein-Barr virus (EBV) infection.[67] Children may be somewhat more prone to this complication, because they are frequently seronegative for EBV infection at the time of transplantation and are therefore likely to acquire a primary EBV infection during their post-transplantation life. Reduction in immunosuppression is the mainstay of early therapy, although this may be insufficient and not uncommonly leads to the subsequent development of bronchiolitis obliterans. Rituximab, an anti-CD20 monoclonal antibody, has been used effectively in the treatment of PTLD.[60] Other treatment modalities include conventional chemotherapy,[68] irradiation, and infusion of human leukocyte antigen–matched T lymphocytes.[69]

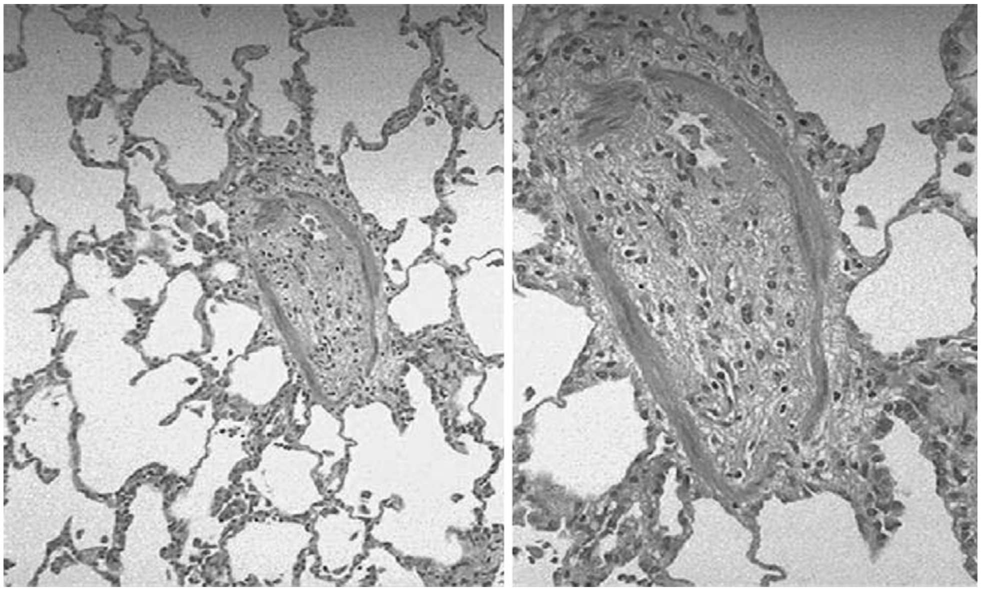

**FIGURE 51-2** Histologic slide taken from the lung of a patient undergoing retransplantation for bronchiolitis obliterans. Small airways are obliterated by fibrous tissue.

## INFECTION

Although infection is generally common after any solid organ transplantation, lung transplantation recipients are at greater risk. Donors are all on mechanical ventilation, resulting in colonization of the airway with bacteria from an intensive care unit. The lung is the only solid organ constantly in contact with the nonsterile outside world. An endotracheal tube necessary early after the transplantation bypasses some of the natural defenses available to the respiratory tract. Obligate denervation of the lung that occurs with transplantation results in the cough reflex being markedly diminished or absent altogether. These and numerous other factors demand that the caregivers maintain constant vigilance in the diagnosis and treatment of respiratory infections and also emphasize to the recipient the importance of pulmonary toilet.

All potential candidates are screened for the presence of organisms in the airway and evidence of previous infections. Evidence of prior viral infections is evaluated by serologic testing for antibodies to cytomegalovirus; herpes simplex virus; varicella; EBV; hepatitis A, B, and C; and human immunodeficiency virus. Viral serologic screening is less informative in young infants whose immunoglobulin pool reflects passively transferred maternal antibodies. The initial antimicrobial therapy given in the early post-transplantation period is directed in part by the results of pretransplantation studies. Ganciclovir is given at a dose of 5 mg/kg/day for 6 weeks for any positive donor or recipient serology for cytomegalovirus. If patients have evidence of present or past *Aspergillus* infection, antifungal therapy with either intravenous anidulafungin or voriconazole followed by oral voriconazole is used, depending on the clinical situation.

A number of viral respiratory infections are quite common in pediatric patients. Adenovirus and parainfluenza viruses are particularly bothersome in children. As for cytomegalovirus, primary disease is generally more likely to be severe than reactivation disease.[2] As mentioned earlier, primary infection with EBV is an important risk factor for the development of PTLD.

Fungal infections are uncommon but potentially devastating. Nystatin oral suspension is employed to reduce the risk of infection from *Candida* species. Virtually all infections caused by *Candida* species can be successfully treated with oral or intravenous triazole antifungal agents. Invasive *Aspergillus* infections, however, are much more difficult to treat and may result in widespread dissemination if appropriate antifungal therapy is delayed.

Bacterial infections are common after lung transplantation. Bacterial lower respiratory tract infections, which include both purulent bronchitis and pneumonia, occur in most patients at some point after transplantation. Patients with CF are more likely to experience this complication, with the organism usually the same as that colonizing the airway before transplantation. Prophylaxis against lower respiratory tract infections in CF lung transplantation recipients may be accomplished by administering aerosolized antibiotics (tobramycin or colistin) just as one might for end-stage CF.

## OTHER COMPLICATIONS

Hypertension is a common problem after transplantation and is presumably due to treatment with the calcineurin inhibitors cyclosporine and tacrolimus, as well as prednisone. Renal insufficiency occurs with increasing time after transplantation and is also related to treatment with cyclosporine and tacrolimus. Diabetes mellitus occurs in approximately 15% of patients after transplantation, primarily in patients with CF.[2] Tacrolimus predictably increases the likelihood for the development of hyperglycemia.

# Survival

The 3- and 5-year actuarial survival for children undergoing lung transplantation is approximately 54% and 45%, respectively, according to the International Society for Heart and

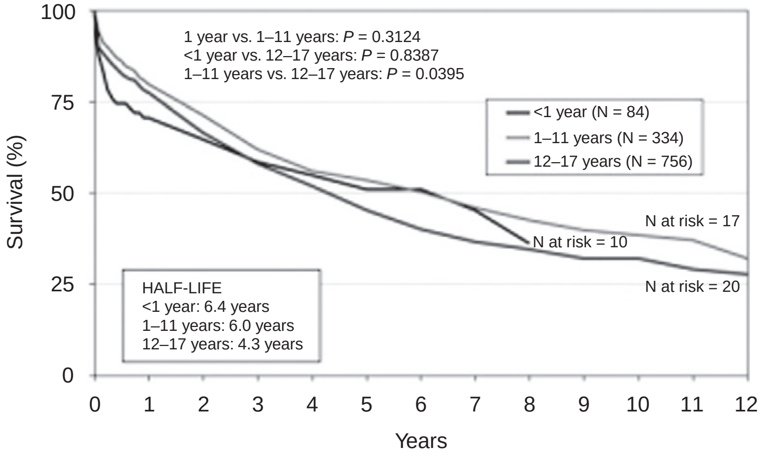

**FIGURE 51-3** Kaplan-Meier survival curve for pediatric lung transplantation. (From Aurora P, Edwards LB, Kucheryavaya AY, et al: The Registry of the International Society for Heart and Lung Transplantation: Thirteenth Official Pediatric Lung and Heart/Lung Transplantation Report—2010. J Heart Lung Transplant 2010;29:1129-1141.)

Lung Transplantation registry (Fig. 51-3).[3] Acute graft failure accounts for the majority of deaths in the first 30 days. Infection is the cause of death in approximately 50% of those dying in the first year beyond the transplantation hospitalization. Bronchiolitis obliterans is the cause of death in 50% of patients beyond 1 year after transplantation and is clearly the major impediment to long-term survival.[30]

## Pulmonary Function and Growth

It is unclear whether transplanted lungs grow in terms of number and size of alveoli, and experimental data are inconclusive.[70,71] Measurement of lung growth is fraught with a number of complicating factors. One cannot use pulmonary function tests and lung volume size as measured by either chest radiograph or computed tomography, because there are a number of elements that affect these studies that would not accurately reflect the number or size of alveoli. The impact of lung growth is particularly critical in small infants, because their transplanted lungs will have to grow substantially over the rest of their lives to handle the physiologic load presented to them. Those children in our series too young to undergo standard pulmonary function testing underwent infant pulmonary function tests that provide a measurement of functional residual capacity, a reasonable surrogate for lung volume. The average functional residual capacity per centimeter in height at 3 months after transplantation was 2.3 mL/cm and remained between 2.1 and 2.8 mL/cm through 15 months after transplantation. During this time, substantial somatic growth occurred in these infants.[72] Thus in the absence of central or peripheral airway obstruction, these data suggest that lung growth appropriate for size is occurring. However, we do not know whether this represents an increase in the number of alveoli and/or an increase in the size of existing alveoli.

## Future Considerations

Factors that limit the success of lung transplantation in children are similar to those in adults: donor shortage, balance of immunosuppression and prevention of infection, and development of bronchiolitis obliterans. Xenotransplantation may eventually offer another solution, but realistically, this is many years from application. Transplantation across ABO blood groups, now commonplace in infant cardiac transplantation, is another possibility in small children, though the overall impact of this would be minor. Newer immunosuppressive agents aimed at more specific areas of the immune response involved with organ recognition are necessary. Bronchiolitis obliterans remains the "Achilles heel" of long-term survival after lung transplantation. Although still not completely characterized as to its precise cause, most investigators ascribe this development to airway injury leading to chronic rejection. To that end, clinical and basic research aimed at understanding the vectors of injury and disease progression in bronchiolitis obliterans are of paramount importance to the field of lung transplantation. Because the airway as the site of injury is accessible for assessment and therapy, bronchiolitis obliterans may provide a model system whereby chronic rejection, which also affects long-term success in heart, kidney, and liver transplantation, can be understood and overcome.

# CHAPTER 52

# Surgical Implications Associated with Pediatric Bone Marrow Transplantation

Thomas E. Hamilton and Robert C. Shamberger

Fifty-three years after the seminal report of hematopoietic stem cell transplantation (HSCT) in children and adolescents by Thomas and colleagues,[1] pediatric surgeons have retained an important role in successful implementation of this therapy. The expansion of HSCT to a variety of malignant and nonmalignant diseases has grown based on successful use of multiple stem cell sources and innovative conditioning regimens.[2] A fundamental understanding of these processes will assist pediatric surgeons when called upon for access or complications associated with patients undergoing HSCT.

Stem cells can be derived primarily from bone marrow, umbilical cord blood, or peripheral blood stem cells (PBSC). Along with advances in infection prophylaxis and supportive care, the switch to PBSC has led to mortality rates of less than 5% for autologous transplantation in many studies. One of the major advances of PBSC compared with autologous marrow is more rapid engraftment of the recipient. Faster hematopoietic recovery results in an abbreviated period of neutropenia, thrombocytopenia, and anemia, resulting in lower rates of infection and hemorrhage, less risk of transfusions, and earlier discharge. Harvest and storage of a patient's own hematopoietic stem cells (HSC), followed by reinfusion after high-dose chemotherapy (HDC), is commonly referred to as autologous HSCT or stem cell rescue. HDC is generally administered beyond the tolerance of the patient's marrow (myeloablative), meaning no recovery is possible without stored HSC.[3]

The transplantation process is divided into five phases: (1) conditioning, (2) stem cell infusion, (3) neutropenia, (4) engraftment, and (5) postengraftment phase. The conditioning phase involves intensive chemotherapy with or without total body irradiation to eliminate the disease. This period lasts between 7 and 10 days. The stem cell processing and infusion time varies based upon the size of the patient and source of the stem cells. The neutropenic phase lasts 2 to 4 weeks and is an interval when the patient is extremely vulnerable to infections because of the lack of an effective immune system. Wound healing is impaired, and empiric antibiotics are generally administered to minimize infectious complications. Mucus membranes are rapidly dividing tissues, and therefore susceptible to ulceration and the risk for nosocomial infections is high. Total parenteral nutrition is widely used in children during this phase.

The engraftment phase takes several weeks as transplanted cells incorporate into recipient tissues. The development of graft versus host disease (GVHD) and viral infections are the greatest clinical obstacles of this phase. The postengraftment phase lasts months to years as the gradual development of tolerance, weaning of immunosuppression, and immune reconstitution occur.[4] Pediatric surgeons are consulted frequently for access or associated complications in all phases of the transplantation process.

## Stem Cell Harvest and Vascular Access

Multiple ports of access are required for peripheral stem cell harvest. Unlike adults, where large-bore antecubital catheters can be used for both harvest and infusion, pediatric patients generally require indwelling central venous catheters. The extracorporeal separation of blood components from patients or donors has spawned an entire field termed apheresis. As technologies of separation evolve, the one constant is the need for adequate access to withdraw and return blood components. Standard Broviac catheters collapse with the negative pressure required for apheresis (approximately 1 to 2 mL/kg/minute). Specially designed apheresis catheters allow faster flow rates because of larger-diameter stiffer walls and shorter catheter length. Most apheresis catheters are dual lumen offset with multiple ports to avoid mixing processed and unprocessed blood. Children weighing more than 10 kg will accommodate 8-Fr or larger (MedComp, Harleysville, Pa.) catheters. When children weigh less than 10 kg, temporary femoral or

subclavian catheters may be used.[3] Because of the larger size and stiffness of the apheresis catheters and dilators, fluoroscopic guidance and respect for tissue is paramount. As one of my surgical mentors always said, "placing the line in is never as interesting to the surgeon as taking out the tumor, but it is just as important to the care of the child."

# Complications of Immune System Ablation and Immunosuppression

## INTESTINAL COMPLICATIONS

Abdominal pain and diarrhea are common post-HSCT. A substantial component of the initial inflammatory cascade is thought to occur in the gastrointestinal tract, and patients with higher volumes of diarrhea at the time of the preparative regimen have an increased risk of acute GVHD.[5] Barker and associates[6] performed a retrospective study of 132 consecutive pediatric HSCT patients, and diarrhea occurred in 67% of patients. Common etiologic agents included GVHD (27%), viral (6%), *Clostridium difficile* (8%), and unknown (28%). When stool cultures are negative, endoscopy is considered to differentiate infectious etiologies from GVHD. Gastric antral biopsies and small bowel biopsies may be preferred, because duodenal hematomas have been reported by Ramakrishna and Treem.[7] They recommended avoiding the duodenum if possible and maintaining platelet counts greater than 55,000/mm$^3$ for 48 hours postbiopsy when a duodenal biopsy is necessary. A prospective multicenter study of pediatric bone marrow transplantation (BMT) patients who underwent 1120 small bowel biopsies did not report hematoma as a complication.[8,9] Silbermintz and co-workers[10] reported successful identification of small bowel graft versus host disease by capsule endoscopy in a child with refractory hemorrhage, when upper and lower endoscopies were nondiagnostic. Identification of small intestinal cytomegalovirus (CMV) disease has also been reported by capsule endoscopy.[11] The future role for capsule endoscopy is increasing as the intestinal complications after HSCT predominate in the small intestine.[12] Accurate visualization may help guide the need for more intensive immunosuppressive therapy or to avoid immunosuppressive therapy.

Neutropenic enterocolitis (typhlitis) is characterized by necrotizing inflammation of the colon in a severely immunocompromised patient (Table 52-1). Clinically, fever, abdominal pain, tenderness, and neutropenia are present (Fig. 52-1). The incidence is low in children after HSCT. Barker's retrospective review of 132 consecutive pediatric HSCT patients reported an incidence of 3.5%.[6] Early experience with neutropenic enterocolitis was marked by controversy regarding the timing of surgical intervention, and mortality exceeded 50%.[13–16] Delineation of the criteria for surgical intervention reserved for clearly identified surgical complications has contributed to a substantial decrease in mortality and morbidity.[15,17]

Multiple contemporary series now report excellent outcomes using a strategy of bowel rest, prompt institution of appropriate intravenous fluid resuscitation, broad-spectrum antibiotics and antifungal therapy, nutritional support with total parenteral nutrition (TPN), and the use of granulocyte colony-stimulating factor (GCSF).[18–21] In 2002, Otaibi reported a series of 142 HSCT transplantations performed in Alberta Children's Hospital. Ninety-seven patients developed abdominal pain, and only five developed radiographically proven typhlitis. No patients required surgical intervention.[20] Mullassery, from The Royal Liverpool Children's Hospital reported a 5-year retrospective series in 2009 in which 18 of 596 patients had radiographically confirmed typhlitis and three required surgical intervention. One child, each, had extensive colonic necrosis, perforated gastric ulcer, and perforated appendix. A single mortality was also reported from fulminant gram-negative sepsis without intervention.[19]

**TABLE 52-1**
**Neutropenic Enterocolitis: Criteria for Appropriate Surgical Intervention**

1. Persistent gastrointestinal bleeding after resolution of neutropenia and thrombocytopenia and correction of clotting abnormalities
2. Evidence of free intraperitoneal perforation
3. Clinical deterioration requiring support with vasopressors or large volumes of fluid, suggesting uncontrolled sepsis
4. Development of symptoms of an intra-abdominal process, in the absence of neutropenia, which would normally require surgery

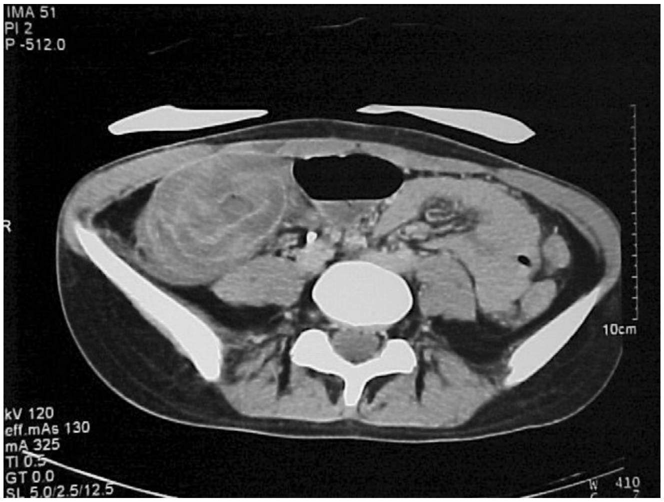

**FIGURE 52-1** Typhlitis in a teenager with acute myelocytic leukemia who had undergone bone marrow transplantation (BMT). Note the thickened, onionskin appearance of the cecal wall and the pinpoint lumen. This patient underwent right hemicolectomy with ileostomy and mucous fistula; 1 year later, still in clinical remission from her leukemia, her condition was successfully reversed. Most cases of typhlitis are handled nonoperatively.

## HEPATOBILIARY COMPLICATIONS

Abnormal liver function studies are commonly identified in HSCT patients. An extensive 40-year review of hepatobiliary complications in HSCT has recently been published by McDonald.[22] Liver complications have become far less frequent as the understanding of how to prevent and treat severe hepatobiliary problems has emerged. Surgeons are frequently consulted to discern whether abnormal liver function studies are secondary to obstruction or parenchymal dysfunction. Biliary obstruction occurs secondary to calculous disease.

Safford and colleagues[23] reported a series of 575 patients, of which 235 received ultrasonography of the abdomen for pain, jaundice, sepsis, or metastases. Cholelithiasis was identified in 20 cases (8.5%). The overall incidence of cholelithiasis reported in the study was far greater than the 0.13% to 0.21%. incidence in children.[24] When the reason for HSCT was considered in Safford's series, 27% of patients who had HSCT for bone marrow failure versus 7.4% for neoplasia developed cholelithiasis ($P < 0.01$). This suggests a role for hemolysis. Despite the high incidence of cholelithiasis, 85% of children did not require surgical intervention. Nine (45%) died from primary disease, five (25%) showed sonographic resolution, and three (15%) had nonoperative follow-up for persistent cholelithiasis. Surgical interventions included one cholecystostomy, one open cholecystectomy, and one laparoscopic cholecystectomy in three (15%) patients who developed acute cholecystitis, with a mean time to operative intervention of 1.9 years without complication. There was no morbidity or mortality associated with conservative management of cholelithiasis in any child.[23]

Hepatic veno-occlusive disease (VOD), also known as sinusoidal obstruction syndrome (SOS) is a serious and frequent complication after HSCT. It is clinically heralded by a triad of (1) painful hepatomegaly, (2) hyperbilirubinemia, and (3) unexplained fluid retention. Milder cases resolve spontaneously, but severe cases may become rapidly fatal. Prognosis varies with extent of injury and the development of multiorgan system failure.[25] The pathogenesis involves sinusoidal endothelial cell and hepatocyte damage from high-dose alkylating chemotherapeutic agents.[22,25] Plasminogen activator inhibitor (PAI-1) serum levels have both diagnostic and prognostic value as a marker for VOD.[26] The intensity of the conditioning regimen and type of transplantation are important determinants for risk of VOD. Pediatric patients younger than 6.5 years at transplantation appear to be at increased risk of hepatic VOD.[27] Defibrotide (DF) is a polydisperse mixture of single-stranded oligonucleotide with local antithrombotic, anti-ischemic, and anti-inflammatory activity that has clinical efficacy in severe VOD. DF appears to modulate endothelial cell injury without enhancing systemic bleeding and protects the hepatic sinusoids without compromising the antitumor cytotoxic effects of therapy.[28] Ho and associates[25] reviewed hepatic VOD and multiple clinical trials with DF, where 30% to 60% complete remission rates are reported, even in patients with severe VOD and multiorgan system failure. Corbacioglu and colleagues[29] reported that 34 (76%) patients with severe VOD post-HSCT, treated with DF, achieved a complete response, and in multivariate analysis, early intervention (1 day vs. 5.5 days in nonresponders) was the only significant factor. Richardson and coworkers[30] recently reported a phase II multicenter randomized trial in adult and pediatric patients that established the safety and efficacy of defibrotide. Early stabilization or decreased bilirubin was associated with better response and day +100 post-HSCT survival, and decreased plasminogen activator inhibitor type 1 (PAI-1) during treatment was associated with better outcome; changes were similar in both treatment arms. A dosage of 25 mg/kg/day was selected for ongoing phase III trials of the treatment of VOD.

Focal nodular hyperplasia following pediatric HSCT has been identified in 17 of 137 patients prospectively studied, with a median delay of 6.4 years from a series reported by Sudour and associates.[31] The authors postulate an iatrogenic vascular origin, because 16 patients received myeloablative preconditioning, and only three had evidence of SOS. No complication or malignant transformation was reported; clinical and diagnostic imaging follow-up is recommended.

## HEMORRHAGIC CYSTITIS

Hemorrhagic cystitis (HC) occurs in 10% to 20% of pediatric HSCT patients. Decker and colleagues[32] have recently reviewed the pediatric experience. HC is characterized by diffuse vesical bleeding which ranges from microscopic hematuria to gross hemorrhage with clot formation and urinary obstruction requiring instrumentation for evacuation. With severe HC, prolonged hospitalization with significant morbidity may occur. High-dose chemotherapy and immunosuppression that accompany HSCT make the pediatric patient particularly susceptible. Investigations point to a multifactorial pathophysiology of HC. Damage to the transitional epithelium by radiation, chemotherapy, and infectious agents have been postulated. BK virus is now a known pathogen with increasing evidence for a major role in HC. High-dose cyclophosphamide and bisulfan are well studied alkylating agents used in conditioning protocols for HSCT that are known to cause HC. Three main strategies for HC prophylaxis include mesna, hyperhydration with forced diuresis, and continuous bladder irrigation (CBI). Three-way catheter drainage is often difficult in pediatric populations and may require a suprapubic tube. Ultrasonography may underestimate the clot burden, and cystoscopy provides visualization with the opportunity for clot evacuation and fulguration of the bladder epithelium. Escalation to more intensive therapies, such as instillation of drugs into the bladder (intravesical therapy), carry increased risk. Many agents, including aluminum potassium sulfate, prostaglandins, and ϵ-aminocaproic acid and cidofovir have been used for intravesical therapy, but none are well studied in a pediatric population. HC is a self-limiting condition once engraftment and immune reconstitution occur, effective defense barriers of the bladder mucosa are reconstituted, and viral replication is controlled. More intensive therapies should be undertaken under the auspices of a multidisciplinary team.[33]

## PULMONARY COMPLICATIONS

Opportunistic infections are common in HSCT patients. Pneumonia is the most common infectious complication but must be distinguished from noninfectious causes, such as bronchiolitis obliterans, diffuse alveolar hemorrhage (DAH), and a constellation of noninfectious fever accompanied by either skin rash, pulmonary infiltrates, or diarrhea—termed engraftment syndrome.[34] Early recognition and treatment of post-HSCT pneumonia favorably impacts survival.[35,36] A recent article from Shannon and co-workers[37] from M.D. Anderson Cancer Center has examined the utility of early versus late fiberoptic bronchoscopy (FOB) with bronchoalveolar lavage (BAL) post-HSCT in 501 consecutive adult patients. Five hundred and ninety-eight fiberoptic bronchoscopies (FOB) with bronchoalveolar lavage (BAL) were performed for the evaluation of pulmonary infiltrates. The overall diagnostic yield was 55%. The diagnostic yield was 2.5-fold higher when the FOB was performed within the first 4 days

and highest (75%) when performed within 24 hours of clinical presentation. The rates of adjustment in antimicrobial therapy were not different with early versus late treatment (51%); however, late FOB-guided antibiotic adjustments were associated with 30-day pulmonary-associated deaths that were threefold higher (6% vs. 18%, $P = 0.035$). The authors conclude early referral for FOB may yield a higher diagnostic yield and favorably impact survival in adult patients.

The utility of lung biopsy in pediatric patients post-HSCT is controversial. Shorter and colleagues[38] reported a 10-year experience of 126 HSCT patients from Children's Hospital of Philadelphia from 1976 to 1986. Twenty-one patients had open lung biopsies; 14 showed no causative organisms. One patient had CMV, and three patients had *Pneumocystis carinii*. Thirteen patients died because of continued deterioration postbiopsy. Hayes-Jordan and associates[39] reported a retrospective series of 528 patients post-HSCT from St. Jude's Children's Research Center from 1991 to 1998. Eighty-three patients developed pulmonary infiltrate within 6 months; 43 (52%) had BAL and 19 (23%) had open lung biopsies, 6 (7%) underwent needle biopsy, and 5 (7%) underwent transbronchial biopsy. Histology identified infections in 6 (30%), bronchiolitis obliterans organizing pneumonia (BOOP) in 5 (26%), interstitial pneumonia in 4 (21%), gangliosidosis in 1, and lymphocytic infiltrate in 1. Despite changing the clinical plan, based on histology in 17 of 19 (90%) patients, improvement in outcome was only seen in 8 (47%). Postoperative morbidity at 30 days was 47%, including prolonged intubation (7 patients), pneumothorax (2 patients), and pleural effusion (1 patient). Thirty-day survival was 63.2%, and no patient with multiorgan system failure, ventilator dependence, or postoperative complication survived post–open lung biopsy. Careful patient selection and consideration of less-invasive modalities should be strongly considered in these extremely high-risk patients. Minimally invasive surgical techniques have been applied both diagnostically and therapeutically in childhood cancer;[40] however, the decrease in pulmonary compliance and increase in cardiac afterload is often prohibitive for thoracoscopic techniques in the post-HSCT patient population.

Invasive pulmonary aspergillosis (IPA) is a common infection in the HSCT population. A potentially lethal complication of HSCT is pulmonary hemorrhage secondary to the angioinvasive nature of this agent. IPA is one specific opportunistic infection where surgical therapy remains beneficial. Gow and colleagues[41] reported on 43 patients with invasive pulmonary aspergillosis, spanning 9 years, from St. Jude's Children's Cancer Research Hospital. Eighteen patients had surgical intervention, (16 thoracotomies [89%] and 2 thoracoscopies). Fourteen had one operation; 4 patients had two. Surgical resection of the affected parenchyma significantly improved survival ($P < 0.001$). The four survivors had disease amenable to wedge resection, the longest interval at the time of report being 43.5 months. When feasible, a surgical approach should be strongly considered, because, left untreated, invasive pulmonary aspergillosis is almost always fatal.

### SOFT TISSUE INFECTIONS

Necrotizing soft tissue infections are rapidly progressive and carry a significant mortality and morbidity without prompt surgical intervention. Neutropenia makes the clinical picture even more challenging. As opposed to the otherwise healthy child, who typically has a solitary organism after a traumatic event, immunocompromised patients may have enteric translocation of gram-negative organisms. Extreme pain (often out of proportion to physical findings), fever, and tachycardia are the hallmarks of soft tissue infection. Johnston and colleagues[42] presented a retrospective series over an 11-year period, where seven neutropenic patients with deep soft tissue infections were identified. The median number of days postinitiation of chemotherapy was 14, pain was present in all patients, and 86% had fever and tachycardia. The pathogenic organism was from the gastrointestinal tract in four of seven patients. Five patients survived and were treated with urgent surgical debridement, intravenous antibiotics, GCSF, and hyperbaric oxygen. Butterworth and associates[43] reported an 11-year retrospective series of 19 patients with necrotizing soft tissue infections in healthy and immunocompromised children. An interesting finding in this series was that the immunocompromised patients were less likely to have severe tenderness and more likely to have polymicrobial perineal/buttock infections. When diagnostic uncertainty exists, judicious use of magnetic resonance imaging (MRI) may prove beneficial if tolerated by the patient's clinical status.

#### Post-transplantation Malignancies

As survival increases post-HSCT, attention has become directed toward late effects, including post-tranplant malignancies (PTMs). New malignancies post-HSCT fall into three broad categories: post-tranplant lymphoproliferative disorders (PTLD), hematologic malignancies (primarily treatment-related myelodysplastic syndrome and acute myeloid leukemia [MDS/AML]) and solid tumors. Baker and co-workers,[44] from the University of Minnesota, reported 147 PTMs in 137 pediatric and adult patients of 3,372 patients post–stem cell transplantation. The majority of PTMs were PTLD (44), with MDS/AML in 36 patients. Sixty-two solid tumors were reported in 57 patients. A significant finding was the risk of solid tumor malignancy continues to increase with each successive year of follow-up. The cumulative incidence of developing a solid tumor did not plateau and was 3.8% (95% confidence interval [CI], 2.2 to 5.4) at 20 years post-HSCT. The most common solid tumors reported were 11 basal cell and 8 squamous cell carcinomas of the skin, 4 breast, 5 carcinoma in situ, 8 melanoma, and 4 soft tissue sarcomas. Age greater than or equal to 20 years at the time of HSCT was the only significant predictor for development of a solid tumor (relative risk [RR] 2.0; 95% CI, 1.1 to 3.5; $P = 0.03$).[44] Forty-two percent of patients died from their post-transplantation solid tumor. Future efforts at long-term surveillance are warranted.

## Conclusion

HSCT has evolved into a well-established clinical modality with increasing utility for multiple malignant and nonmalignant disease processes in children. Pediatric general surgeons are integral members of the multidisciplinary team required for HSCT because of the multitude of organ systems involved.

Pulmonary, gastrointestinal, hepatic, genitourinary, and soft tissues are all subject to surgical complications. Vascular access will continue to be required for medications, apheresis, and transfusions. Pediatric surgeons must have knowledge of the HSCT process and the surgical complications during all phases of transplantation, including long-term survivors, in order to provide expert advice for treatment and to contribute to the understanding of this rapidly expanding field.

CHAPTER 53

# Craniofacial Anomalies

Jason J. Hall and H. Peter Lorenz

In 1967, Dr. Paul Tessier presented his modifications of Gilles' previously little known and underutilized techniques to correct congenital or post-traumatic bony anomalies to the International Society of Plastic Surgeons in Rome. Over the next 30 years, his teachings formed the basis of a new subspecialty of plastic surgery—craniofacial surgery. Tessier developed precisely placed osteotomies, autologous nonvascularized bone and soft tissue grafts, and intracranial approaches to the facial skeleton. His techniques gave children and adults with previously "unfixable" craniofacial anomalies a chance for a more normal appearance. Currently, most major medical centers have a multidisciplinary team dedicated to the care of this special subset of patients. The craniofacial anomaly teams span many different specialties, which include plastic surgery, pediatric otolaryngology, pediatric neurosurgery, speech pathology, audiology, oral surgery, dentistry and orthodontics, social work, pediatrics, and genetics.

Fortunately, many of the anomalies discussed in this chapter are relatively rare, but for surgeons in a pediatric tertiary care center, these patients are seen as daily occurrences. This chapter is not meant as a definitive tome on the diagnosis and treatment of these disorders, but is meant to paint a picture of the spectrum of craniofacial anomalies with broad brushstrokes.

The first two sections discuss two of the more common skeletal anomalies treated by craniofacial surgeons: craniosynostosis and jaw anomalies that require orthognathic surgical correction. The final section deals with facial asymmetry and hypoplasia disorders that are rare and complex to treat.

## The Craniosynostoses

Craniosynostosis refers to the premature closure of one or more cranial sutures and encompasses a wide range of anatomic derangements. Isolated, premature fusion of a single suture causes a predictable cranial deformity that can typically be recognized without the need for radiologic imaging by an experienced practitioner. However, complex craniosynostosis, consisting of multiple suture fusions, can be difficult to diagnose without radiologic imaging. Despite the wide range of clinical presentation, treatment for craniosynostosis cases is similar to any other surgical problem in children: accurate diagnosis, appropriate treatment planning, proper timing of surgery with respect to current and future growth, and surgical technique that gives a predictable correction and minimizes adverse long-term sequelae.

### ETIOLOGY AND PATHOLOGIC ANATOMY

The infant skull undergoes a period of rapid expansion during the first year of life, which is driven by brain growth. Bone growth at patent cranial sutures causes calvarial expansion in a distinct morphologic pattern. Typically, suture fusion occurs from anterior to posterior and lateral to medial.[1] The metopic suture, which normally closes by 8 to 9 months of age, is the only suture to close completely during infancy; the remaining sutures do not completely fuse until adulthood. Most patients presenting with craniosynostosis have prenatal onset of suture fusion. However, in severe cases of syndromic craniosynostosis, progressive, multiple suture fusion can occur over the first 3 to 4 years of life.[2] In this situation, the calvarial deformity is typically not detected at birth except when quite severe. After a few months of rapid growth, the deformity typically becomes more apparent.

In 1851, Virchow published his landmark paper that laid the foundation for our understanding of craniofacial deformities associated with craniosynostosis. He described the growth pattern of the skull as being restricted in a plane perpendicular to the fused suture while being amplified in a plane parallel to the direction of the suture. This compensatory growth pattern causes predictable deformities in patients with single suture synostosis. The growth constriction, however, is not confined to the cranial vault, but also affects the cranial base to varying degrees. Moss proposed that the cranial base pathology was the inciting event, and that the calvarial fusion occurred as a secondary phenomenon.[3] However, cranial base anomalies are not corrected by calvarial vault surgery and are now not thought to be the inciting event.

Recent research has focused on the role of the dura and its influence on suture patency in the growing skull. A number of dural-related cytokines, such as heparin-binding factor, fibroblast growth factors (FGFs), bone morphogenic proteins (BMPs), transforming growth factor(s)-β (TGF(s)-β), and transcription factors Msx2 and TWIST, have a role in the regulation and coordination of suture patency.[4] A mutation of the *TWIST*

gene on chromosome 7p21 has been linked with Saethre-Chotzen syndrome.[5,4] FGF receptor mutations causing constitutive activation of the receptor occur in many of the human craniosynostosis syndromes, including Apert, Crouzon, Muenke, and Pfeiffer syndromes.[4] Interestingly, one mechanism of bony fusion across the suture occurring with the *FGF-R* mutation is the loss of Noggin expression in the involved suture mesenchyme. Noggin is a BMP-inhibitor that prevents bony fusion in the mesenchyme. When Noggin is not present, bone forms across the mesenchyme, and the suture fuses.[6] Most incidences of craniosynostosis are the result of sporadic genetic anomalies. Yet, a number of both autosomal dominant and autosomal recessive syndromes, whose most striking phenotype is the pattern of craniosynostosis, are known. Patients with a family history of craniosynostosis should thus be referred to a dedicated craniofacial team and be evaluated by a skilled geneticist, as new genetic mutations linked to the craniosynostosis syndromes are being discovered frequently.

The treatment for craniosynostosis is surgical calvarial vault remodeling, which is performed to avoid future adverse sequelae. Chief among these is the avoidance of intracranial hypertension, which has been linked to brain damage, optic nerve compression, and cognitive impairment.[7] Early surgical correction (between 3 to 6 months of age) has the advantages of prevention of elevated intracranial pressure and its attendant consequences, improved reossification of calvarial bone defects, and the need for a less extensive surgical correction. Correction at a more advanced age (6 to 9 months) is reported to have more stable long-term results and lower rates of reoperation. These factors are taken into account by the craniofacial surgeon and pediatric neurosurgeon during the treatment planning process.

**FIGURE 53-1** A lateral view of a patient with scaphocephaly resulting from sagittal synostosis. Note the frontal bossing, elongation along the anteroposterior (AP) axis, and prominent occiput, all of which are characteristic of this condition.

**FIGURE 53-2** A child with left unicoronal synostosis. Characteristic findings include ipsilateral fronto-orbital retrusion, prominent contralateral forehead bossing, and nasal root deviation toward the affected side. The C-shaped facial deformity is notable here.

## Common Patterns of Single Suture Craniosynostosis

The most common form of craniosynostosis is sagittal synostosis, with an incidence of approximately 2 per 10,000 live births. In concordance with Virchow's law, premature fusion of the sagittal suture leads to compensatory growth in the anteroposterior dimension, resulting in *scaphocephaly* (Fig. 53-1).

Unilateral coronal synostosis is less common, with an incidence of approximately 0.9 per 10,000 live births. The growth pattern in unicoronal synostosis is more complex, albeit leading to a stereotypical calvarial phenotype. Ipsilateral to the fused coronal suture, the supraorbital rim is flattened and recessed, and the forehead is flattened. As calvarial growth occurs, the contralateral forehead becomes bossed and the nasal bridge starts to twist, producing a C-shaped facial deformity (Fig. 53-2).

Premature fusion of the metopic suture results in constriction of growth in an axial plane centered on the caudal forehead. A palpable bony ridge is present in the midline of the forehead (described as a "keel-shaped forehead" or *trigonocephaly*). The forehead is narrow and pointed. The medial orbital rims are consequently closer to the midline, giving the appearance of hypotelorism. Bilateral lateral brow recession and temporal hollowing also occurs and exaggerates this appearance.

The least common form of single suture craniosynostosis affects the lambdoid suture. Common findings are posterior plagiocephaly, ipsilateral mastoid bossing, and both anterior and inferior ipsilateral ear displacement. A posterior skull base cant and contralateral forehead bossing occur in more advanced cases.

Multiple suture craniosynostoses are rare, and may present with a variety of skull-shaped deformities.

## Syndromic Craniosynostosis

Children born with craniofacial dysostosis syndromes require multiple staged procedures to correct their bony deformities during their childhood years and extending into early adulthood. These patients have a higher relapse rate because

multiple affected midface and skull base sutures are usually present. The syndromic craniosynostoses carry a greater risk of intracranial hypertension, as well.

Many of the craniofacial dysostosis syndromes are inherited in an autosomal dominant pattern and are the result of mutations in the *FGF*-receptor genes, which alter the signaling pathway. Although penetrance is complete in most syndromes, the expression of the mutation is highly variable. Examples of these include Crouzon, Apert, and Pfeiffer syndromes, the three most common craniofacial dysostosis syndromes, all of which have mutations in the *FGF*-receptor genes.

Crouzon syndrome is the most common syndromic craniofacial dysostosis, with an estimated incidence of 1 in 25,000 live births.[8] Crouzon syndrome is caused by a mutation in the *FGFR2* gene, causing increased receptor activation.[9] The syndrome is characterized by the triad of bicoronal craniosynostosis, exorbitism, and midface retrusion (Fig. 53-3). Exorbitism is the feature of this syndrome, which results in prominent globes. As such, ocular protection is a key feature the clinician must keep in mind when assessing these children. Exposure keratitis and conjunctivitis may prompt earlier surgical intervention to avoid permanent visual impairment.

Apert syndrome has an incidence of 1 per 160,000 live births and is also caused by an *FGFR2* mutation.[10] Unlike Crouzon syndrome, the genetic defect in Apert syndrome is a missense mutation, and the vast majority of Apert patients are the result of a sporadic mutation. The triad of bicoronal craniosynostosis, midface hypoplasia, and syndactyly of the hands and feet characterize Apert syndrome. The craniofacial findings include bicoronal suture fusion, a large anterior fontanelle, midface retrusion, and varying degrees of exorbitism.

**FIGURE 53-3** Brachycephaly, exorbitism, and midface retrusion, which are common findings in both Apert and Crouzon syndromes.

Neonatal respiratory distress from a narrowed nasal vault, sometimes severe enough to warrant tracheostomy, may occasionally occur.[11] A specialist in congenital hand anomalies typically addresses complex syndactyly of the hands and feet. Unlike Crouzon syndrome, mental retardation is common, and affects nearly 50% of children with Apert syndrome.

Other craniofacial dysostosis syndromes include Pfeiffer syndrome, Saethre-Chotzen syndrome, and Carpenter syndrome. These are much less common than either Crouzon or Apert syndrome and share varying degrees of craniosynostosis, midface retrusion, digital anomalies, and mental retardation. Management priorities in these children are similar to that of children with either of the previously mentioned syndromes.

## DIAGNOSIS

A thorough history and physical examination is the cornerstone of diagnosing synostosis of the calvarial sutures. Single suture fusion results in the characteristic patterns of calvarial morphology described previously and are readily diagnosed by physical examination.

Measurement of head circumference with plotting on a standard growth curve gives an indication of head growth relative to the child's body. Physical examination should accurately define asymmetries in the infant skull. Head shape should be assessed from anterior, posterior, and top-down views to identify areas of relative bossing or recession. Ear position in both anterior-posterior and craniocaudal planes should be examined. Lateral examination of the forehead and face will identify forehead bossing and the position of the midface and orbits. Facial examination is especially important in identifying children with the craniofacial syndromes that have midface retrusion as part of their phenotype. Stigmata of intracranial hypertension should be investigated. For infants, these include a history of irritability, "burrowing" behavior, or repetitive head slapping.

Since the advent in the early 1990s of the American Academy of Pediatrics "Back to Sleep" campaign, designed to decrease the incidence of sudden infant death syndrome (SIDS), a sharp increase in the incidence of *positional plagiocephaly* has occurred. Positional plagiocephaly is the deformation of the calvarium despite the presence of widely patent cranial sutures. This condition may be difficult to differentiate from unilateral coronal or lambdoid craniosynostosis, which both result in forms of plagiocephaly. Usually, an experienced craniofacial surgeon can make the correct diagnosis based on physical examination findings alone. However, sometimes computed tomography (CT) imaging is needed. The correct diagnosis is critical, however, because children with positional plagiocephaly are treated with changes in sleeping position or, in more severe cases, a custom orthotic molding helmet.

Children who are suspected of having craniosynostosis should be referred to a craniofacial team for evaluation. This evaluation includes detailed cranial measurements and a thorough physical examination. CT scanning is rarely needed for diagnosis, but is obtained by many craniofacial surgeons prior to calvarial vault remodeling to assess for intracranial abnormalities. Given the additional cost, risks of sedation, and potential harmful effects of ionizing radiation on the growing child, radiologic imaging should be undertaken on a case-by-case basis as determined by the craniofacial surgeon.[12]

In addition to findings of suture fusion, stigmata of intracranial hypertension, such as a "moth-eaten" appearance of the calvarium on CT images or a "copper-beaten" appearance on plain radiographs will be seen. Papilledema may be seen on fundoscopic examination and is an indication for urgent cranial vault expansion.

### TREATMENT

The mainstay of treatment for premature fusion of cranial sutures is surgical cranial vault remodeling. The two goals of surgery are to release the involved suture through resection and reconstruction of the cranial vault to a more normal shape. Surgery is a combined procedure between a craniofacial plastic surgeon and a pediatric neurosurgeon. In general, the pediatric neurosurgeon performs the initial craniotomy, and the craniofacial surgeon performs the bony reshaping. However, the procedure is mainly "bone surgery" and not "brain surgery." Cranial vault remodeling is accomplished by removing the abnormally shaped calvarial bones and recontouring them. The plasticity of the infant calvarium is utilized as the bones are bent and shaped to a more anatomic contour. Barrel stave osteotomies are commonly performed to expand the cranial vault. Wedge osteotomies are done to reduce the vault in areas of bony excess or bossing. Except in cases of isolated sagittal or lambdoid synostosis, the orbits are deformed, which necessitates advancement of the supraorbital rim in addition to reshaping of the forehead and anterior cranial vault. Bones are fixed into their new position with resorbable hardware consisting of polyglactic/polyglycolic acid plates and screws. This type of hardware undergoes degradation over the course of a year, and is not prone to intracranial migration, which can occur with traditional titanium hardware. After initial reconstruction in infants, bony defects remain after surgery. The unique osteogenic potential of the dura and overlying periosteum in infants results in primary bone formation and complete healing of these large bone defects. Bone defects that remain after 2 years of age typically require secondary bone grafting. Endoscopic techniques have been described for correction of both sagittal and coronal synostosis.[13,14] Although resection of the involved suture is performed, these techniques rely on a long period of postoperative molding helmet therapy to achieve final head shape. Despite their reported benefit of reduced blood loss and transfusion requirements, endoscopic techniques have not gained wide acceptance, primarily due to their poor head shape outcomes.

Timing of surgery is somewhat controversial among craniofacial surgeons. Some surgeons advocate "early" correction at 3 to 6 months of age, believing that the rapidly growing brain will assist in remodeling the skull if the fused suture is released and the calvarium reshaped. This theoretically reduces the amount of correction that needs to be performed in the operating room. Delaying surgery until 9 to 12 months of age allows the infant skull growth to begin to plateau prior to surgery. Although this reduces the amount of intrinsic bone shape normalization resulting from brain growth, the thicker calvarial bone may provide a more stable skeletal correction with less relapse. In reality, a large window exists when the surgery can be performed with acceptable risks and outcomes. Children who present late for corrective surgery present unique challenges to the craniofacial surgeon. Bone in these children is typically thicker and more difficult to contour with bone-bending forceps and simple barrel stave osteotomies. The asymmetric skull base is more developed and resistant to normalization, which increases the chances of a permanent deformity. Also, the diploic space between the inner and outer table has begun to form, subjecting the child to increased blood loss during surgical exposure and bony resection. The entire reconstructive procedure is more extensive, as even subcentimeter bone defects must be grafted in order to heal. Extracranial bone grafts (rib and/or iliac) are needed when the diploic space has not yet formed (before 5 years of age).

In children with syndromic craniosynostosis and midface retrusion, further reconstruction is frequently needed. A midface advancement consisting of either a Le Fort III or a monobloc osteotomy is performed between the ages of 5 and 8 years, unless the need for ocular protection forces earlier correction. The choice between procedures depends on forehead projection—a subcranial Le Fort III is performed if forehead projection is adequate, whereas a monobloc frontofacial advancement is needed if forehead retrusion has occurred. At the age of skeletal maturity (typically between the ages of 14 and 16), a Le Fort I maxillary osteotomy, with or without mandibular osteotomies, is usually needed to formally correct any malocclusion that commonly exists in these patients.

## Orthognathic Surgery

The term *orthognathic* is derived from the Greek "orthos," meaning to straighten, and "gnathos" meaning jaw. Orthognathic surgery is a discipline that crosses the boundaries of many different specialties, principally oral and maxillofacial surgery and craniofacial surgery (a distinct subspecialty of plastic surgery). Orthognathic surgery repositions the dentofacial skeleton to correct either congenital or acquired malocclusions and restore a harmonious balance to the underlying bony facial form. These movements can involve both the maxilla and the mandible, either in segments or in conjunction with varying portions of the craniofacial skeleton. Certain procedures mandate the assistance of a pediatric neurosurgeon, because they require intracranial osteotomies to fully mobilize the bony segments for repositioning. An orthodontist who is familiar with the necessary dental movements is also needed to prepare a patient for surgery. The orthodontist also "fine-tunes" the dental occlusal relationships postoperatively, which is imperative for a successful outcome.

Although secondary trauma can lead to orthognathic surgery, the field predominantly addresses congenital and developmental deformities leading to malocclusion that cannot be corrected orthodontically. Nearly 25% of all patients who have undergone correction of a cleft lip and palate will develop severe maxillary hypoplasia that warrants surgical correction. Whether this is due to an intrinsic growth disturbance or restriction of growth of the midface due to postcleft surgical scarring is a hotly debated topic among craniofacial surgeons.

The age at which orthognathic procedures are performed is an important consideration in planning subsequent surgeries. Any skeletal facial advancement procedure performed prior to the age of bony maturity carries a significant rate of relapse as the remainder of the face grows; merely advancing the hypoplastic segments will not "unlock" their growth potential. For this reason, definitive orthognathic procedures are carried out

in mid- to late adolescence, once the majority of facial skeletal growth is complete. Thus orthognathic surgery is usually done between 14 and 16 years for girls and 15 and 17 years for boys. Epiphyseal closure on anteroposterior hand radiographs is a good indicator of overall skeletal maturity.

Preoperative evaluation of patients with congenital dentofacial deformities usually occurs in the setting of a cleft/craniofacial team visit. An orthodontist is present for discussion of treatment options and will be intimately involved in both the preoperative and postoperative care of these patients. The patient's occlusion is determined according to the Angle classification, with class 1 being a "normal" occlusal relationship, class 2 as the typical "overbite," and class 3 being an "underbite." The facial profile and aesthetics are analyzed with special attention paid to the soft tissue bony landmarks. A lateral cephalometric radiograph, which is a standardized view with the head aligned in the neutral position, is used for treatment planning. The positions of the maxilla and mandible are determined with respect to the cranial base. Dental models are cast and mounted on an articulator in their anatomic relationship. Model surgery is performed wherein the models are precisely moved to place the teeth in proper planned postoperative occlusion. An acrylic splint is made from the models after each jaw is repositioned, which will be wired into place in the operating room to assure the bony segments are in proper position. This splint can be a final interdental splint for wear postoperatively.

In 1901, René Le Fort, a French surgeon and anatomist, carried out a series of rather grotesque experiments and defined a classification system for facial fractures that bears his name.[15,16] These "fault lines" of the facial bony skeleton were then subsequently adapted for use in elective orthognathic surgery and have become the mainstay of therapy to correct midfacial skeletal anomalies. The most common is the *Le Fort I osteotomy*, which repositions the tooth-bearing segment of the maxilla in either the anteroposterior or craniocaudal planes, or both. This osteotomy can be modified to divide the maxilla into two or three tooth-bearing segments, which can be moved independently to provide a functional, Angle class 1 occlusion and correct both sagittal and transverse maxillary deficiency. The Le Fort I osteotomy is used to correct cleft lip and palate-related maxillary hypoplasia. It is also used to correct vertical maxillary excess or rotational abnormalities of the maxilla.

Another commonly used corrective procedure in craniofacial surgery is the *bilateral sagittal split osteotomy* (BSSO). In this technically demanding procedure, the mandible is split in the sagittal plane from midramus to proximal body, sparing the inferior alveolar nerve on both sides. The BSSO movements can be adjusted to correct mandibular asymmetry, level the occlusal plane, or correct overall facial disharmony caused by overgrowth or undergrowth of the mandible. The BSSO is often combined with the Le Fort I osteotomy to correct larger mandibular–maxillary discrepancies. *Genioplasty* refers to reduction, advancement, or lateral movements of the bony chin point. It is generally considered a purely aesthetic procedure that can be added to enhance the facial skeletal balance.

Although not usually considered an orthognathic procedure, but rather a "craniofacial" procedure, the *Le Fort III osteotomy* is performed to reposition the midface (maxilla and zygomas) relative to the cranial base. In this procedure, osteotomies are created across the ascending portion of the zygoma, the zygomatic arch, orbital floor and both medial and lateral walls, frontonasal junction, and pterygomaxillary junction. The nasal septum is divided in the coronal plane. This allows for complete separation of the facial skeleton from the cranial base and subsequent advancement of the Le Fort III segment to correct midface hypoplasia. The Le Fort III advancement is used to correct severe malocclusion or upper airway obstruction from overall midface growth restriction. The majority of patients who undergo a Le Fort III osteotomy have a named syndrome (Crouzon, Apert, and Pfeiffer being the most common), and have their first midface advancement at age 5 or 6 years. Because the growth of the midface is not complete until mid- to late adolescence, a second advancement is frequently necessary. When midface retrusion is accompanied by growth restriction of the supraorbital rim and forehead, a *monobloc frontofacial advancement* may be necessary. This is an intracranial and extracranial procedure and requires both a pediatric neurosurgeon and a craniofacial surgeon for intracranial access. A monobloc advancement is similar to a Le Fort III osteotomy, except that the supraorbital rim and forehead are advanced along with the midface. This procedure has fallen out of favor because of infectious complications arising from difficulty obtaining adequate separation of the intracranial space and nasal cavities.[17] Thus the monobloc is now usually performed as a staged procedure (fronto-orbital advancement, followed by a Le Fort III osteotomy a few months later) or is performed with the use of distraction osteogenesis to allow the soft tissues to grow along with bony skeletal expansion, which minimizes the risk of intracranial infectious complications.

*Distraction osteogenesis* was pioneered by Ilizarov (a Russian orthopedist) in 1958, and adapted for use in the mandible by McCarthy in 1992.[18,19] It is now commonly used for a number of applications in craniofacial surgery. The principle behind distraction osteogenesis is that gradual expansion of the bony skeletal gap left by a surgically placed osteotomy will allow lengthening of the bone by gradual osteoblastic activity and ingrowth of new bone. This results in lengthening of the skeleton in the direction of the vector of expansion. Distraction is useful in situations that would require extensive bone grafting to obtain adequate bone length, or in cases in which opposing soft tissue forces would result in skeletal relapse if the bone was rapidly advanced and grafted. Clinically, maxillary distraction is most commonly applied when a large discrepancy exists between the maxilla and mandible as a result of a complete cleft lip and palate and resultant maxillary hypoplasia. Scarring from the numerous previous procedures makes maxillary advancement alone prone to relapse; by applying the principle of distraction, the bone and soft tissue are gradually expanded, and the cleft maxilla can be advanced into a normal occlusal relationship (Angle class 1) with minimal chances of relapse resulting from soft tissue resistance. Distraction is also useful to correct severe mandibular hypoplasia accompanying conditions such as hemifacial microsomia or Pierre Robin sequence, which will be discussed in subsequent sections of this chapter.

## Craniofacial Clefts

Dr. Paul Tessier, the father of the field of craniofacial surgery, also developed a classification system for craniofacial clefts that is arguably the most widely used of those available today.

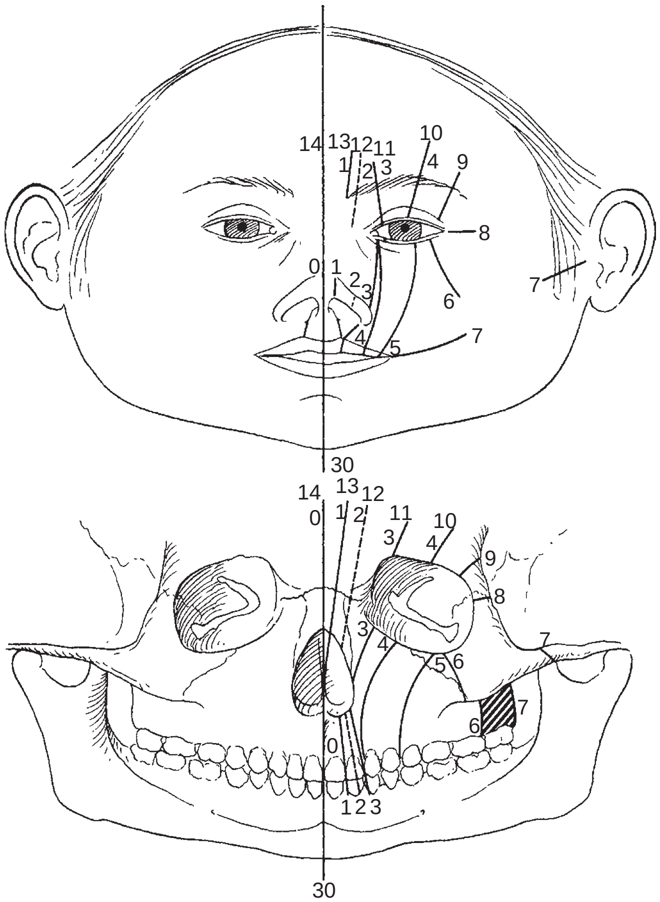

**FIGURE 53-4** Tessier's pre-computed tomography classification system of rare craniofacial clefts. The lower image represents the cleft location of the bony skeleton, while the upper illustrates the cutaneous manifestations of the various bony clefts.

The Tessier system is based on specific anatomic derangements that fall along embryonic lines of fusion within the face (although these were not known at the time they were initially described) (Fig. 53-4). Tessier's classification system is notated 0 to 14, with clefts 0 to 7 describing facial clefts and clefts 8 to 14 describing cranial vault clefts. Each cleft has unique soft tissue and bone lines of clefting. Also, the facial and cranial clefts coincide such that the sum of the two components is 14 (i.e., 0 and 14 clefts coincide, as do 3/11 and 5/9, etc.). A thorough search along the meridian of the cleft will usually elucidate subtle (or not-so-subtle) findings.

The majority of craniofacial clefts are rare and will be seen infrequently during an individual surgeon's career. As such, the remainder of this section of the chapter will be spent dealing with those more common Tessier clefts.

## CLEFT NUMBER 7

A number 7 cleft can be protean in physical manifestation and is known by a number of different names. Hemifacial microsomia, oculoauriculovertebral syndrome (OAV), first and second branchial arch syndrome, and otomandibular dysostosis syndrome all refer to the physical findings associated with a number 7 cleft. The number 7 cleft is thought to have an incidence of between 1 in 3000 and 1 in 5642[20] live births. A number 7 cleft is usually unilateral, but approximately

**FIGURE 53-5** A child with a typical Tessier number 7 soft tissue cleft.

10% of affected children will have symmetric, bilateral involvement.[21]

The derivatives of the first and second branchial arch are abnormal, albeit to varying degrees. Macrostomia is a common finding, with the commissure of the lip being displaced laterally toward the affected side, resulting in an enlarged oral opening (Fig. 53-5). Preauricular "ear tags," embryologic remnants of the developing ear, are present anterior to the external auditory canal and contain small "stalks" of cartilage remnants (Fig. 53-6). The external ear can likewise be affected and can range from mild hypoplasia to near complete absence. A conductive hearing loss on the ipsilateral side is commonplace. The mandible is commonly affected, and the defect of the ascending ramus and condyle may range from mild hypoplasia to complete absence (Fig. 53-7). The facial nerve may be affected to varying degrees, as well, which in turn contributes

**FIGURE 53-6** Multiple accessory external ear tags as seen in Tessier 7 clefts.

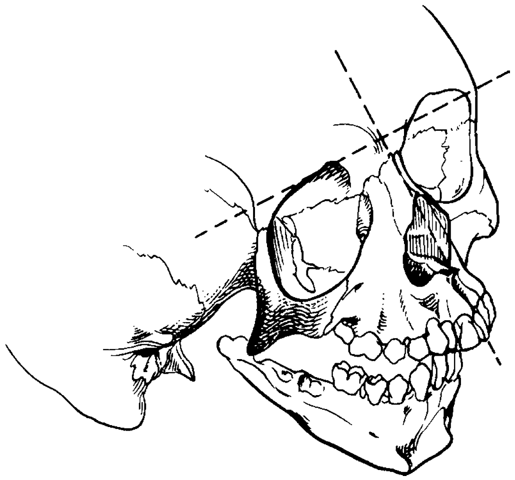

FIGURE 53-7 Skeletal findings in hemifacial microsomia. Note the absence of the ascending ramus and condyle of the mandible.

to weakness and underdevelopment of the muscles of facial expression that they supply.

Given that the manifestations of the number 7 cleft vary, so do the treatment options. In general, more severely affected children require earlier and more significant reconstruction. Cutaneous manifestations—macrostomia and branchial arch remnants—are usually treated with excision and local flap reconstruction during infancy. Underlying bony anomalies are treated based on severity. Children with mild hypoplasia of the ramus and condyle are followed throughout growth, and will usually develop an occlusal cant (Fig. 53-8) as they age. These children can be treated with orthognathic surgery after cessation of skeletal growth to reposition the hypoplastic mandible and maxilla with the combination of a Le Fort 1 osteotomy, bilateral sagittal split osteotomies, and an osseous genioplasty to align the chin point. Those with more severely hypoplastic rami will undergo distraction osteogenesis of the ramus during childhood, but will usually need formal orthognathic correction during late adolescence.[22] Children who are born with complete absence of an ascending ramus need an extensive reconstruction to achieve normal function of their mandible and a normal occlusal relationship. This is typically accomplished through the use of a free costochondral rib graft, which is performed around 7 years of age. Ear reconstruction with costal cartilage is performed at the same age, when necessary.

## TREACHER COLLINS SYNDROME

First described in 1847,[23] Treacher Collins syndrome (or mandibulofacial dysostosis) is a relatively common syndrome made up of Tessier clefts 6, 7, and 8. Its incidence is estimated at 1 in 10,000 live births. Treacher Collins is caused by a mutation on chromosome 5q31.3-33.3 (the *TCOF1* gene) and is an autosomal dominant disorder with variable penetrance.

Treacher Collins patients manifest bilateral anomalies of the eyelids, zygomas, maxilla, mandible, and ears (Fig. 53-9). There is typically an antimongoloid slant to the palpebral fissures, with lower lid notching present. Eyelashes are often absent on the medial two thirds of the lower eyelid. The zygomas are severely hypoplastic or absent. The maxilla is hypoplastic with a shortened vertical height, which can impede or block nasal airflow. Shortening of both the length and height of the mandible results in narrowing of the posterior pharyngeal airway and can contribute to upper airway obstruction in these children, which in the past necessitated placement of a tracheostomy. Within the past 20 years, however, distraction osteogenesis has been applied to these patients to relieve early upper airway obstruction and avoid the need for long-term tracheostomy dependence. Severe microtia is often accompanied by atresia of the middle and inner ear; placement of bone-anchored hearing aids (BAHA) is commonly necessary to allow for improved hearing and speech development. As is the case with either isolated or syndromic microtia, reconstruction of the external ears is usually undertaken at age 7 or 8 with autologous costal cartilage grafts. At around this same time, onlay bone grafting of the maxilla and zygoma is performed to add projection and give a more normal midfacial profile. Correction of the eyelid notching with local tissue transfers is also performed at this age should it not be needed earlier because of corneal protection issues. Definitive orthognathic surgical correction of the associated deformities of the occlusal plane is performed in late adolescence.

FIGURE 53-8 A child with hemifacial microsomia and an occlusal cant. Note the upward slant of the mandible caused by right-sided ramus hypoplasia.

FIGURE 53-9 Typical findings in a patient with Treacher Collins syndrome. Down-slanting palpebral fissures, malar hypoplasia, and microtia are common hallmarks of this syndrome. This child lacks true colobomas of the lower eyelid but has loss of lower eyelid support and excess scleral show.

CHAPTER 54

# Understanding and Caring for Children with Cleft Lip and Palate

James Y. Liau, John A. van Aalst, and
A. Michael Sadove

## Epidemiology

The incidence of orofacial clefting varies among racial backgrounds. Because of the close association between cleft lip and palate, the presence of cleft lip is often described as being with or without cleft palate. Worldwide prevalence of cleft lip and palate is 1 per 700 live births.[1] People of African descent have the lowest incidence of cleft lip with/without cleft palate at 0.5 per 1000 live births, followed by whites (1 per 1000 live births), and Asians (1.3 per 1000 per live births). Overall, an isolated cleft lip makes up approximately 21% of all patients with cleft lip and palate. Unilateral clefts are roughly 9 times more prevalent than bilateral cleft lips, and males are more affected than females. The U.S. incidence of cleft palate alone ranges from 0.3 to 0.5 per 1000 live births.[2] A child with a cleft lip with or without cleft palate has an approximately 30% chance of having an associated syndrome; interestingly, a child with an isolated cleft palate has a 50% incidence of an associated syndrome.[2,3] Because of this association, genetic workup and counseling is mandatory, as is heightened suspicion for other physical and physiologic anomalies.

## Etiology

Genetic and environmental factors have both been associated with clefting. If other family members are affected by a cleft, offspring have an increased chance of being affected. For example, if a family already has a child with a cleft, or one parent has a cleft, the chance that the next child will have a cleft is 4%; with two affected children, the chance that a third child will have a cleft increases to 9%. The probability increases to 17% in a family if both a child and parent have a cleft.[4] This increase in frequency is seen in spontaneous clefting not associated with syndromes. There are some syndromes in which clefting can be passed down in an autosomal dominant fashion, such as van der Woude syndrome, where presence of the cleft palate is an autosomal dominant trait.

Environmental causes of clefting include the use of anticonvulsants, including phenytoin, which is associated with 10-fold increase in clefting; maternal smoking increases the incidence twofold. Other environmental influences, such as alcohol use, the use of retinoic acid, and dietary causes, including zinc and folate deficiencies, can cause syndromes with clefting; however, these are not directly linked to isolated cleft lip/palate. People with certain genotypes are more susceptible to certain environmental exposures; hence, women with less efficient methyl tetrahydrofolate reductase enzymes are more prone to clefting in the face of folic acid deficiency.[5–12]

## Embryology

Basic understanding of midface and palatal embryologic development helps elucidate the pathoanatomy of cleft lip with or without palate. Orofacial clefting occurs when there is failure of fusion of maxillofacial structures migrating from lateral to medial during the initial 4 to 10 weeks of embryonic development. A key anterior–posterior embryologic and anatomic landmark in understanding clefts is the incisive foramen. The structures that form anterior to the foramen ultimately develop into the nose, lip, and alveolus; embryologically, these structures form first and are designated as the primary palate. The structures that form posterior to the foramen become the hard palate and soft palate, and are referred to as the secondary palate, because they fuse secondarily. Clefting of the lip (primary palate) occurs when the nasomedial and nasolateral prominences of the frontonasal prominence do not meet with the maxillary prominence (Fig. 54-1, *A*). Clefting of the palate (secondary palate) occurs when the lateral palatine shelves do not elevate and fuse at the midline to each other or to the primary palate (Fig. 54-1, *B*). Because the development of this craniofacial area is complex, deformities can occur at multiple points along the embryologic time line, resulting in a full spectrum or combination of anomalies.

## Anatomy

### UNILATERAL CLEFT LIP

A cleft lip affects the anatomy of the lip, philtrum, nose, as well as the alveolus, depending on the severity of the defect. Microform clefts are the mildest form of clefting, involving

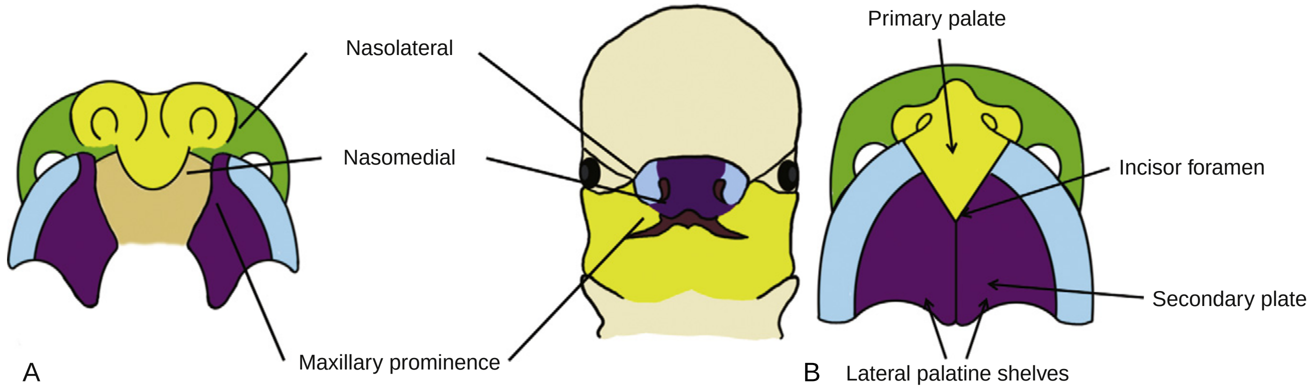

**FIGURE 54-1** **A,** The nasolateral and nasomedial prominence fuse to make the lip and nose. Lack of fusion between the maxillary nasal prominence with the nasomedial prominence will yield a cleft lip. **B,** The lateral palatine shelves fuse in the midline, thus forming the secondary palate. The primary palate fuses posteriorly with the palatine shelves to form a complete palate.

the vermillion and white roll, and can be quite subtle (Fig. 54-2, *A*). Incomplete clefts are associated with absence of skin, mucosa, and orbicularis muscle but have a retained webbing of skin across the floor of the nasal aperture, referred to as a Simonart band (Fig. 54-2, *B*). A complete unilateral cleft involves the alveolus, and can be associated with a cleft of the palate (Fig. 54-2, *C*).

The most obvious deformity involving a cleft lip is discontinuity of the lip itself. However further analysis of the defect demonstrates deviation of the nasal septum and columella, as well as widening or flattening of the cleft-side nasal cartilage. Other defects include the lack of nasal floor and discontinuity of the lip, muscle, and the alveolar ridge. Successful surgical correction of the lip must address all of these structures.

## BILATERAL CLEFT LIP

Bilateral clefts have a two-sided discontinuity of the lip, with a central portion, the premaxilla, which is discontinuous from either of the lateral segments. The premaxilla contains

**FIGURE 54-2** **A,** Microform cleft can be seen with mild notching of the lip's vermilion along with the minimal distortion of the nose. **B,** Incomplete cleft has some webbing across the cleft with some retention of the lateral nose; however, the skin across the cleft is devoid of orbicularis oris muscle and is functionless. This skin is also called a Simonart band. **C,** Complete cleft lip has lateralization of the lip and lateral nasal element. Notice the deviation of the nasal columella and philtrum away from the cleft, and the flattened nose on the cleft side. This picture also demonstrates the clefting of the palate, which allows an unobstructed view into the nasal airway.

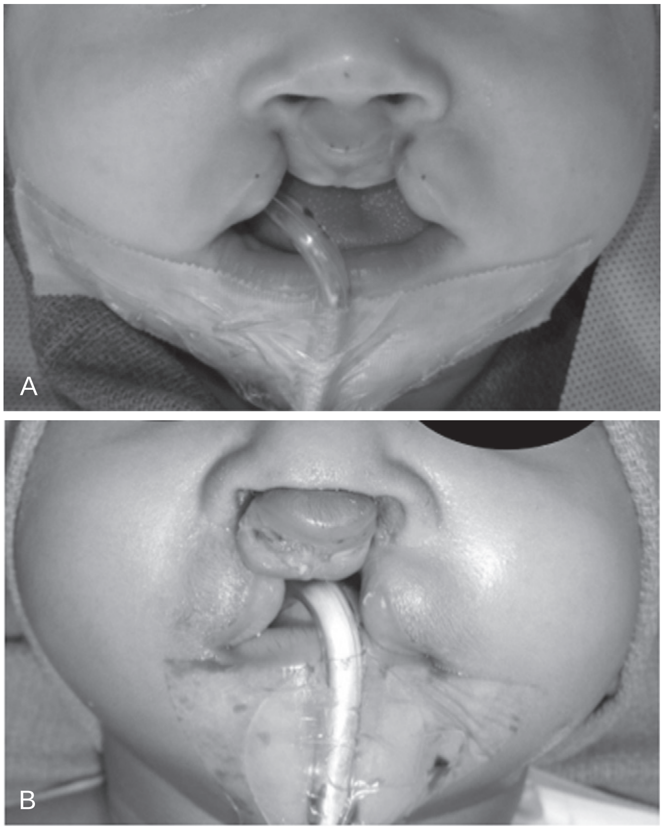

**FIGURE 54-3** **A,** Bilateral cleft lip with a Simonart band transversing both clefts. **B,** Complete bilateral cleft lip. The midline protuberance is called the premaxilla and is much more protruding than an incomplete bilateral cleft; tethering of the Simonart bands help in keeping the premaxilla in a more anatomic position. Absence, or shortening of the columella, widening of the alar bases, and anterior projection of the premaxilla are all trademarks of bilateral cleft lips.

elements of skin, mucosa and bone, which can be asymmetrically deviated to one side or the other, and can be anteriorly positioned, depending on the severity of the deformity. Bilateral clefts can be incomplete with Simonart bands (Fig. 54-3, *A*), or complete with defects that proceed through the alveolar ridges (Fig. 54-3, *B*). A central feature of the bilateral cleft lip deformity is depression of the nasal tip, a shortened columella, and widely splayed alae.

## CLEFT PALATE

Clefts of the palate can exist with clefts of the lip or may be present alone. Anatomically, the hard palate begins immediately posterior to the incisive foramen, with embryologic fusion of the palate from anterior to posterior. Hence, an isolated cleft of the soft palate may exist; however, an isolated cleft of the hard palate cannot. A complete cleft of the secondary palate includes both the hard and soft palate, extending anteriorly from the incisive foramen to the uvula, and this can be bilateral as well (Fig. 54-4). The primary function of the palate is to separate the oral cavity from the nasal cavity. This function is lost in the presence of a cleft. The function of the soft palate is primarily speech related and dependent on five paired muscles, the two most important of which are the levator veli palatini and the tensor veli palatini. Ordinarily, these muscles form a transverse sling enabling the palate to rise and move posteriorly to close the oropharynx from the nasopharynx. In a cleft palate, these muscles abnormally insert onto the posterior shelf of the hard palate, and as a consequence, the palate is deficient in its ability to seal off the oropharynx from the nasopharynx.

A submucous cleft is the most minor expression of the clefting spectrum. The soft palate mucosa is actually intact, but split posteriorly, resulting in a bifid uvula; there is a midline lucency in the soft palate, referred to as a zona pellucidum, which is a muscle diastasis, and a notch at the midline, posterior edge of the hard palate.[13] As in a full cleft, the levator and tensor veli palatine abnormally insert onto the posterior hard palate, preventing the soft palate from moving appropriately during speech, potentially leading to nasal sounding speech. The incidence of submucous clefts is roughly 1 in 1,200 to 2,000; however, this is likely an underestimation, because many patients may not seek treatment or even know of their submucous cleft unless there is functional speech deficit.[14]

# Treatment Protocols

The timing for cleft lip repair in the United States is generally between 3 to 6 months of age. Depending on the severity of the deformity, various forms of presurgical orthopedics can be used to prepare the child for lip surgery. In general, the goals of these techniques are to improve the alignment of the alveolar segments, decrease the size of the soft tissue cleft, and to

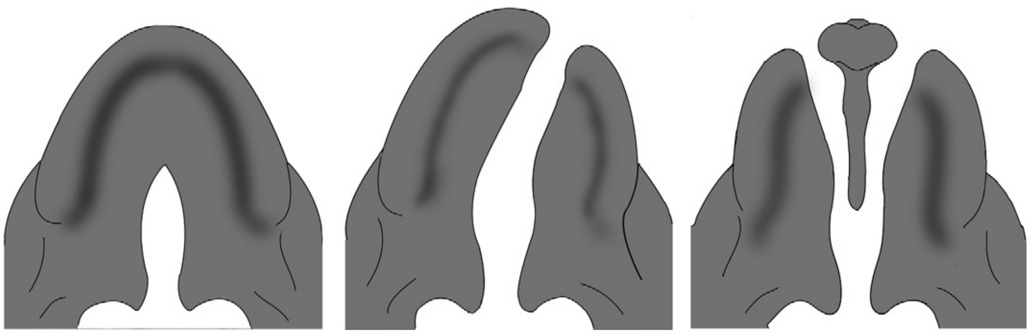

**FIGURE 54-4** The figure on the *left* depicts a cleft of the secondary palate only; there is an intact hard palate. The *middle* figure depicts a complete unilateral cleft. The figure on the *right* depicts a complete bilateral cleft.

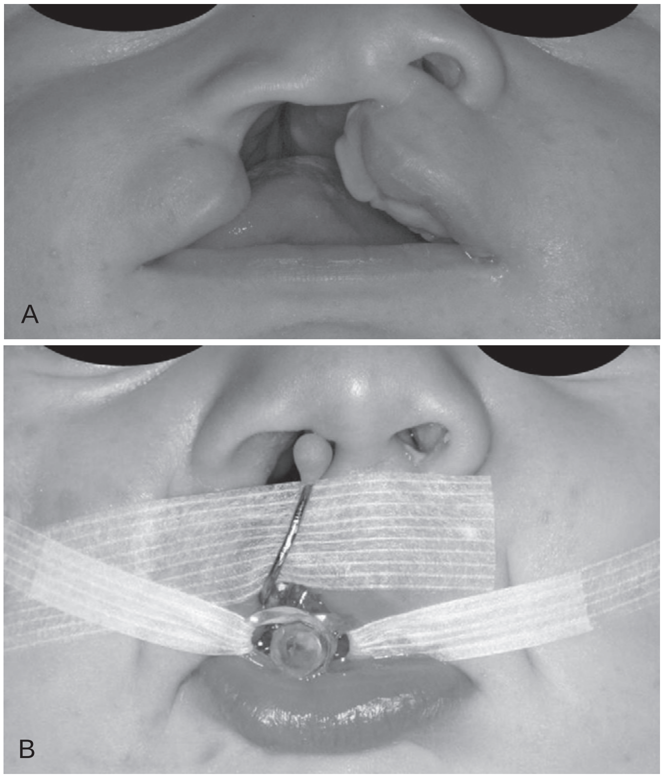

**FIGURE 54-5** **A,** A unilateral cleft lip prior to nasoalveolar molding (NAM) has a wide alveolar cleft, slumping of the nasal cartilage on the cleft side, and lateralization of the alar base of the cleft side. **B,** Nasoalveolar molding assists in realigning the alveolar segments, reshaping the slumping nasal cartilage of the cleft side, and medializing the alar base of the cleft side.

improve the symmetry of the nose. The simplest form is a taping regimen (literally from cheek to cheek) that helps to pull the two sides of the clefts together, with the goal of narrowing the cleft and realigning the tissues in an anterior-posterior dimension. Some centers also use a technique termed nasoalveolar molding (NAM) to address the three major components of the cleft deformity (Fig. 54-5). NAM addresses the slumping of the nasal alar cartilage, helps realign the alveolar ridges, and brings the soft tissue of the lips into closer proximity.[15,16]

## CLEFT LIP SURGICAL REPAIR

### Unilateral

There are multiple surgical techniques for cleft lip repair. A recent survey of U.S. cleft surgeons found three predominant surgical techniques for unilateral cleft lip repair: the Millard rotation-advancement technique (46%), the Millard rotation-advancement technique with modifications (38%), and triangular flap techniques (9%).[17] Techniques for bilateral cleft lip repair include variations of techniques introduced by Millard and by Mulliken.[18]

In a unilateral cleft lip, there is absence of central tissue of the lip and philtrum, as well as of the nasal columella, depending on the severity of the cleft. The overall goals of surgery are restoration of lip continuity, which starts with functional orbicularis oris muscle reapproximation, establishing symmetry of the lip (especially at the central cupid's bow) and nose, with aesthetic placement of scars in anatomic subunits. The rotation-advancement repair, as described by Dr. Ralph Millard

**FIGURE 54-6** Markings for the rotation-advancement lip repair (Millard lip repair).

in 1976, addresses all of these goals (Fig. 54-6). Because there is a paucity of tissue medial to the cleft, the downward *rotation* of the remaining philtrum helps to provide adequate tissue that matches the contralateral, noncleft side. *Advancement* of the lateral tissue reconstructs the affected philtrum, thus providing lip continuity. Medialization of the base of the nose, as well as further soft tissue dissection of the nose, results in a symmetric reconstruction. Reapproximation of the orbicularis oris muscle provides oral competence. Further soft tissue arrangement in the nasal floor allows final closure of the lip and nose. Surgical details are found in several references.[19–21] A potential shortcoming of the rotation-advancement technique is the inability to provide adequate philtral length despite aggressive downward rotation of this tissue. This may result in the high point of the cupid's bow on the cleft side being located in a position higher than on the noncleft side.

Some of the more commonly used modifications of the rotation-advancement technique are the Mohler repair, the Noordoff vermilion flap, and the triangular advancement flap, although the details of these techniques are beyond the scope of this chapter (see the referenced articles for more complete descriptions).[22–24]

Another technique for unilateral cleft lip repair is the triangular flap technique (also known as the Tennison repair), introduced by Charles Tennison in 1952. Tennison approached the lack of central soft tissue of the cleft in a very different fashion than Millard. In this technique lip length is achieved by designing a triangular flap of the lateral, cleft side, which then inserts into a cut of the medial, noncleft side, thus providing the extra tissue for appropriate lip height. The muscle is repaired, as in the rotation-advancement technique, followed by reconstruction of the floor of the nose (full surgical details are found in the references).[25,26] Shortcomings of the Tennison repair include placement of the scar in a nonanatomic location, thus drawing attention to the repair, as well as an overly long lip, depending on the size of the triangular flaps.

### Bilateral Cleft Lip Repair

Bilateral cleft lip repairs are especially challenging because of a central lack of soft tissue, and the anterior displacement of the premaxilla, which functionally increases the transverse width of cleft defect. Many surgeons use presurgical orthopedics to decrease premaxillary protrusion, thus increasing the columellar length and nasal tip projection. This technique also decreases the distance of the cleft, potentially making surgical repair easier for the surgeon (Fig. 54-7). The primary goals of surgery include lip and nasal symmetry, which is achieved through the creation of a philtral column, including the cupid's bow, reapproximation of the orbicularis oris, repositioning the nasal alar cartilages, lengthening the columella, and closure of the nasal floor (Fig. 54-8). The absence of the philtral column and cupid's bow is especially problematic since these structures are difficult to replicate in a repair. Postoperatively, these imperfections can be quite noticeable at conversational distances.[27] Realistically, patients with bilateral cleft lips will ultimately require revisional surgeries to correct the secondary stigmata of the repair, which include a shortened columella, blunted nasal tip, widened nasal ala, and a widened philtrum.

FIGURE 54-7 Nasoalveolar mold (presurgical orthopedics) for bilateral cleft lip, designed to align the alveolar segments, as well as realign the premaxilla into a more anatomic position.

## CLEFT PALATE SURGICAL REPAIR

Following surgical repair of the lip, repair of the palate is generally performed between 9 to 12 months of age. The choice of techniques for palate repair depends on the type of cleft. Recent surveys show that the most commonly used techniques are the Bardach two-flap palatoplasty (45%) (Fig. 54-9) and the Furlow palatoplasty (42%) (Fig. 54-10); the Veau-Ward-Kilner (VWK) pushback (Fig. 54-11) and the von Langenbeck (Fig. 54-12) techniques, although less common, are also used.[28] The common denominators for all of these techniques are repair in three layers (nasal mucosa, muscle layer of the soft palate, and the oral mucosa), and anatomic repositioning of the soft palate musculature. Bilateral cleft palate repair is similar in principle in that a three-layer repair is achieved (Fig. 54-13). See the references for complete descriptions of these techniques.[29]

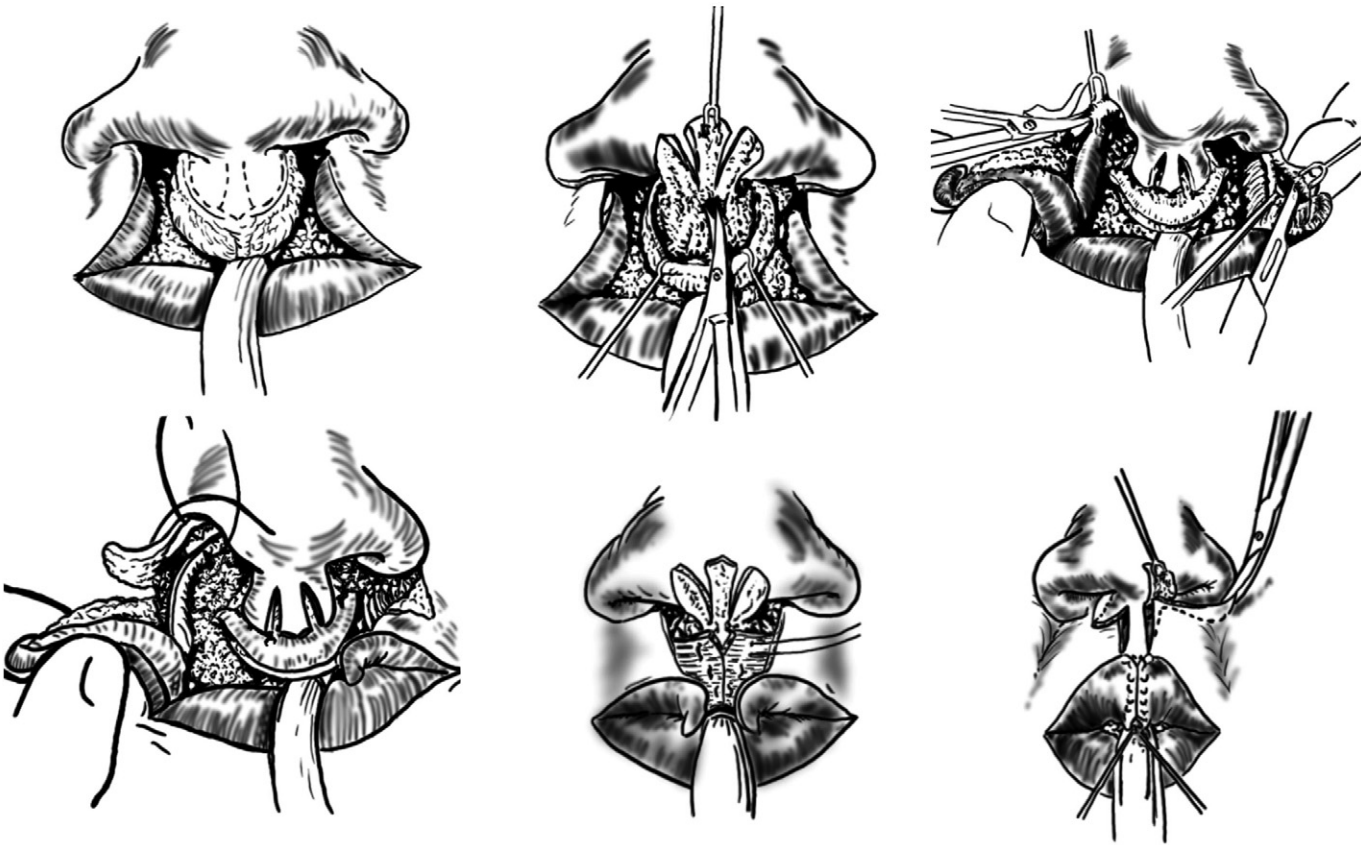

FIGURE 54-8 Schematic of the steps involved with a bilateral cleft lip repair. Re-creation of the columella, dissection of the muscle in the lateral lip elements, re-creation of the nasal floor, reapproximation of the lateral lip muscle, and insetting of the nasal alar bases with trimming of skin for final closure are all integral parts of bilateral cleft lip repair.

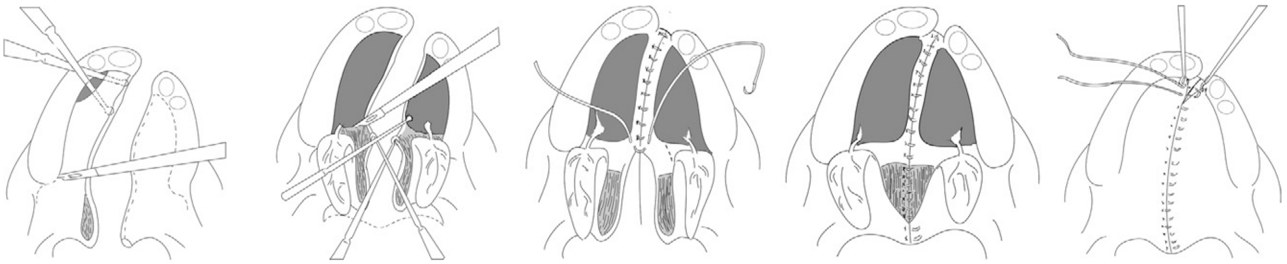

**FIGURE 54-9** The Bardach two-flap palatal reconstruction consists of elevating the palatal mucosa off the hard palate bone as a flap, elevation of the nasal mucosa, and closure of these two layers separately for the hard palate. Pedicles for the mucosal flaps come from the greater palatine arteries posteriorly. Closure of the soft palate is a three-layer repair, including a nasal mucosal layer, muscle layer (levator veli palatini and tensor veli palatini realignment), and oral mucosal layer.

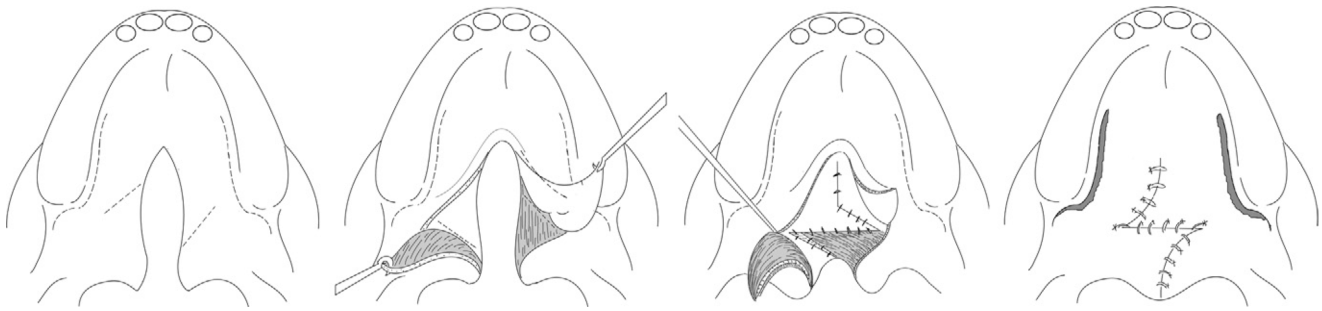

**FIGURE 54-10** The double opposing Z-plasty, (Furlow palatoplasty) of the soft palate includes realignment of the levator and tensor veli palatine muscles in the form of Z-plasty. One flap has oral mucosa only, whereas the contralateral side has oral mucosa and muscle. The nasal layer consists of a separate nasal mucosal layer, which is on the side with oral mucosa and muscle flap, and the contralateral side has nasal mucosa and muscle. Closure of both layers in a double opposing Z-plasty assists in elongating the soft palate, which should subsequently improve palatal speech function.

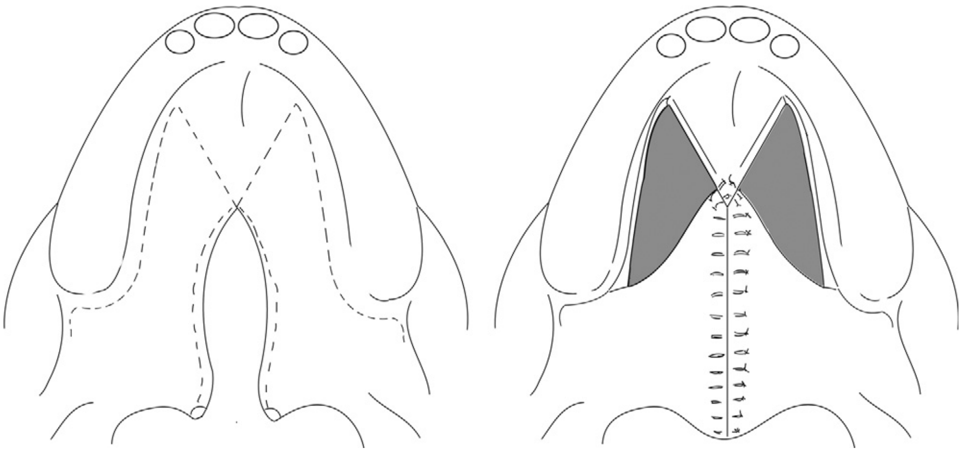

**FIGURE 54-11** The Veau-Ward-Kilner repair consists of advancing the oral mucosal flaps posteriorly to allow closure of the hard palate. Muscle realignment of the soft palate assists in palatal function.

Muscle repair is integral to the palate's primary function, namely speech. Any repair that does not address the muscle will fail in the development of normal speech.[30] As previously noted, the levator veli palatine and the tensor veli palatine are the two most integral muscles in producing a functional palate. Detaching these muscles from their abnormal insertions to the remnant shelves of the posterior hard palate, and then reapproximating them to each other in a transverse palatal sling, is referred to as an intravelar veloplasty. Failure to perform this step will result in a nonfunctional palate.

# Multidisciplinary Care

Patients with orofacial clefts require multidisciplinary care that is provided by plastic surgeons, otolaryngologists, dentists, orthodontists, oral surgeons, geneticists, audiologists, and speech and language pathologists. This team approach yields more comprehensive and coordinated care, which benefits the patient.[31–33] Longitudinal follow-up in a team environment is mandatory, because many issues, including the ability

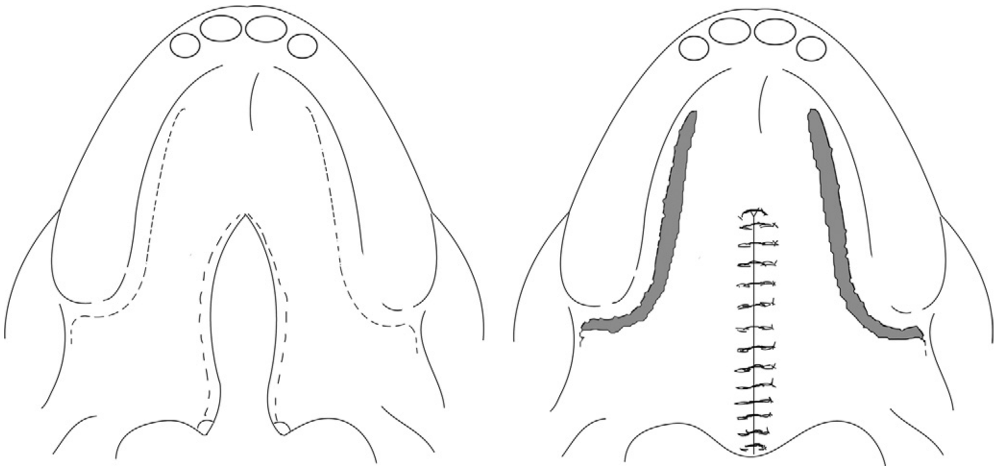

FIGURE 54-12 The von Langenbeck repair consists of relaxing incisions on the lateral palate with subsequent advancement to midline, allowing a palatal repair of both mucosa and muscle layers. Benefits include keeping a bipedicled flap; however, the advancement can be limited and inadequate with wider cleft defects.

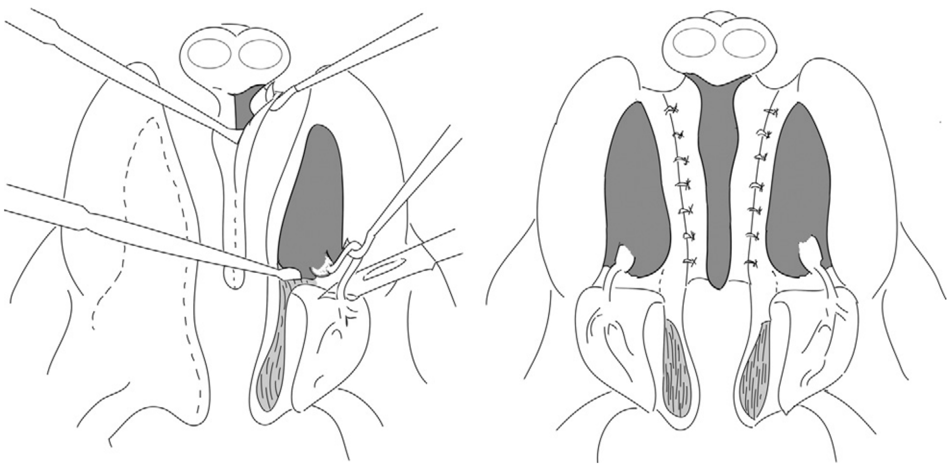

FIGURE 54-13 Closure of bilateral cleft palate follows in the same principles. Nasal mucosal layers are dissected off the vomer and palatine shelves and closed. Dissection of the hard palate oral mucosa allows closure separately, thus providing a two-layer closure. The soft palatal muscles are dissected and realigned to provide palatal function.

to produce normal speech, and dental eruption, continue to evolve as the patient grows.

Care of the cleft patient begins prenatally when a screening ultrasound makes the initial diagnosis. Ideally, counseling with the family begins during the perinatal period, and focuses on potential feeding concerns postnatally, the time line for surgical repair of the clefts, and team-centered care. In the neonatal period, feeding is the primary concern, especially in children with clefts of the palate. Appropriate weight gain must be monitored, as well as the family's overall psychological comfort with the child's cleft. A genetic evaluation, looking for evidence of associated anomalies and syndromes, and further counseling within a cleft team, prepare the family for the ongoing care of their child.

## Secondary Cleft Management

Although patients with cleft lip and palate undergo initial repair of their clefts in the first 12 to 18 months of life, these patients will ultimately require further surgical interventions. Nasal and lip revision, if needed, can be pursued at 5 years of age, which coincides with greater self-awareness of physical differences, and exposure to an expanding group of peers in school.

Between the ages of 7 and 9 years, during the period of mixed dentition (when the adult lateral incisor is ready to erupt through the area of the alveolar cleft), a bone graft generally harvested from the hip, is required in the alveolar cleft. The new bone allows eruption of the lateral incisor, and completes the continuity of the maxilla. Both before and after the bone graft, additional dental and orthodontic work may be required to align the teeth in normal anatomic position.

At facial skeletal maturity, generally at 15 years of age for females and 17 to 19 years of age for males, orthognathic surgery, with surgical movement of the maxilla, mandible, or both, may be required to achieve normal occlusion, overall facial appearance and profile. During the teenage years, further revisions of the lip and nose may be required to give these patients the desired aesthetic outcome that prepares them for adult life.

Velopharyngeal insufficiency (VPI) is the condition in which the repaired cleft palate is physically incapable of isolating the nasopharynx from the oropharynx, resulting in

air escape through the nose during speech. The patient with VPI has a nasal quality to his or her speech. Usually the most affected sounds are plosives, /p/ and /b/, in words such a "papa" and "buggy." In a patient with VPI, the pressure is dissipated through the nose, making these sounds more nasal in quality: "mama" and "muggy." Depending on the severity of the condition, VPI can range from being barely audible to rendering speech unintelligible. VPI usually occurs in patients whose palates are short and scarred or who have an inadequately functioning soft palate muscle sling. The advent of VPI is usually noticed as children become more verbal, between 3 and 5 years of age. Another time period during which VPI may arise is during tonsillar and adenoid regression. As these tissues atrophy, the nasopharyngeal and oropharyngeal spaces enlarge; a marginally functional soft palate may no longer be able to seal the nasopharynx from the oropharynx, resulting in VPI. Because of these ongoing changes, vigilance for VPI must be maintained throughout a child's growth and development.

In patients suspected of VPI, evaluation by a speech therapist is vital in determining whether additional speech therapy or surgical intervention is required. Nasoendoscopy and video-fluoroscopy may be required to determine the degree of soft palate incompetence, which in turn helps to determine the optimal surgical technique to correct the child's VPI.

## Conclusions

Cleft lip and palate can be visually and functionally devastating to a child. Multispecialty and interdisciplinary team care is both ideal and necessary for the care of these children because of the complexity of the anomalies and the longitudinal nature of cleft care. Establishing rapport with patients and their families, as well as among team specialists, can lead to life-changing differences in patients with clefts, allowing them to lead normal, productive lives, as well as making the formidable problems of cleft care rewarding to treat.

CHAPTER 55

# Otolaryngologic Disorders

Lisa M. Elden, Ralph F. Wetmore,
and William P. Potsic

This chapter is divided according to anatomic structures: the ear, the nose, the oral cavity and pharynx, the larynx, and the neck. In each section we review anatomy, embryology, and examination, before discussing congenital and acquired disorders, including infections, trauma, and tumors.

## Ear

### ANATOMY

The ear is divided into three anatomic and functional areas: the external ear, the middle ear, and the inner ear. The external ear consists of the auricle, external auditory canal, and the lateral surface of the tympanic membrane. The auricle is a complex fibroelastic skeleton that is covered by skin and subcutaneous tissue that directs sound into the external ear canal.

The external auditory canal is oval with the long axis in the superior to inferior direction. In neonates, the external canal is almost entirely supported by soft, collapsible cartilage. As the temporal bone grows over several years, the bony portion of the canal enlarges to comprise the inner one third, leaving the outer two thirds supported by firm cartilage. Hair and cerumen glands are present in the outer two thirds of the external canal. The ear canal is lined by skin that is continuous with the lateral surface of the tympanic membrane, and it is innervated by cranial nerves V, VII, IX, and X and by the great auricular nerve.

The tympanic membrane separates the external ear canal from the middle ear. It has three layers: an outer layer of squamous epithelium (skin); a middle layer of fibrous tissue that is attached to the malleus, the most lateral middle ear ossicle; and an inner layer of mucosa that is continuous with the mucosa lining the middle ear. The fibrous layer is also attached to a thick fibrous annulus that anchors the tympanic membrane to the temporal bone.

The middle ear is an air-filled space within the temporal bone of the skull that is lined by ciliated, columnar respiratory epithelium. The middle ear communicates with the mastoid air cell system posteriorly and is lined by the same mucosa. It also communicates with the nasopharynx anteriorly through the eustachian tube. The mucociliary transport system of the middle ear moves mucus and debris into the nasopharynx, where it is swallowed. Secretory cells are not evenly distributed throughout the middle ear and mastoid complex and are more numerous anteriorly near the eustachian tube.

Three ossicles are present in the middle ear—the malleus, incus, and stapes—that transmit sound from the vibrating tympanic membrane to the stapes footplate. Stapes movement creates a fluid wave in the inner ear that travels to the round window membrane and is dissipated by reciprocal motion to the stapes.

There are two striated muscles in the middle ear. The tensor tympani muscle lies parallel to the eustachian tube, and its tendon attaches to the medial surface of the malleus. The stapedius muscle lies along the vertical portion of the facial nerve in the posterosuperior part of the middle ear. Its tendon attaches to the head of the stapes. These muscles stiffen the ossicular chain in the presence of sustained loud noise.

The facial nerve traverses the middle ear with its horizontal portion lying superior to the stapes. Posterior to the stapes, the facial nerve turns inferiorly in a vertical fashion to exit the stylomastoid foramen deep to the tip of the mastoid. The chorda tympani nerve is a branch of the facial nerve that innervates taste to the anterior two thirds of the tongue. It exits the facial nerve in the vertical segment and passes under the posterosuperior surface of the tympanic membrane, crossing the middle ear lateral to the long process of the incus and medial to the malleus. The facial nerve lies within a protective bony canal throughout its course in the middle ear. However, the bony canal may be absent (in the horizontal portion) in as many as 8% to 30% of patients.[1] Cranial nerve IX supplies sensation to the floor of the middle ear.

The inner ear consists of the cochlea, semicircular canals, and vestibule. The cochlea is a coiled fluid-filled tube consisting of 2½ to 2¾ turns surrounded by dense bone. It contains the membranes that support the organ of Corti and has hair cells that detect the fluid wave from vibration of the stapes footplate. The hair cells create the neural impulses that are transmitted from the auditory nerve (cranial nerve VIII) to the brain, providing the sensation of hearing.

The three paired semicircular canals (horizontal, superior, and inferior) are also fluid-filled tubes surrounded by dense bone. The semicircular canals each have a hair cell–containing structure (the ampulla) that detects motion. The utricle and saccule of the vestibule also have hair cell structures that detect acceleration.[2]

## EMBRYOLOGY

The external ear develops during the sixth week of gestation and is completely developed by the 20th week. Six hillocks fuse to form the basic units of the pinna. Defects in the fusion of the hillocks lead to preauricular tags and sinuses. The external auditory canal develops from the first branchial cleft. A solid epithelial plug forms during the beginning of the third month of gestation and canalizes in the seventh month to form the external auditory canal.

The middle ear space develops from the first pharyngeal pouch. The ossicles develop from the first and second pharyngeal arches. The inner ear arises from neuroectodermal tissue within the otic placode that forms the otic pit.[2]

Any combination of anomalies may occur. Abnormalities of the development of the ear may create anomalies of the pinna, external auditory canal, middle ear structures, and inner ear. One of the anomalies that involves the external and middle ear is aural atresia (absence of the external auditory canal). Absence of the external canal may occur with a deformed or normal external ear. The ossicles may be deformed and are usually fused to each other as well as the bony plate representing the undeveloped tympanic membrane. The facial nerve may also be altered in its course through the temporal bone. Reconstruction of the atretic canal, removal of the bony tympanic plate, release of the fused ossicles, and reconstruction of a new eardrum is a complex surgical procedure that may improve hearing. Rarely, there is incomplete development of the inner ear structures. The most common of these is dysplasia of the cochlea, and it may vary in severity. Dysplasia is associated with sensorineural hearing loss in most cases.[3,4]

## EXAMINATION

The examination of the ear should always start with inspection of the outer ear and surrounding structures. Deformities of the outer ear structure may suggest the presence of other anomalies, such as a first branchial cleft sinus. A first branchial cleft sinus usually presents below the ear lobe near the angle of the jaw. The sinus tract may connect to the ear canal or, rarely, the middle ear.

The external auditory canal and tympanic membrane are best examined with a handheld otoscope that has a bright fiberoptic light source and a pneumatic bulb attached to its head. The largest speculum that comfortably fits in the external canal should be used to maximize visualization and minimize pain. A very small speculum may be inserted deeply, but it might lacerate the ear canal as well as limit visibility of the tympanic membrane. The otoscope permits visualization of the ear canal and tympanic membrane. A translucent tympanic membrane will also permit visualization of the contents of the middle ear.

A healthy middle ear contains air and is ventilated via the eustachian tube that connects to the nasopharynx. Insufflation of air into the ear canal via the pneumatic bulb should cause the tympanic membrane to move if the middle ear is normal (aerated) and fail to move if it is filled with effusion (mucus or pus). Cerumen may be encountered in the ear canal that obstructs the view of the tympanic membrane or fails to allow insufflation to occur with pneumatic otoscopy. Removal of cerumen may be performed by using an operating otoscope head and an ear curette. However, the use of a headlight, such as the Lumiview (Welch Allyn, Skaneateles, NY) or operating microscope, permits the use of both hands and superior visualization. Care should be taken to secure the child to prevent sudden movement, and the ear curette should be used gently to avoid causing pain and a laceration of the ear canal. A mechanical test of tympanic compliance (tympanometry) may also be useful to help determine if the middle ear is normally aerated (type A, peaked tracing), fluid-filled (type B, flat tracing), or has negative pressure because it is poorly ventilated, suggesting eustachian tube dysfunction (type C, negative pressure tracing). Examination of a child with an apparent or suspected ear condition often requires objective assessment of hearing by audiometry. Current technology and expertise makes it possible to test a child at any age.

Behavioral audiometry can usually be accurately performed for a child who is older than 6 months of age by sound-field testing. Older children are presented with a tone through insert earphones and are tested across a range of frequencies between 250 and 8000 Hz for ear-specific testing. The hearing thresholds are recorded at each presented frequency, and this represents the air conduction threshold. The sound has to traverse the ear canal, tympanic membrane, and middle ear. The inner ear must respond by creating electrical impulses that are transmitted to the brain. Normal thresholds are less than 20 dB for children.

Bone conduction thresholds test the sensorineural component of hearing. A bone oscillator is used to test a range of frequencies by vibrating the skull, which stimulates the inner ear directly, bypassing the external and middle ear. Normally, air conduction thresholds require less energy than bone conduction thresholds. If bone conduction thresholds require less sound intensity to be heard than air conduction, the child has a conductive hearing loss. If air conduction and bone conduction thresholds are elevated but the same, the child has a sensorineural hearing loss. Most sensorineural hearing loss in children is a result of hair cell dysfunction in the organ of Corti. Hearing loss may be conductive, sensorineural, or mixed. Objective electrophysical tests, such as brainstem auditory-evoked response and sound emission tests that measure the intrinsic sounds from the inner ear (otoacoustic emissions), may be used in young infants and children who cannot participate in behavioral audiometry. All of these tools are used by pediatric audiologists.[5]

For purposes of describing hearing loss, a threshold of 20 to 40 dB is considered mild, 40 to 65 dB is moderate, 55 to 70 dB is moderately severe, 70 to 90 dB is severe, and greater than 90 dB is profound. Four of 1000 children are born with a hearing loss, and 1 of those children is born with a severe to profound hearing loss.

Conductive hearing loss may be corrected with otologic surgery. Hearing aids and frequency modulation (FM) amplification systems may be helpful to children with both conductive and sensorineural hearing loss. Assistance may be needed through auditory training, speech language therapy, and education to maximally develop communication skills. When a child has a sensorineural hearing loss that is too severe to be helped with hearing aids, a cochlear implant may be considered.

A cochlear implant is an electrical device that is implanted under the scalp behind the ear. Its processor converts sound to electrical impulses. A cable travels through the mastoid and facial recess to reach the middle ear, and the electrode array

is inserted into the scala tympani of the cochlea through an opening that is made in the cochlea.

Cochlear implants stimulate the neural elements of the cochlea directly and bypass the hair cells. Because the vast majority of sensorineural hearing loss in children is due to hair cell dysfunction, nearly all children get sound perception from a cochlear implant. Rare conditions, such as an absent auditory nerve or an absent cochlea, preclude the use of a cochlear implant.

A multidisciplinary evaluation by a cochlear implantation team is required to evaluate a child and determine family expectations before performing a cochlear implantation. A temporal bone computed tomographic (CT) scan and/or magnetic resonance imaging (MRI) is performed to assess the cochlea and auditory nerves.

Children who are born deaf and are younger than the age of 3 years, as well as children who have already developed communication skills, language, and speech before losing their hearing, derive the greatest benefit from cochlear implants. Cochlear implantation is approved for children 12 months of age or older by the U.S. Food and Drug Administration. Children with cochlear implants should be vaccinated against *Streptococcus pneumoniae,* according to high-risk schedules, and against *Haemophilus influenzae,* according to standard schedules, because the implant wire crosses from the middle ear into the cochlea, increasing the risk of meningitis if the child gets otitis media. After a cochlear implant is performed, considerable auditory oral training is required to maximize a child's benefit to develop skills of audition, speech, and language. A child who has been deaf and without sound perception for several years is expected to benefit to a lesser degree.[6]

## OTITIS MEDIA WITH EFFUSION AND INFLAMMATORY DISORDERS

Otitis media with effusion is the most common chronic condition of the ear during childhood. All children are born with small and horizontally oriented eustachian tubes that may at times be unable to clear mucus that is secreted in the mastoid and middle ear normally and when the child has an upper respiratory tract infection. The excess mucus usually clears within a few weeks as the upper respiratory tract infection resolves. Younger children (infants to 3 years of age) and children with craniofacial anomalies, such as cleft palate and Down syndrome, are more prone to having persistent middle ear effusions; there is no medication that is consistently effective in resolving such effusions.

Persistent effusion may cause a conductive hearing loss in the range of 20 to 40 dB. A middle ear effusion may also function as a culture medium and predispose children to recurrent acute otitis media (AOM).

When fluid persists in the middle ear for 3 to 4 months, causing a hearing loss or is associated with AOM, myringotomy and tympanostomy tube placement is helpful to resolve the hearing loss and reduce the frequency and severity of infection.

Myringotomy and placement of a tube is performed under general anesthesia using an operating microscope. A small incision is made in any quadrant of the tympanic membrane except the posterosuperior quadrant, where there would be risk of injuring the ossicles. The mucus is suctioned from the ear, and a Silastic tube is placed in the myringotomy to provide prolonged ventilation of the middle ear. The tube will usually extrude and the tympanostomy will heal in 6 months to 1 year. When the ear is no longer ventilated by a tube, the eustachian tube must ventilate the middle ear. If fluid recurs and persists, a repeat procedure may be needed. Most children outgrow this problem as their eustachian tube grows. Occasionally, adenoid tissue in the nasopharynx may contribute to the persistence of middle ear effusion and may also be removed at the time that a tube is placed. Children who have had multiple sets of tubes are candidates for adenoidectomy.

## ACUTE OTITIS MEDIA

Acute otitis media is the most common infection of childhood except for acute upper respiratory tract infections. It is the most common bacterial infection for which children seek medical care from their primary care physician. Usual pathogens causing AOM include *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis.*[7]

AOM usually causes severe deep ear pain, fever, and a conductive hearing loss in the affected ear. The purulence in the middle ear is also present in the mastoid air cells because they are connected.

To prevent the overuse of antibiotics, the American Academy of Pediatrics (AAP) and the American Academy of Family Practitioners (AAFP) developed guidelines in 2004 to improve accuracy of diagnosis of AOM.[8] Three components should be present to diagnose AOM, including history of acute onset of symptoms within 48 hours of presentation, presence of middle ear effusion confirmed by pneumatic otoscopy or tympanometry, and signs of middle ear inflammation. The tympanic membrane typically is reddened and bulging, with obliteration of normal landmarks.[8]

Once an accurate diagnosis is made, the AAP/AAFP guidelines offer options for treatment in otherwise healthy children. They advocate that a period of observation (48 to 72 hours) is justified because AOM spontaneously resolves in many children (80% of episodes of AOM resolve within 2 to 7 days of symptom onset). Very young children (less than 6 months old) and those with Down syndrome, immune disorders, craniofacial anomalies, or chronic medical conditions should not be considered candidates for observation, because they are at higher risk of developing complications such as mastoiditis or meningitis.

Table 55-1 describes specific recommendations for treatment in otherwise healthy children aged 6 months to 12 years,

**TABLE 55-1**
**AAFP/AAP Guidelines for Treatment of Acute Otitis Media in Children Younger Than 12 Years**

| *Child Age* | *Certain Diagnosis* | *Uncertain Diagnosis* |
|---|---|---|
| Younger than 6 months | Antibiotics | Antibiotics |
| 6 months to 2 years | Antibiotics | Antibiotic if severe illness*; observe if nonsevere illness† |
| $>$ 2 years to 12 years | Antibiotic if severe illness*; observe if nonsevere illness† | Observe |

*Severe illness: fever $> 39°$ C and/or moderate to severe otalgia.
†Nonsevere illness: fever $< 39°$ C and/or mild otalgia.
AAFP, American Academy of Family Practitioners; AAP, American Academy of Pediatrics.

based on age, certainty of diagnosis, and severity of symptoms. All affected children should be given pain control, and children who are treated with observation should be followed up in 48 to 72 hours and treated if they continue to manifest symptoms.

Recommended first-line antibiotic therapy is higher-dose amoxicillin (80 mg per kilogram per day in two divided doses for 5 to 10 days). Higher dose therapy can effectively cover even intermediate and some highly resistant strains of *S. pneumoniae*. Infections caused by this organism are most likely to cause more serious complications and are least likely to spontaneously resolve. Azithromycin, erythromycin, or clarithromycin can be used as alternatives in patients with type 1 allergy (anaphylaxis or hives to amoxicillin). Second-line antibiotics should be considered in patients who fail to improve after several days of first-line antibiotics and includes higher-strength amoxicillin-clavulanate (90 mg per kilogram per day in two divided doses for 10 days) or oral cefdinir, cefuroxime, cefpodoxime, clindamycin, and, less commonly, intravenous or intramuscular ceftriaxone.

Occasionally, AOM does not respond as expected to standard antibiotic therapy. When this occurs, culture and sensitivity testing can be obtained by tympanocentesis. After sterilizing the ear canal with alcohol, a 22-gauge spinal needle can be placed through the posterior or anterior inferior quadrant of the tympanic membrane and fluid can be aspirated with a small syringe.

Complications of AOM are uncommon if appropriate antibiotic therapy is used. The conductive hearing loss resolves as the middle ear effusion clears. However, infection may necrose the tympanic membrane, causing a spontaneous perforation. Small perforations usually heal in less than 7 days, but larger perforations may persist, cause a conductive hearing loss, and require a tympanoplasty for closure. The ossicular chain may also be disrupted by necrosis of the long process of the incus requiring ossicular reconstruction to restore hearing.

Acute coalescent mastoiditis occurs when infection erodes the bony mastoid cortex and destroys bony septae within the mastoid. A subperiosteal abscess may also develop over the mastoid process. There is usually postauricular erythema and edema over the mastoid area. The auricle is displaced laterally and forward (Fig. 55-1). Otoscopy reveals forward displacement of the posterior superior skin of the ear canal.

In addition to antibiotics, treatment should include a wide-field myringotomy from the anterior inferior quadrant to the posterior inferior quadrant, a tympanostomy tube placement for middle ear drainage, and a postauricular mastoidectomy to drain the subperiosteal abscess and the mastoid.

Facial nerve paralysis may occur from inflammation of that portion of the facial nerve that is exposed in the middle ear during AOM. Treatment with parenteral antibiotics and ototopical antibiotic drops applied in the ear canal through a tympanostomy tube almost always results in complete recovery of facial function. A short course of oral steroids may also be helpful. Facial nerve recovery may take a few weeks to several months.

Intracranial complications of AOM include meningitis, epidural abscess, brain abscess, otitic hydrocephalus, and lateral sinus thrombosis. Meningitis is the most common intracranial complication of AOM and may be associated with profound sensorineural hearing loss and loss of vestibular function. Treatment of the intracranial complications of AOM is focused on appropriate treatment of the intracranial process, in addition to a wide-field myringotomy and tympanostomy tube placement in the affected ear.[9]

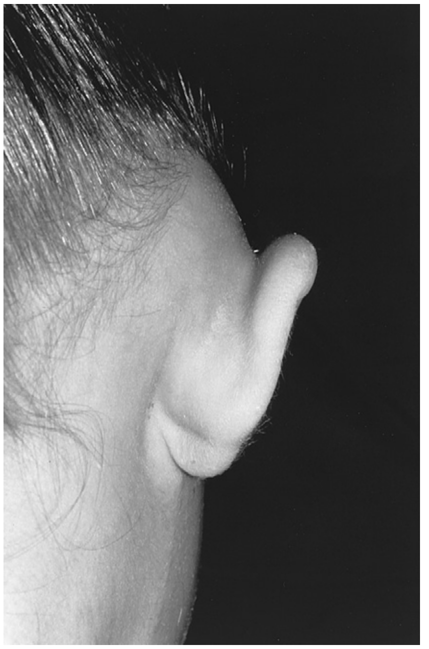

**FIGURE 55-1** Acute mastoiditis. Extension of the acute inflammatory process from the middle ear and mastoid air cell systems to the overlying soft tissues displaces the auricle in an inferior and lateral direction from the side of the head. Fluctuance may be palpated over the mastoid cortex, and a defect in the cortical bone can frequently be appreciated. Surgical drainage with mastoidectomy is required.

## OTITIS MEDIA WITH EFFUSION/CHRONIC OTITIS MEDIA/CHRONIC SUPPURATIVE OTITIS MEDIA

Otitis media with effusion is a descriptive term that refers to persistent middle ear effusion that usually is serous or mucoid in nature. Chronic otitis media is a term used to describe the effusion if it lasts longer than 3 months. Otitis media with effusion may occur following an ear infection, but can occur spontaneously, especially when the nose has been congested. It may be associated with hearing loss and the child may or may not be symptomatic with pain, irritability, or poor balance. Most effusions resolve spontaneously within weeks, and most children affected are younger than 5 years of age.

In otherwise healthy children, hearing tests or hearing screens should be performed once the effusion has been present for more than 3 months, and sooner if significant hearing loss is suspected or if the child is at high risk for developing significant speech and language delays. The associated hearing loss usually falls in the mild range (30 dB), but even in normal children, may contribute to the development of speech and language delays. Speech and language tests should be considered if hearing loss is documented. Children should be evaluated for surgical treatment with bilateral myringotomy and tube placement if they have ongoing pain or irritability attributable to the effusion, structural changes to the tympanic membrane (such as thinning or deep retractions), documented speech and language delays, or those who are at high risk for complications if observed (Down syndrome, those with

existing speech delay, autism, or neurocognitive delays). Adenoidectomy would be considered as well if the adenoids are found to be enlarged, especially if the child has symptoms of heavy snoring, sleep apnea, or chronic nasal congestion.[10]

Chronic suppurative otitis media occurs when otorrhea (drainage of pus or mucous) persists for more than 3 months, either through a perforation of the tympanic membrane or through a tube in the tympanic membrane. A cholesteatoma of the middle ear may also be present in patients who have perforated tympanic membranes. A cholesteatoma is a squamous epithelial-lined cyst that may be congenital or acquired. Congenital cholesteatomas are caused by epithelial rests that persist in the middle ear during temporal bone development. They present behind an intact tympanic membrane and appear as a white, smooth mass, most often located in the anterior superior quadrant of the middle ear. They expand over time and are filled with squamous debris and may erode the ossicular chain and extend into the mastoid.

Acquired cholesteatomas develop from skin entering the middle ear after a tympanic membrane perforation or a retraction pocket from eustachian tube dysfunction and are usually located in the posterior-superior quadrant of the middle ear space. Cholesteatomas are usually painless, cause a conductive hearing loss, and, in acquired cases, often present as otorrhea. The otorrhea should be treated with ototopical antibiotic eardrops, but the only treatment of cholesteatomas is complete surgical excision by tympanomastoid surgery and ossicular reconstruction.[11] The potential complications of cholesteatomas are the same as those for acute suppurative otitis media (ASOM).

## TRAUMA

Objects stuck deeply into the ear canal, such as a cotton-tipped applicator, may perforate the tympanic membrane. This usually causes acute pain, bleeding, and a conductive hearing loss. If the ossicular chain is not disrupted, the vast majority of these perforations will heal spontaneously in about 2 weeks. If the tympanic membrane is perforated and the middle ear is contaminated with water, topical antibiotics should be given.

Lacerations of the auricle should be cleaned to prevent tattooing and repaired by careful approximation of the skin and soft tissue to restore the contours of the ear. The cartilage itself does not usually need to be sutured. Partially or totally avulsed tissue should be replaced. If necrosis of tissue occurs, it can be debrided as needed. In severe injuries of the auricle, oral antibiotic treatment to cover *S. aureus* and *Pseudomonas* species is helpful to prevent chondritis and loss of the cartilage framework.

Blunt trauma to the ear is commonly seen in wrestlers, in children with poor neuromuscular tone, or in children with self-injurious behaviors. Blood or serum collects between the periosteum and the auricular cartilage. If the cartilage is fractured, the collection may occur on both sides of the ear. Evacuation of the collection is required to restore the contours of the ear, prevent infection, and prevent scarring with formation of a "cauliflower ear." Aspiration of the fluid and placement of a mastoid dressing for compression may be tried but is most often unsuccessful. Incision and drainage provides for complete evacuation of the blood or serum. Cotton dental rolls placed on each side of the auricle and held in place with bolster mattress sutures is the most effective management. The dental rolls should be left in place for 7 to 10 days while the patient also continues with a course of oral antibiotics. No outer dressing is required except in a child with cognitive impairment, who may pick at the bolsters.[11]

Blunt head trauma may disrupt the inner ear membranes causing sensorineural hearing loss and vertigo. No treatment is required, and the injury and symptoms may resolve spontaneously, but the sensorineural hearing loss may persist. Severe head trauma may cause fracture of the temporal bone of the skull. Temporal bone fractures can be classified as longitudinal, transverse, or mixed (Fig. 55-2) but are often

FIGURE 55-2 **A,** Longitudinal temporal bone fracture. These fractures run parallel to the petrous pyramid. The otic capsule is generally not affected by the fracture lines. Balance, hearing, and facial function are generally preserved. **B,** Transverse temporal bone fracture. These fractures generally extend through the cochlea and facial canal and result in deafness, vertigo, and facial nerve paralysis of immediate onset. Facial nerve exploration with repair should always be considered in these cases.

complex and do not neatly fit into one category or another. A high-resolution, thin-section CT scan of the temporal bone will define the extent of the fracture. The middle ear and mastoid are filled with blood when a fracture is present. The blood causes a conductive hearing loss that resolves when the ear clears.

Otoscopic evaluation of a child with a temporal bone fracture may reveal a laceration of the ear canal and tympanic membrane. Blood is usually present in the ear canal, and the tympanic membrane appears to be dark blue because the middle ear is filled with blood. There is often ecchymosis of the mastoid area (Battle's sign).

It is important during evaluation of a skull and temporal bone fracture to note and record the function of the facial nerve if the patient is not unconscious. Facial nerve paralysis may be immediate or delayed in onset. Delayed facial nerve paralysis has a good prognosis for spontaneous recovery. Immediate complete facial paralysis may indicate disruption of the nerve or compression by bone fragments. Immediate facial nerve paralysis requires exploration and repair once the patient is stable and sufficiently recovered from any associated trauma. The facial nerve should be decompressed in the mastoid, middle ear, and middle cranial fossa. Bone chips impinging on the nerve should be removed, and the nerve should be sutured or grafted if needed. All patients with temporal bone fractures should have an audiogram once their condition has stabilized. If the fracture disarticulates the ossicles, a conductive hearing loss will persist after the blood has cleared from the middle ear and mastoid.

Fractures of the temporal bone may transverse the cochlea and vestibular apparatus. These fractures usually cause a severe sensorineural hearing loss and loss of vestibular function on the affected side. Most children compensate for vestibular injuries within weeks, but sensorineural hearing loss is less likely to improve. A concussive injury of the cochlea may also simultaneously be present in the opposite ear in severe head trauma.

Temporal bone fractures may permit leakage of cerebrospinal fluid (CSF) into the middle ear and mastoid. CSF may also drain through the lacerated tympanic membrane, causing CSF otorrhea. These leaks usually stop spontaneously, but persistent CSF otorrhea may require a lumbar drain to reduce the pressure and permit healing. Rarely, tympanomastoid exploration is required to close the leak. Persistent CSF leaks in the ear are associated with meningitis.

### TUMORS

Benign and malignant tumors of the ear are rare. Glomus tympanicum tumors and neuromas of the facial nerve may present in the middle ear. Also, eosinophilic granuloma and rhabdomyosarcoma may involve the structures of the temporal bone.[12,13]

## Nose

### ANATOMY

The nose can be divided into three anatomic sections. The bony vault is the immobile portion of the nose. It consists of the paired nasal bones, the frontal process of the maxillary bone, and the nasal process of the frontal bone. The cartilaginous vault is supported by the upper lateral cartilages and the cartilaginous nasal septum. The nasal lobule is supported by the lower lateral cartilages and the cartilaginous septum. The nasal septum is formed by the quadrilateral cartilage anteriorly. The posterior septum is composed of bone from the vomer, perpendicular plate of the ethmoid, nasal crest of the maxillary bone, and palatine bone.

Both the internal and external carotid artery systems supply blood to the nose. The roof and lateral wall of the internal nasal cavity are supplied by the anterior and posterior ethmoidal arteries, sphenopalatine artery, and greater palatine artery. The septum is supplied by the anterior and posterior ethmoidal arteries, palatine artery, and the superior labial artery. The convergence of these vessels in the anterior segment of the nose is referred to as the Kiesselbach plexus or the Little area. Venous drainage is accomplished mainly by the ophthalmic, anterior facial, and sphenopalatine veins.

The olfactory bulb is positioned high in the roof of the nasal cavity and is responsible for the sense of smell. Sensory information is transported by nerves that penetrate the cribriform plate and traverse cranial nerve I (the olfactory nerve) to the brain. Smell is also an important component of what is perceived as taste.

Bony projections, called turbinates, form the lateral nasal wall and significantly increase the surface area of the nose, allowing for more efficient humidification and warming of the air to 36° C. Three turbinates are usually present (i.e., inferior, middle, and superior). A supreme turbinate, which is essentially a flap of mucosa, is occasionally present. The turbinates contribute to the turbulent airflow that creates approximately 50% of the total airflow resistance to the lungs.

Cleaning of air is accomplished through the nasal hairs (vibrissae) and the mucosal surface. Anteriorly, the nose is lined with stratified squamous epithelium, which changes to respiratory epithelium immediately anterior to the turbinates. Trapped debris is transported in a posterior direction into the nasopharynx by a mucociliary transport mechanism.

Speech is affected by nasal anatomy and pathologic conditions. Hyponasality from nasal obstruction or hypernasality from an excessive air leak can affect voice quality and intelligibility of speech.

### EMBRYOLOGY

The nose serves as a drainage port for the paranasal sinuses. The meati are spaces between the lateral aspect of the nasal turbinates and the medial aspects of the lateral nasal wall. Each meatus is named for the turbinate that surrounds it. The maxillary, frontal, and anterior ethmoidal sinuses drain into the middle meatus. The posterior ethmoidal sinuses drain into the superior meatus. The sphenoidal sinus drains into an area known as the sphenoethmoidal recess that is located posterior and superior to the superior turbinate. The nasolacrimal duct drains into the inferior meatus.

The nasal cavities develop from the nasal pits in the 4-week embryo. These pits deepen and move medially to form the nasal cavity. The oronasal membrane that separates the nose from the mouth resolves in the seventh week to permit communication between the nose and nasopharynx.

The paranasal sinuses develop from an outpouching of the lateral nasal walls during the third and fourth months of

development. The maxillary and ethmoidal sinuses are present at birth. The frontal and sphenoidal sinuses develop several years after birth. The frontal sinus begins to develop at 7 years of age but is not fully aerated until adulthood.[14]

## INFLAMMATORY CONDITIONS

Viral rhinosinusitis (the common cold) accounts for the majority of nose and sinus infections. It is caused by many strains of viruses and is a self-limited infection. Symptoms of fever, nasal congestion, headache, and clear rhinorrhea usually resolve over 5 to 7 days. Treatment is symptomatic.

## BACTERIAL RHINOSINUSITIS

Acute bacterial rhinosinusitis may often follow an acute viral upper respiratory tract infection. The most common bacteria causing rhinosinusitis are *Streptococcus pneumoniae, Haemophilus influenzae,* and *Moraxella catarrhalis*. Acute rhinosinusitis causes malaise, headache, and nasal congestion. There may also be pain localized to the sinus region or pain on palpation over the maxillary or frontal sinuses. Chronic sinus infection may persist after the acute phase, and symptoms often last longer than 30 days.

The gold standard for diagnosing sinusitis is CT of the sinuses, but a thorough history and nasal examination is usually sufficient to diagnose acute rhinosinusitis. The nasal cavity can be visualized by using a large speculum on an otoscopic head. The posterior nasal cavity can be visualized with either a straight-rod endoscope or a flexible fiberoptic nasopharyngoscope.

The treatment of rhinosinusitis includes oral antibiotics, short-term use of topical nasal decongestants (e.g., oxymetazoline), and saline nasal sprays. Topical nasal corticosteroid sprays may be helpful for the treatment of both acute and chronic sinusitis.

Chronic sinusitis in a child may be exacerbated by gastroesophageal reflux disease, immunodeficiencies, mucociliary dysfunction, and, more commonly, upper respiratory allergy. These predisposing conditions should be managed while treating the sinus infection. If the signs and symptoms of chronic sinus infection persist, a sinus CT is required to evaluate the condition of the sinus mucosa and the drainage pathways. Endoscopic sinus surgery may be necessary to open the involved sinuses to provide drainage.

Chronic inflammation of the nasal and sinus mucosa may lead to nasal and sinus polyp formation that chronically obstructs the nose and sinuses. Antrochoanal polyps are large polyps that originate from the walls of the maxillary sinus and extend through the nasal cavity into the nasopharynx. Nasal polyps may be removed endoscopically, but a large antrochoanal polyp may require removal through an open maxillary sinus procedure. Nasal polyps in a child should always prompt an evaluation for cystic fibrosis.

## COMPLICATIONS OF SINUSITIS

The sinuses surround the orbit so a common complication of acute rhinosinusitis in children is orbital cellulitis with erythema and edema of the eyelids. Chemosis (edema of the ocular conjunctiva) is usually absent. However, if a periorbital subperiosteal abscess forms adjacent to an infected sinus, there may be proptosis, chemosis, ophthalmoplegia, and loss of vision. Infection in the ethmoidal sinuses most commonly results in this complication. Subperiosteal periorbital abscess is demonstrated best by sinus CT (with axial and coronal cuts). Initial treatment should include intravenous antibiotics. Endoscopic or external drainage may be required in some cases.

Intracranial complications of sinusitis include cerebritis, meningitis, cavernous sinus thrombosis, as well as epidural, subdural, and brain abscesses. Treatment of impending or confirmed intracranial complications requires surgical drainage of the involved sinus and concurrent treatment of the intracranial lesion by a neurosurgeon.[15]

## FUNGAL SINUSITIS

Fungal sinusitis may occur in immunocompromised children, specifically severe diabetics, children undergoing chemotherapy, and bone marrow transplant recipients. The more common invasive fungi include *Mucor* and *Aspergillus* species. The treatment of fungal sinusitis involves surgical drainage and intravenous antifungal agents.

However, a chronic form of fungal sinusitis is allergic fungal sinusitis. The presence of fungi causes inflammatory cells to proliferate in the sinuses, causing symptoms of nasal plugging and facial pain, along with discharge or polyps. These patients usually have other signs of allergy, such as asthma. The treatment of this condition is corticosteroids and debridement of the involved sinuses. The diagnosis is made by sinus CT findings and the presence of eosinophils as well as fungi in the sinus secretions that are removed at the time of surgery.[16]

## CONGENITAL MALFORMATIONS

### Pyriform Aperture Stenosis

Congenital stenosis of the anterior bony aperture causes partial nasal obstruction that may be severe enough to cause difficulty feeding, respiratory distress, and failure to thrive. Anterior rhinoscopy demonstrates a very constricted nasal opening bilaterally. CT of the nose shows marked narrowing of the pyriform aperture.

Neonates are obligate nasal breathers, and severe stenosis must be surgically corrected. Because the stenotic segment is very anterior and the remainder of the nasal cavity is normal, removal of the constricting bone with drills is done through a sublabial approach. The nasal openings are stented with 3.0-mm endotracheal tube stents that are sutured in place and removed after a few days.

### Choanal Atresia

Choanal atresia may be unilateral or bilateral. The obstructing tissue is usually a bony plate, but a few cases will have only membranous atresia. Unilateral choanal atresia presents as chronic unilateral rhinorrhea. There is no significant respiratory distress. Because neonates are obligate nose breathers, bilateral choanal atresia is associated with severe respiratory distress, difficulty feeding, and failure to thrive. The diagnosis is suspected if catheters cannot be passed through the nose and into the pharynx. The obstruction may be visualized with a narrow flexible nasopharyngoscope after the nasal cavity has

FIGURE 55-3 Choanal atresia. This disorder frequently presents at birth with respiratory distress.

FIGURE 55-4 Nasal dermoid presenting in the midline as a pit.

been suctioned of mucus and the nasal mucosa has been constricted with a nasal decongestant (e.g., oxymetazoline). The diagnosis is best made with CT of the nasal cavity. CT will demonstrate the atresia, define the tissue (bony or membranous), and show the configuration of the entire nasal cavity.

Choanal atresia may be successfully treated by removing the obstructing tissue transnasally. Curettes, lasers, microdebriders, bone punches, and drills may all be effective to remove the atresia plate. However, when the bony plate is very thick and there is an extremely narrow posterior nasal cavity, a transpalatal repair is more direct. A transpalatal repair provides better access for more effective removal of the bony plate and posterior septum (Fig. 55-3). Stents fashioned from endotracheal tubes are placed and secured with sutures to the septum. They are removed after several weeks. The stents must be moistened with saline and suctioned several times daily to prevent mucus plugging and acute respiratory distress. Transpalatal repair of choanal atresia has a lower incidence of restenosis.[11]

## Nasal Dermoid

Nasal dermoid cysts or sinuses present in the midline of the nasal dorsum (Fig. 55-4). They usually appear as a round bump or a pit with hair present in the pit (Fig. 55-5). They also may become infected. Nasal dermoid sinuses may extend through the nasal bones into the nasofrontal area and have an intracranial component. Both CT and MRI may be necessary to demonstrate the extent of the dermoid. Surgical removal is required to prevent infection and recurrence. This may be done between ages 3 and 5 years if prior infection has not occurred. Dermoids confined to the nose are resected completely using a midline incision with an ellipse around the sinus tract. The tract is followed to its termination, and the nasal bones may need to be separated to reach the end of the tract.[11] If an intracranial component is present, a combined craniotomy and nasal approach with a neurosurgeon is recommended.

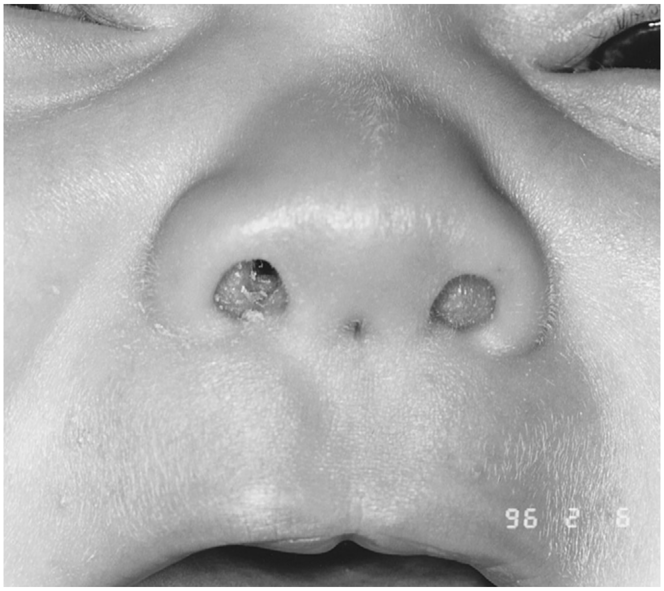

FIGURE 55-5 Nasal dermoid. These lesions typically present on the nasal dorsum as a single midline pit, often with a hair extruding from the depths of the pit. The pits may also be found on the columella. The dermoid will then tract through the septum toward the cranial base.

### Nasal Glioma and Encephalocele

A nasal glioma presents as an intranasal mass and may be confused with a nasal polyp. The mass contains dysplastic brain tissue and may have an intracranial connection. CT and MRI are important to define the extent of the glioma and intracranial component as well as to plan the surgical approach.

An encephalocele presents as a soft compressible mass and may also be confused with a nasal polyp or a nasal dermoid. Intranasal encephaloceles extend through a defect in the skull at the cribriform plate. CT and MRI define the extent of the encephalocele and are necessary to design the surgical approach. Surgical removal often includes a frontal craniotomy. Nasal encephaloceles may be associated with CSF rhinorrhea and meningitis.

## TRAUMA

### Anosmia

Head trauma can lead to temporary or permanent anosmia (lack of sense of smell). In one large study of head trauma patients ($n = 190$), 11% reported loss of sense of smell that persisted after their initial recovery and later was confirmed by smell tests. Those at higher risk had trauma that led to intracranial hematoma and/or hemorrhages or injury near the skull base.[17]

### Nasal Fracture

An infant may be born with the soft nasal bones and the septum deviated to one side either as a result of a difficult delivery or from persistent intrauterine compression of the nose. The nasal structures can most often be returned to the midline with digital manipulation. If the nasal deformity is partially reduced, the nose usually straightens with growth during the first 12 to 18 months of age.

Nasal bone and nasal septal fractures in older children usually occur from a blow to the face during sports. There is usually a brief period of epistaxis and deviation of the nasal dorsum to one side. Swelling occurs rapidly, and the degree of the cosmetic deformity or the need for fracture reduction may not be easily determined. At the fourth to sixth day after injury, the edema subsides and the need for reduction can be determined. Nasal bone radiographs are of little help in making this judgment; so, the need for nasal fracture reduction is usually based solely on clinical examination. Effective closed nasal fracture reduction may be done up to 2 weeks after the injury. Closed reduction under general anesthesia is the method of choice. Oral antibiotics prevent infection and are essential if nasal packing is used to support the nasal bone.

Although nasal fracture reduction is not urgent, a septal hematoma from a fractured septum should be excluded by the initial physician seeing the child. A septal hematoma that remains untreated may cause cartilage necrosis and loss of nasal support, with a resulting saddle-nose deformity. Treatment of a septal hematoma is with incision and evacuation of the clot. The mucoperichondrial flap should then be sutured in place by bolster sutures through the septum. A small rubber band drain may be required and, if used, should remain in place for 12 to 24 hours, and antibiotics be given for 10 to 14 days to prevent secondary infection while a drain is in place.

Epistaxis in children usually occurs in Little's area of the anterior septum and frequently results from digital trauma (nose picking). The bleeding usually stops with pressure by squeezing the nasal ala. Infrequently, cauterization of the vessels under general anesthesia is needed to reduce the frequency of bleeding. In cases that fail to stop with pressure, the nose should be packed with absorbable materials (such as Gelfoam or cellulose) or nonabsorbable gauze. Finally, in severe cases, embolization or emergent surgery has been used to control bleeding from the internal maxillary and anterior ethmoid arteries, which are the primary sources of nose bleeds. Hematology consultation should be considered in severe or recurrent cases to evaluate for coagulopathies.

### Nasal Foreign Bodies

Children may be observed inserting a foreign body into their nose, or they may inform their parents of the event. Most children, however, present with a foul-smelling unilateral purulent nasal discharge and deny putting anything into their nose.

Most nasal foreign bodies are painless and do no harm to the nose but cause a foul nasal discharge. Disc batteries, on the other hand, cause very rapid alkali burns of the nasal cavity and pain. Batteries must be removed from the nose quickly because the chemical burn occurs in minutes to hours. If extensive tissue necrosis occurs, it may cause a nasal stenosis or septal perforation.

Removal of a nasal foreign body is aided by decongesting the nasal mucosa and using a headlamp to visualize the foreign body. A variety of forceps or hooks may be used. If the object is deep in the nose, the removal is best performed under general anesthesia. The endotracheal tube prevents aspiration of the object into the tracheobronchial tree if it is pushed back into the nasopharynx. One must remember that multiple foreign bodies may be present on one or both sides of the nose.

### Nasal Lacerations

Nasal lacerations should be closed with care to match edges and restore the contours of the nose. Standard wound closure technique is used. The nasal mucosa does not need to be sutured unless a large flap is displaced.

## NASAL/NASOPHARYNGEAL TUMORS

Rhabdomyosarcoma, lymphoma, squamous cell carcinoma, and esthesioneuroblastoma may occur in the nose and sinuses of children. Fortunately, these malignant tumors are very rare in children. The treatment of children with malignant tumors of the nose and sinuses usually involves a multidisciplinary, multimodal approach.

Juvenile nasopharyngeal angiofibroma is a benign tumor of adolescent males that originates from the lateral wall of the nose and nasopharynx. The tumor may completely obstruct the nose and fill the nasopharynx. This type of angiofibroma may also extend intracranially through the base of the skull. Patients with these tumors present with nasal obstruction, recurrent epistaxis, and rhinorrhea.

The tumor may be seen with a flexible fiberoptic nasopharyngoscope or a rod lens telescope after decongesting the nasal mucosa. It appears as a smooth reddish mass. Biopsy of the mass should be avoided because of the potential for severe bleeding. CT and MRI define the extent and location of the tumor. On imaging, the mass originates in the pterygopalatine

fossa within the aperture of the pterygoid (vidian) canal. It causes anterior bowing of the posterior wall of the maxillary sinus and erosion of the greater wing of the sphenoid as it grows into the nose and nasopharynx. MR angiography helps to delineate the blood supply, which may originate from both the internal and external carotid arteries. Contrast angiography may be reserved for presurgical planning and embolization of the copious blood supply that is often present.

The treatment of juvenile nasopharyngeal angiofibroma is complete surgical resection after preoperative embolization. Depending on the material used, the embolization may be effective for days to weeks. A variety of surgical approaches may be used, including endoscopic resection of small tumors using instruments to reduce blood loss, such as suction cautery or coblation tools. Extensive tumors may require a combined midfacial and craniotomy approach.[18]

Some authors have proposed radiation therapy as the primary treatment of juvenile nasopharyngeal angiofibroma, but many surgeons are concerned about the long-term effects of radiation in children, including the induction of malignant tumors.

Nasopharyngeal carcinoma can occur in adolescents and is more common in those of Asian or African descent. It arises from the epithelium of the nasopharynx and histologically is composed of lymphoepithelial cells of variable stages of differentiation. Epstein-Barr viral infection has been implicated as a possible cause in some cases, but genetic factors appear to make some individuals more susceptible to developing this tumor. Most children present with advanced disease and tend to have undifferentiated subtypes. They usually have a history of unilateral nasal plugging and otalgia or hearing loss caused by a blocked eustachian tube. They may also present with metastasis in the posterior triangle lymph nodes. Treatment consists of radiotherapy and, in some cases, adjuvant chemotherapy.

# Oral Cavity/Pharynx

## ANATOMY

The boundaries of the oral cavity include the lips anteriorly, the cheeks laterally, and the palate superiorly. The posterior boundary is a plane that extends from the soft palate to the junction of the anterior two thirds and posterior one third of the tongue. The oral cavity is composed of the vestibule, the space between the lips and cheeks and alveolar ridges, and the oral cavity proper. The vestibule and oral cavity proper are separated by the alveolar ridge and teeth. The vestibule is divided in the midline by the frenula of the upper and lower lips. The alveolar ridge is contiguous superiorly with the hard palate. The parotid ducts (Stensen ducts) enter the vestibule opposite the second maxillary molars. The submandibular ducts (Wharton ducts) enter the floor of mouth near the lingual frenulum.

The palate is formed by a fusion of the primary palate anteriorly and medial growth of the palatal processes that form the secondary palate. The hard palate divides the nasal and oral cavities and is formed by the premaxilla and the horizontal plates of the palatine bones. The soft palate is formed by a muscular aponeurosis of the tensor veli palatini tendon. Five muscles insert into this aponeurosis and include the tensor veli palatini, levator veli palatini, palatoglossus, palatopharyngeus, and the musculus uvulae. Defects in formation of the hard and/or soft palate result in clefting. The sensory and motor innervation of the palate is through the trigeminal nerve and pharyngeal plexus.

The circumvallate papillae divide the tongue into the anterior two thirds that lies in the oral cavity and the posterior one third lying in the oropharynx. The innervation and vascular supply to the two major divisions of the tongue reflect their differences in origin—the anterior two thirds of the tongue being a first branchial arch derivative (trigeminal), whereas the posterior one third being a combination of third and fourth arch derivatives (pharyngeal plexus). The hypoglossal nerve supplies motor innervation to the intrinsic musculature. In addition to the intrinsic tongue musculature, the action of four extrinsic muscles combine to provide mobility. The genioglossus protrudes and depresses, the hyoglossus retracts and depresses, the styloglossus retracts, and the palatoglossus elevates. In addition to the circumvallate papillae, other taste buds on the tongue surface include conical, filiform, fungiform, and foliate papillae.

The pharynx is a fibromuscular tube that extends from the skull base to the level of the cricoid cartilage of the larynx and can be divided into three levels. The nasopharynx extends from the skull base to the level of the soft palate, the oropharynx extends from the soft palate to the tongue base, and the hypopharynx extends from the tongue base to the cricoid cartilage. Three muscular constrictors combine to form the muscular portion of the pharynx: superior, middle, and inferior constrictors. The Passavant ridge is a muscular segment of the superior constrictor that is involved in velopharyngeal closure. Lower fibers of the inferior constrictor help to form the upper esophageal sphincter. The motor and sensory innervation of the pharynx is from the glossopharyngeal and vagus nerves via the pharyngeal plexus.

A collection of lymphoid tissue within the pharynx forms the Waldeyer's ring, which includes the palatine tonsils, the adenoids (pharyngeal tonsil), and lymphoid follicles lining the lateral and posterior pharyngeal walls.

## ACUTE PHARYNGOTONSILLITIS

In addition to the acute onset of sore throat, viral pharyngitis typically presents with fever and malaise. Signs include erythema of the pharynx and cervical lymphadenopathy. Depending on the viral agent, associated symptoms of nasal obstruction and rhinorrhea may also be present. Rhinovirus, coronavirus, parainfluenza virus, respiratory syncytial virus, adenovirus, and influenza virus are agents responsible for viral pharyngitis.

Primary herpetic gingivostomatitis, caused by herpes simplex virus types 1 or 2, presents as fever, adenopathy, and vesicles and ulcers on the lips, tongue, buccal mucosa, soft palate, and pharyngeal mucosa. Herpangina and Coxsackie virus (hand-foot-and-mouth disease) are viral infections that involve the oropharynx. Epstein-Barr virus (EBV) infection (infectious mononucleosis) presents as acute pharyngotonsillitis (often with white sloughing debris on the tonsils), fever, generalized adenopathy, malaise, and splenomegaly. Although EBV infection is suspected by the appearance of 10% or more atypical lymphocytes on a complete blood cell count and the presence of a positive Monospot test, the definitive diagnosis is confirmed by elevated titers of EBV. A short course of

corticosteroids has been proven to reduce the lymphoid hypertrophy that can cause acute airway obstruction.

Group A beta-hemolytic streptococci (GABHS, i.e., *S. pyogenes*) commonly infect the pharynx. In addition to sore throat, associated symptoms include fever, headache, and abdominal pain. Associated signs include pharyngeal erythema, halitosis, tonsillar exudates, and tender lymphadenopathy. Lack of cough helps differentiate it from other upper respiratory tract infections. Diagnosis may be confirmed initially with a rapid streptococcal antigen test. Because rapid antigen testing is more sensitive than formal plating on blood agar, a negative test does not need confirmation, but positive rapid streptococcal tests should be confirmed with formal plating. Other bacterial pathogens that cause acute pharyngitis include *Haemophilus influenzae* and groups C and G beta-hemolytic streptococci. Occasionally, concurrent infection with penicillin-resistant *Staphylococcus aureus* may interfere with treatment of a GABHS infection.[19] Although many cases of GABHS infections respond to treatment with penicillin V or amoxicillin, emerging resistance to oropharyngeal pathogens mandates treatment of recalcitrant cases with an antibiotic having known effectiveness against beta-lactamase–producing organisms. In cases in which a lack of compliance is suspected, intramuscular benzathine penicillin or ceftriaxone may be used.

Acute pharyngitis may also be associated with acute bacterial infections of the nose, nasopharynx, and sinuses. These infections may be caused by a variety of viral and bacterial pathogens; in addition to a sore throat, symptoms include fever, mucopurulent nasal drainage, nasal obstruction, and facial pain.

## RECURRENT PHARYNGOTONSILLITIS

Recurrent infection of the pharynx may be either viral or bacterial. GABHS are the most worrisome bacterial organisms, because recurrent infection may lead to complications such as scarlet fever, acute rheumatic fever, septic arthritis, and acute glomerulonephritis. In addition to a history of multiple positive cultures for *S. pyogenes*, elevated antistreptolysin-O (ASO) titers may identify patients with chronic infection who are at risk for developing complications. Some asymptomatic children may be chronic carriers of GABHS, and elevated ASO titers may not be a reliable indicator for distinguishing between an active infection and the carrier state.

Treatment of recurrent streptococcal infection or the child who is a carrier should include a trial course of an antibiotic shown to reduce carriage (e.g., clindamycin, vancomycin, or rifampin). Children with recurrent pharyngotonsillitis unresponsive to medical therapy or those who suffer a complication should be considered for surgical management. Whereas treatment of each child should be individualized, suggested guidelines for surgical candidates include seven infections in 1 year, five or more infections per year for 2 years, or three or more infections per year for 3 years.[20] Other factors to be considered in using a surgical option include severity of infection, response to antibiotic therapy, loss of time from school, and need for hospitalization.

## CHRONIC PHARYNGOTONSILLITIS

The pharynx and, specifically, the tonsils may be the target of chronic infection. Affected children complain of chronic throat pain, halitosis, and production of white particles or tonsilliths. Signs include erythema of the tonsils, cryptic debris, and chronically enlarged cervical lymphadenopathy. A variety of viral and bacterial agents can be blamed for chronic infection of the pharynx. Cultures may or may not be positive in these patients because surface cultures may be negative while core tissue is positive. Antibiotic therapy directed at oral anaerobes or *S. aureus* may be helpful in resistant cases. Children with infections unresponsive to medical management are candidates for tonsillectomy.

Periodic fever, aphthous ulcers, pharyngitis, and cervical adenitis (PFAPA) is a syndrome that occurs most commonly in young children (mean age 39 months). The cause is unknown. It is characterized by recurrences of fevers that usually last 3 to 7 days, along with aphthous stomatitis, pharyngitis, cervical adenitis, and headache. The recurrences occur in cycles of every 1 to 2 months, and the child is well between episodes. Throat cultures are negative. Antibiotics are not effective in treating this condition, but steroids (prednisone 1 mg per kilogram in a single dose) have been shown to reduce the duration of fever in individual episodes (from 4 days to 1 day in one study); however, sometimes steroids may also reduce the duration of intervals between infections. Most children have spontaneous resolution of these fevers over several years (mean time to resolution is 32 months). Tonsillectomy has been shown to be effective in significantly reducing the duration of this syndrome and frequency of episodes.[21,22]

## ORAL TRAUMA

Injuries to the oropharynx and palate are relatively common in children, usually occurring when a child runs with a toy or stick in his mouth. Most result in mucosal lacerations that spontaneously heal, but larger lacerations may require sedation or anesthesia to repair. Use of prophylactic antibiotics is reserved for larger wounds. Although rare, blunt (and less often penetrating) injuries can occur when the object strikes the jugular vein or the carotid artery that can result in immediate neurovascular injury and poor neurologic outcomes. However, more subtle injuries to the intima of the carotid can lead to pseudoaneurysms that may later develop emboli. These emboli can cause brain infarcts with severe neurologic sequelae over the following several days. Ideally, if a vascular injury has been identified, then aspirin, or, less often, anticoagulant therapy could be used to prevent these emboli from forming. Unfortunately, no specific clinical factors (including size or location of wound) have been shown to correlate with the presence of a subtle vascular injury. Computed tomography angiography (CTA) has been used to rule out a significant vascular injury, but benefit from CTA remains controversial, because only 2.8% of studies are positive.[23]

## PERITONSILLAR CELLULITIS/ABSCESS

Localized extension of tonsillar infection may result in peritonsillar cellulitis. The same pathogens that cause acute pharyngotonsillitis are responsible for peritonsillar cellulitis. In addition to a severe sore throat, symptoms and signs include drooling, trismus, muffled voice, ipsilateral referred otalgia, and tender lymphadenopathy. The affected tonsil is usually displaced in a medial and inferior position. Peritonsillar cellulitis may progress to frank abscess formation (quinsy).

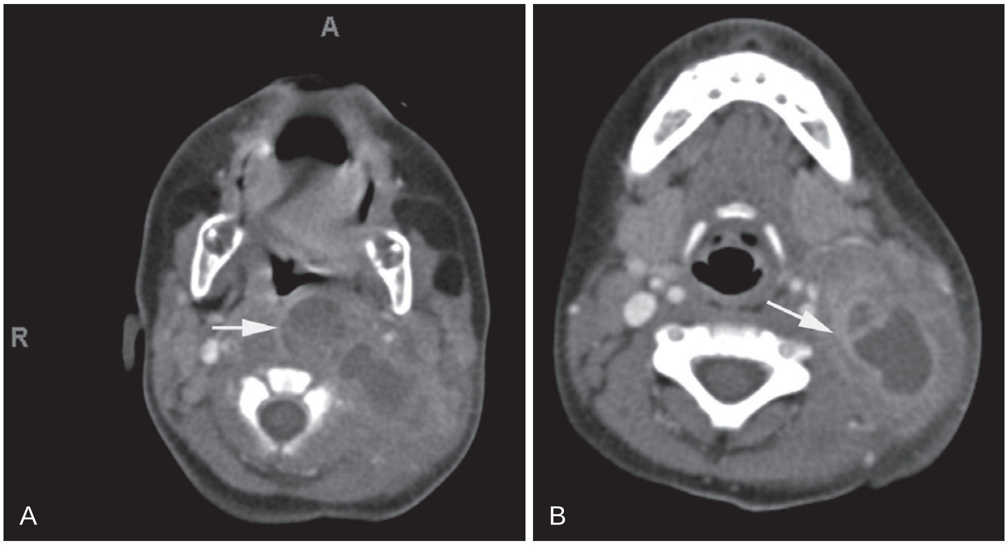

**FIGURE 55-6** **A,** Retropharyngeal abscess. Computed tomography of the cervical area demonstrates fluid loculated in the retropharyngeal space. The abscess is typically unilateral and frequently extends into the medial aspect of the peripharyngeal space. In the absence of associated complications, drainage can be done intraorally (*arrow*). **B,** Lateral neck abscess on the left side (*arrow*).

Early cases of peritonsillar cellulitis may respond to oral antibiotics, such as the penicillins, cephalosporins, erythromycins, or clindamycin. Unresponsive cases of cellulitis or abscess should be treated with intravenous antibiotics. In children with suspected abscess formation, a variety of surgical drainage procedures can be performed. Needle aspiration or incision and drainage have been shown to be equally effective.[24] In persistent cases or in those children who will require general anesthesia for drainage, consideration should be given to performing a tonsillectomy (quinsy tonsillectomy).

## RETROPHARYNGEAL/PARAPHARYNGEAL SPACE INFECTIONS

Signs and symptoms of deep neck space (retropharyngeal/parapharyngeal) infections that involve the pharynx typically are as fever, drooling, irritability, decreased oral intake, torticollis, and/or trismus. Often there is a history of a preceding viral illness. Stridor or symptoms of upper airway obstruction may be seen in half of patients.[25] A neck mass or enlarged cervical nodes may be present, depending on the location of the infection. Usual pathogens include coagulase-positive staphylococci and GABHS. Anaerobic bacteria have been found in as many as 50% of cases.[25] Complications of deep neck space infections include airway obstruction, bacteremia, rupture of the abscess into the pharynx with aspiration, mediastinal extension of infection, jugular thrombosis, and carotid artery rupture.

In suspected cases, the diagnosis of a retropharyngeal/parapharyngeal space infection is confirmed with either contrast medium–enhanced CT or MRI. Widening of the retropharynx on a lateral neck radiograph suggests a retropharyngeal infection. Although ultrasonography can detect the presence of an abscess cavity, CT or MRI are most helpful in demonstrating the extent of infection and the location of surrounding structures of importance, specifically the great vessels. Contrast medium–enhanced CT is particularly useful in distinguishing a phlegmon (cellulitis) from cases of frank suppuration. Demonstration of a hypodense region with surrounding rim enhancement has been shown to correlate with an abscess in 92% of cases (Fig. 55-6).

The initial management of a deep neck infection should begin with intravenous antibiotics, including clindamycin, cefazolin, beta-lactamase penicillins, or a combination thereof. Sixty-seven percent of children with these infections (including those presenting with cellulitis or early abscess) require eventual drainage. Surgical drainage should be reserved for those children who present with airway symptoms along with obvious abscess and for those who fail to show clinical improvement or progress to frank abscess formation on CT after 48 to 72 hours of intravenous (IV) antibiotics. The usual approach to surgical drainage is intraoral, if the abscess points medial to the great vessels, or extraoral, if the infection points lateral to the great vessels.

Complications of deep neck infections should be treated aggressively. Mediastinal spread requires prompt surgical drainage in most cases. An infected jugular thrombosis (Lemierre syndrome) can be a source of metastatic spread of infection as septic emboli. Signs and symptoms include spiking chills and fever (picket-fence fevers) and a neck mass despite appropriate antibiotic therapy. Anticoagulation or excision of the infected thrombus may be required to eradicate the infection.

## SLEEP-DISORDERED BREATHING

In the past decade, the impact of sleep-disordered breathing (SDB) on the health of children has been well described, beginning with the report of normative sleep data by Marcus and colleagues.[26] Children appear to have briefer but more frequent episodes of partial (hypopnea) and complete (apnea) obstruction. Because an apnea of less than 10 seconds may represent several missed breaths in a child, an apnea of any duration is abnormal. In most cases the site of obstruction during sleep is in the pharynx. In contrast to adults with this disorder, in whom the pharyngeal impingement is due to

adipose tissue surrounding the pharyngeal musculature, the major cause of airway obstruction in children results from adenotonsillar hypertrophy.

The apnea index (AI) represents the number of apneas in an hour, with a normal value being less than 1 in children. Because most children have an increased frequency of partial obstructions compared with adults, a measure of hypopneas may be more significant. A hypopnea is variably described as a reduction in airflow or respiratory effort or oxygen desaturation or combination thereof. The apnea/hypopnea index (AHI) is a measure of both apneas and hypopneas in an hour and may be a better reflection of SDB in children. An AHI greater than 5 is abnormal in adults, whereas, an AHI greater than 1.0 to 1.5 is abnormal in children. The upper airway resistance syndrome represents obstructed breathing with normal respiratory indices but with sleep fragmentation and electroencephalographic arousals that indicate disordered sleep.

The major group at risk for SDB includes children with adenotonsillar hypertrophy secondary to lymphoid hyperplasia (Figs. 55-7 and 55-8). Whereas the age of affected children ranges from 2 years through adolescence, the prevalence mirrors the age of greatest lymphoid hyperplasia, 2 to 6 years, the age the tonsils and adenoids are largest in size. Other at-risk groups include syndromic children with Down syndrome who also have relative macroglossia and tend to have larger tonsils and adenoids, children with craniofacial disorders, and patients with cleft palate or storage diseases (Hunter and Hurler syndromes). Adverse effects of obstructive sleep apnea on children include poor school performance, failure to thrive, facial and dental maldevelopment, and, rarely, severe cardiac impairment, including systemic hypertension, cardiac arrhythmias, and cor pulmonale with heart failure.

Daytime symptoms include noisy mouth-breathing, nasal obstruction and congestion, hyponasal speech, and dyspnea on exertion. In contrast to adults, hypersomnolence is uncommon in children because of the lower incidence of gas exchange abnormalities, specifically hypercarbia. Children may complain of headaches, seem irritable, and perform poorly in school. Nighttime symptoms are more obvious and include snoring, gasping, and choking respirations, apnea, coughing, and a variety of other behaviors, including sleepwalking, sleeptalking, rocking, head banging, and bruxism. Enuresis may appear in children with airway obstruction and then resolve after surgical treatment. In addition to enlarged tonsils, signs include the presence of a posterior pharyngeal flap in cleft palate patients, a craniofacial disorder, adenoid facies, and, rarely, evidence of right-sided heart failure.

FIGURE 55-8 Adenoid hypertrophy. Hypertrophy of the adenoids may cause the nasopharynx to be obstructed with tissue. Smaller amounts of tissue are also able to obstruct nasal respiration by growing into the posterior choana as shown in this photograph.

FIGURE 55-7 Tonsillar hypertrophy. Tonsillar hypertrophy is rated on a scale of 1 to 4. Grade 1+ tonsils are hypertrophic, grade 2+ tonsils extend slightly beyond the tonsillar pillars, grade 3+ tonsils extend in a medial direction beyond the anterior tonsillar pillars, and grade 4+ tonsils touch in the midline.

The diagnosis of SDB is suggested by history and physical examination. Confirmation of obstruction and apnea may be made with overnight pulse oximetry and video or audio monitoring of sleep. The gold standard in the diagnosis of obstructive sleep apnea remains formal polysomnography, including measures of nasal and oral airflow, transcutaneous oxygen and carbon dioxide, chest wall movements, electrocardiography, extraocular muscle movements, electroencephalography, leg movements, and gastric pH monitoring in selected cases. Depending on the suspected site of obstruction, adjuvant studies, such as a lateral neck radiograph, MRI of the head and neck, and flexible upper airway endoscopy, might be helpful.

The nonsurgical management of SDB consists of weight loss in obese patients and treatment of underlying allergies and gastroesophageal reflux. Nasal and dental appliances to maintain airway patency that may be useful in adults are usually poorly tolerated in children. Nasal continuous positive airway pressure, the mainstay of treatment in adults, is tolerated in many children and should be considered as a treatment option, especially in patients in whom other therapies have been exhausted or proven ineffective.

The initial surgical treatment for most children with SDB remains a tonsillectomy and adenoidectomy, a therapy that is usually curative. In patients with documented sleep apnea or a sleep disorder, both procedures should be used even if the tonsils appear small. Tonsillectomy and adenoidectomy techniques that have been standard for decades have been supplanted in some institutions by new technology, including use of coblation, harmonic scalpel, and the microdebrider. Efficacy of these newer techniques versus established methods remains unproven.

Complications after tonsillectomy and adenoidectomy usually consist of respiratory compromise and acute or delayed bleeding. Since the advent of modern pediatric anesthesia, respiratory complications, such as aspiration with resultant pneumonia and lung abscess, are rare. Humidification, intraoperative corticosteroids, and antibiotics have all been shown to improve the postoperative course after tonsil and adenoid surgery. Young children are most vulnerable to complications, and, in most institutions, children younger than 3 to 4 years of age are observed overnight for signs of dehydration and respiratory compromise.

Adjuvant surgery in the management of SDB includes craniofacial repair or posterior flap revision surgery in appropriate patients. Midface, mandibular, and hyoid advancement have proved useful in selected patients, along with nasal surgery such as septoplasty, partial inferior turbinectomy, or nasal polypectomy. Tracheostomy remains the treatment of last resort in patients who fail to respond to other forms of therapy.

## ANKYLOGLOSSIA

Ankyloglossia or tongue-tie is a common congenital disorder involving the lingual frenulum (Fig. 55-9). Neonates with diminished tongue mobility resulting from a foreshortened frenulum may have problems in sucking and feeding. Because the frenulum is thin and relatively avascular in neonates and young infants, it can often be incised as an office procedure. In older children the greatest effect of ankyloglossia is on speech and it can lead to dental caries because it may be difficult to clean the lower teeth. Because the tip of the tongue curls under on protrusion and has limited lateral and superior movement, speech articulation may be affected. Surgical treatment in these patients may require a short general anesthetic because the frenulum is thicker and more vascular, requiring surgical correction that includes simple division either with or without a Z-plasty repair.

## MACROGLOSSIA

Macroglossia is uncommon. Generalized macroglossia, as seen in association with Beckwith-Wiedemann syndrome, with glycogen storage diseases (Hunter and Hurler syndromes) or hypothyroidism, is rare. Relative macroglossia can be seen normally on occasion but is most common in Down syndrome. The most serious complication of this condition is airway obstruction. In infants, macroglossia should be distinguished from focal enlargement of the tongue seen in patients with a lymphatic malformation or hemangioma. Glossoptosis, posterior displacement of a normal-sized tongue, is seen in association with cleft palate and micrognathia in infants afflicted with the Pierre Robin sequence. The airway symptoms in most of these infants usually improve over the first year or two of life; so, supportive care is most often recommended (including oral airways and upright positioning with feeding). Infants with severe airway obstruction secondary to an enlarged or displaced tongue may require tongue reduction or a temporary tongue-to-lower lip adhesion suture, respectively. Tracheostomy is reserved for the worst cases. Macroglossia in older children that affects cosmesis, interferes with speech, or causes drooling may be treated with a variety of other tongue reduction techniques.

## BENIGN LESIONS

Epulis is a congenital granular cell tumor that typically presents as a soft, pink submucosal mass on the anterior alveolar ridge of the maxilla (Fig. 55-10). Females are more

**FIGURE 55-9** Ankyloglossia. Abnormal development of the lingual frenulum that limits extension of the tongue tip beyond the mandibular incisors frequently causes articulation disorders and should be corrected.

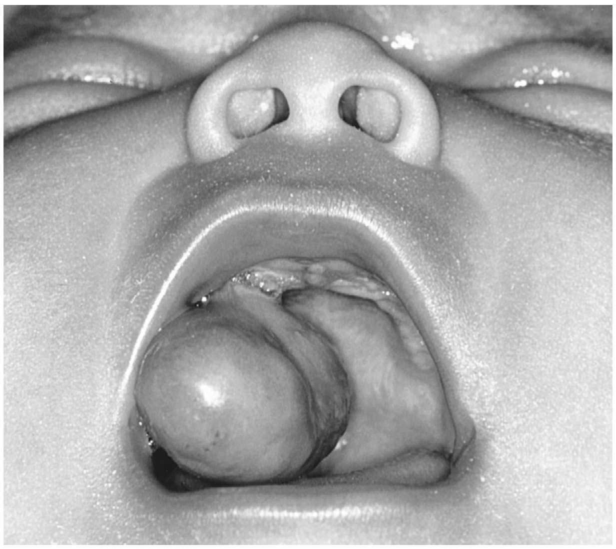

**FIGURE 55-10** Congenital epulis. The congenital epulis is an unusual benign lesion that frequently arises from the anterior maxillary alveolar ridge. Airway and feeding difficulties may develop secondary to large lesions. Surgical excision is required.

**FIGURE 55-11** A ranula is a pseudocyst caused by obstruction of a sublingual gland. It generally presents as a unilateral, painless swelling in the floor of the mouth.

commonly affected, and symptoms are usually confined to feeding problems. Surgical excision is curative.

Ranula is a pseudocyst located in the floor of the mouth that may occur congenitally or result from intraoral trauma (Fig. 55-11). Large ranulas may extend through the mylohyoid musculature and present in the neck as a "plunging ranula." Treatment of ranulas is by excision or marsupialization of the pseudocyst, often in conjunction with excision of the sublingual gland. Mucoceles are also pseudocysts of minor salivary gland origin and frequently rupture spontaneously. Recurrent or symptomatic mucoceles respond to surgical excision.

Hemangioma is a proliferative endothelial lesion found commonly in the head and neck. Their growth characteristics include enlargement during the first year of life, followed by spontaneous resolution. Surgical excision or treatment with corticosteroids may be necessary in lesions that cause ulceration and bleeding, airway obstruction, cardiovascular compromise, or platelet-trapping coagulopathy (Kasabach-Merritt syndrome). Longer-term systemic treatment with propranolol has recently been found to effectively reduce the size of symptomatic hemangiomas and may work by promoting vasoconstriction and downregulation of certain growth factors.[27] Vascular malformations, including venous, arterial, or arteriovenous malformations, rarely occur in the oral cavity and pharynx and necessitate intervention only if they cause pain, bleeding, ulceration, or heart failure. Management of complicated cases is by surgical excision or sclerotherapy for low-flow lesions (venous) and angiographic embolization for high-flow lesions. Lymphatic malformation, formerly known as lymphangioma or cystic hygroma, is congenital and usually presents before 2 years of age. Histologically, lymphatic malformations consist of multiple dilated lymphatic channels or may contain either capillary or venous elements (venolymphatic malformations). Lymphatic malformations have been characterized as microcystic, macrocystic, or mixed based on their histologic patterns. Lymphatic malformations can occur anywhere in the neck and may cause extensive cosmetic deformity and functional problems in cases with involvement of the tongue, floor of mouth, mandible, or larynx. Deep and macrocystic disease may be controlled with aspiration and sclerotherapy performed by interventional radiologists, whereas treatment of microcystic or more superficial disease usually is surgical. Surgical resection of lymphatic malformations may be fraught with difficulty because they lack a capsule and are infiltrative. During surgical excision, care should be taken to avoid damaging nearby vital structures, and debulking is an acceptable option to total radical excision in many cases. Postoperative suction drains can be helpful in preventing the recurrence of lymphatic drainage under skin flaps. Coblation therapy and carbon dioxide laser therapy have been used in superficial lymphatic malformations of the tongue.

Foregut cysts are true cysts, lined with respiratory epithelium, that present in the floor of mouth and should be distinguished from dermoid cysts, lined with stratified squamous epithelium and skin appendages, which may also be found in this location. A thyroglossal duct cyst may rarely present in the base of the tongue. Likewise, aberrant thyroid tissue, lingual thyroid, presents as a purple mass in the tongue base. Thyroid tissue in this location is usually hypofunctioning, and affected children require thyroid supplementation. Other aberrant rests of tissue, choristomas, consist of gastric, enteric, or neural tissue of normal histology in an abnormal location.

Second branchial cleft derivatives will rarely present as a cystic mass near the superior pole of the tonsil. Their extent and associated tracts can be demonstrated on MRI. A Tornwaldt cyst is a blind pouch in the nasopharynx that represents a persistence of an embryonic connection between the primitive notochord and the pharynx. Other benign nasopharyngeal masses include nasopharyngeal teratomas, dermoid lesions (hairy polyp), and nasopharyngeal encephaloceles. Most of these lesions are best evaluated by CT and/or MRI to determine their extent and the presence of an intracranial connection. Surgical excision is curative in most cases.

Squamous papillomas are benign slow-growing lesions typically found on the soft palate, uvula, and tonsillar pillars and are the result of infection with serotypes 6 and 11 of the human papillomavirus (HPV). Because of concern that these lesions could spread to the larynx or trachea, complete surgical excision is usually recommended. Pleomorphic adenoma (mixed tumor) is a benign neoplasm of minor salivary glands with a predilection for the palate, although it may also be found in the lip and buccal mucosa. Treatment is with surgical excision.

## MALIGNANT LESIONS

Rhabdomyosarcoma, the most frequent soft tissue malignancy of childhood, typically occurs in the 2- to 6-year-old group and is derived from embryonic skeletal muscle.[28,29] In the oral cavity and oropharynx, it presents as a rapidly growing mass in the tongue, palate, and uvula or cheek. These tumors metastasize early to local lymph nodes, lung, and bone. Surgical therapy is limited to biopsy, excision of small lesions, or surgical salvage of treatment failures. The usual therapy includes a combination of chemotherapy and radiation therapy.

Lymphoma of the oral cavity and oropharynx typically involves the lymphoid tissue of the Waldeyer ring and presents

as a mass of the tonsil or in the nasopharynx.[30] The diagnosis may be suspected by evidence of involved adenopathy in the neck but is confirmed by surgical biopsy. Treatment is with a combination of chemotherapy and radiation therapy.

Other rare malignant neoplasms of the oral cavity and pharynx include malignant salivary gland tumors (mucoepidermoid carcinoma) and epidermoid or squamous cell carcinoma. This latter tumor has been reported in organ transplant patients and adolescents who use snuff or chewing tobacco.[31] Treatment is usually surgical depending on the site and extent of involvement.

# Larynx

## ANATOMY

With the exception of the hyoid bone, the major structural framework of the larynx consists of cartilage and soft tissue. The hyoid bone lies superior to the larynx and is attached to it by the thyrohyoid membrane and strap muscles. The hyoid bone is derived from the second and third branchial arches. The cartilaginous structures of the larynx are composed of hyaline cartilage, with the exception of the epiglottis, which is composed of elastic cartilage. The cartilaginous structures of the larynx develop from the fourth, fifth, and sixth branchial arches. There are nine laryngeal cartilages, three that are single (thyroid, cricoid, and epiglottis) and six that are paired (arytenoid, cuneiform, and corniculate). The thyroid cartilage consists of two quadrilateral cartilages that form the anterior framework of the larynx. The cricoid cartilage is the only completely cartilaginous structure in the airway and provides posterior stability and a base of support for the cricoarytenoid and cricothyroid joints.

The cricothyroid muscles are paired extrinsic laryngeal muscles that serve to tilt the larynx down and forward, tensing the vocal folds. Paired intrinsic muscles—the thyroarytenoid, thyroepiglottic, and aryepiglottic muscles—act as a sphincter to close the larynx. The vocalis muscle comprises the internal fibers of the thyroarytenoid muscle and attaches to the vocal ligament. Action of this muscle serves to regulate the pitch of the vocal ligament. The other set of paired muscles includes the posterior cricoarytenoid, lateral cricoarytenoid, and interarytenoid muscles. The posterior cricoarytenoid muscles serve to abduct the vocal folds, whereas the cricoarytenoid and interarytenoid muscles adduct the vocal folds.

The quadrangular membrane is a connective tissue covering of the superior larynx that ends in a free margin along the vestibular ligament of the false cord. The conus elasticus is a membrane of elastic tissue that extends superiorly from the cricoid cartilage to form the paired vocal ligaments, the supporting structures of the vocal folds.

The blood supply of the larynx arises from the superior and inferior laryngeal arteries. The former is a branch of the superior thyroid artery, whereas the latter is a branch from the thyrocervical trunk. The intrinsic muscles of the larynx are innervated by the recurrent laryngeal nerve, which also supplies sensory branches to the inferior larynx. The superior laryngeal nerve has two branches: The external branch innervates the cricothyroid muscle, while the internal branch supplies sensation to the superior larynx.

The larynx has multiple functions within the upper airway. During respiration, it regulates airflow by opening during inspiration. The posterior cricoarytenoid muscle contracts with each inspiration to abduct the cords just before activation of the diaphragm. The protective function of the larynx produces two reflexes: cough and closure. Cough is important to expel mucus and foreign objects. The closure reflex serves to prevent aspiration of foreign matter. In addition to closure, the larynx elevates during swallowing. Both closure and elevation occur simultaneously along with relaxation of the cricopharyngeus muscle during the swallow of a bolus. Finally, the larynx plays an important role in speech production by generating sound. Vibration of the mucosa covering the vocalis structures produces sound whose pitch and register is altered by changes in tension, length, and mass of the underlying vocalis muscle and ligament.

The larynx of an infant sits much higher than that of an adult. The cricoid is located at the level of C4, whereas the tip of the epiglottis is at C1. The close approximation of the epiglottis to the soft palate makes the infant an obligate nose breather. By 2 years of age, the larynx has descended to the level of C5 and reaches the adult level of C6 to C7 by puberty. The glottis of the newborn is 7 mm in the anteroposterior dimension and 4 mm in the lateral dimension. The narrowest area of the infant airway, the subglottis, is approximately 4 mm in diameter.

## UPPER AIRWAY ASSESSMENT

Symptoms of acute airway obstruction include dyspnea, cough, vocal changes, dysphagia, and sore throat. Dyspnea and rapid or labored breathing are indications of inadequate ventilation and may be triggered by changes in $PCO_2$ and $PO_2$. A stimulus anywhere in the airway may produce cough. It is difficult to localize the site of the stimulus from the quality of the cough. Changes in the child's vocal character, such as hoarseness or a muffled or weak cry, may help in localizing the area of obstruction. Dysphagia for solids and/or liquids is often associated with airway obstruction. Depending on the cause of airway obstruction, affected patients may complain of sore throat.

The child's overall appearance is the first sign to be assessed in airway obstruction, because airway status often dictates how quickly further evaluation and intervention need to be performed. The level of consciousness should be determined, because the unconscious or obtunded patient may need immediate airway management. Along with cyanosis in a patient without cyanotic heart disease, the presence of anxiety, restlessness, and diaphoresis are all ominous signs of impending airway compromise. Other symptoms of airway obstruction include tachypnea and substernal retractions. The child with airway obstruction is often tachycardic. The presence of bradycardia is a late indicator of severe hypoxia. The presence of a muffled cry often suggests obstruction at the level of the pharynx, whereas a barking cough is associated with laryngeal inflammation and edema. Stertor is a snorting sound whose origin is often in the pharynx. Stridor is noise produced by turbulent airflow in the laryngeal or tracheal airway. Inspiratory stridor suggests turbulence at or above the glottis. Expiratory stridor results from turbulent airflow in the distal trachea or bronchi. Biphasic stridor suggests a tracheal or subglottic source. A barking or croupy cough usually occurs when the

subglottic trachea is involved. The degree and loudness of the sound is not always indicative of the severity of obstruction, because stridor can become softer just before complete obstruction. Other important signs of airway obstruction include drooling and use of accessory respiratory muscles.

In addition to determination of the child's physical status, assessment of the degree of airway obstruction should include an evaluation of the ventilatory status. Pulse oximetry provides an immediate record of arterial oxygenation, while transcutaneous monitoring of carbon dioxide is a good indicator of ventilation. The lateral neck radiograph remains the best study for the initial evaluation of a child with airway obstruction, because it demonstrates the anatomy from the tip of the nose to the thoracic inlet. It can demonstrate findings of retropharyngeal or subglottic swelling from edema or infection and identify free air in the soft tissue spaces. The anteroposterior view of the neck is also helpful, specifically in defining areas of narrowing, such as a steeple sign associated with subglottic edema. A chest radiograph is also important in the initial assessment to identify foreign bodies or other conditions such as unilateral emphysema, atelectasis, or pneumonia that may account for the child's respiratory compromise. If time permits, a barium swallow or airway fluoroscopy may provide additional information.

Additional airway evaluation may include a brief flexible endoscopic examination. The nose is first sprayed with a combination of 2% lidocaine and oxymetazoline, and the child is gently restrained. The airway can be examined from the nares to the glottis. Attempts to pass a flexible scope through the glottis in a child with airway obstruction should be avoided. Likewise, flexible endoscopy should be avoided in a child with supraglottitis because of the possibility of precipitating complete obstruction. Children with suspected airway pathology distal to the glottis or those in whom the possibility that flexible endoscopy could compromise the airway should undergo any airway examination in the operating room where rigid endoscopes and other airway equipment is immediately available to secure the airway if necessary.

Nonsurgical intervention in the child with acute airway obstruction may begin with just observation alone in a high surveillance unit. Humidified oxygen administered by face mask will improve $PO_2$ and clearance of secretions. Racemic epinephrine administered by nebulizer acts to reduce mucosal edema and is useful in conditions such as laryngotracheobronchitis (infectious croup). Because its length of action lasts 30 to 60 minutes, treated patients should be observed for signs of rebound for 4 to 6 hours after administration. Corticosteroids have been shown to have value in the management of postintubation croup, adenotonsillar hypertrophy that results from EBV infection, allergic edema, and spasmodic and viral croup. Corticosteroids and propranolol have been used successfully in infants to treat subglottic hemangiomas.[32,33]

Other adjuvant therapies include antibiotics and inhalation of helium/oxygen mixture (heliox). Although viral agents are often responsible for inflammation in the larynx and trachea, bacterial superinfection is also common. Because of the prevalence of penicillin-resistant organisms, broad-spectrum antibiotics, including a higher-generation cephalosporin, penicillinase-resistant penicillin, or beta-lactamase penicillin, are useful in preventing or eradicating infection. Heliox is a mixture of gas in which helium is used to replace nitrogen. The advantage of the helium-oxygen mixture is that its low density reduces air turbulence and gas resistance, allowing improved delivery of oxygen in patients with airway obstruction.

Nonsurgical airway management may include use of nasal or oral airways, endotracheal intubation, and, rarely, transtracheal ventilation. Nasal airways of rubber or other synthetic material can be easily inserted into the nose of most children after adequate lubrication with a water-soluble lubricant. Their best use is in cases where the pharynx is the site of obstruction. Oral airways are not as readily tolerated by children and only serve as a brief solution to an airway problem. During the 1970s, endotracheal intubation with polyvinyl chloride tubes revolutionized the management of supraglottitis, and even today intubation remains the mainstay of initial airway therapy in most children with severe airway obstruction. The size of the endotracheal tube used correlates with the age of the child. The subglottis, the narrowest part of the infant airway, typically admits a 3.5- or 4.0-mm inner-diameter tube. The tube used in children older than 1 year can be roughly estimated by using the following formula: tube size $=$ (age in years/4) $+$ 4. Once the airway has been established, the tube should be carefully secured and the child appropriately sedated and/or restrained, if necessary, to avoid accidental self-extubation. Another method of airway management should be considered in children with an unstable cervical spine or in whom oral or neck trauma makes visualization difficult. Transtracheal ventilation, insertion of a 16-gauge needle through the cricothyroid membrane for the delivery of oxygen, should be reserved for emergencies and used only until a more stable airway can be obtained.

The surgical management of the child with acute airway obstruction should begin with endoscopy. The larynx can be visualized with one of a variety of pediatric laryngoscopes and the airway secured with a rigid pediatric ventilating bronchoscope of appropriate size. Once the airway is secured, a more stable form of airway management can be used. Rarely, in a child with acute airway obstruction, an airway cannot be established, and a cricothyrotomy may need to be performed. As in adults, this procedure avoids some of the risks of bleeding and pneumothorax inherent in a formal emergency tracheostomy. A small endotracheal or tracheostomy tube can be inserted through the incision in the cricothyroid membrane, but conversion should be made to a more stable airway as soon as possible. Tracheostomy remains the preferred airway in cases of acute obstruction in which a translaryngeal approach is unsuccessful or must be avoided. The emergent tracheostomy should be avoided if at all possible to lessen complications of bleeding, pneumothorax, pneumomediastinum, subcutaneous emphysema, or damage to surrounding structures. The incidence of these complications can be reduced by careful attention to surgical technique, good lighting, and adequate assistance.

## CONGENITAL LARYNGEAL ANOMALIES

Laryngomalacia is the most common cause of newborn stridor and is caused by prolapse of the supraglottic structures (arytenoid cartilages, aryepiglottic folds) during inspiration (Fig. 55-12). Symptoms typically appear at birth or soon thereafter and include high-pitched inspiratory stridor, feeding difficulties, and, rarely, apnea or signs of severe airway obstruction. Gastroesophageal reflux disease (GERD) is common in children with laryngomalacia and tends to worsen the

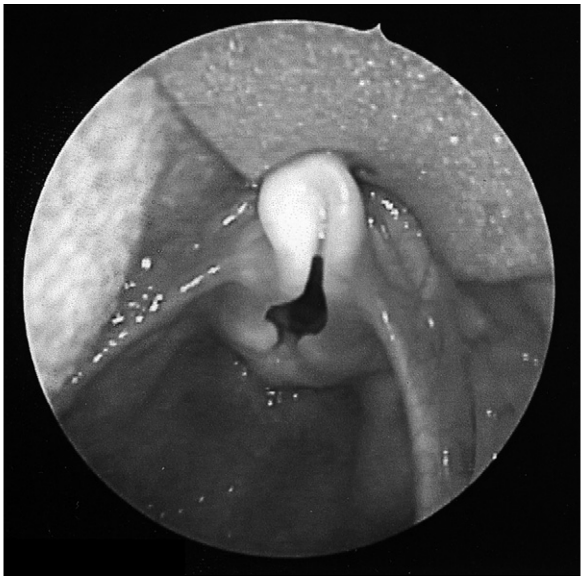

**FIGURE 55-12** Laryngomalacia. This disorder classically presents as an omega-shaped epiglottis. The arytenoid mucosa is redundant, and the aryepiglottic folds are foreshortened. The result is a hooding of tissue over the glottic inlet that leads to airway obstruction on inspiration.

airway symptoms, because it creates swelling of the posterior cricoid region of the larynx. The diagnosis of laryngomalacia is confirmed by flexible endoscopy of the larynx, and other airway pathology can be excluded with lateral neck, chest, and airway fluoroscopy. Barium swallow radiography is helpful to identify the presence of GERD. In most cases, laryngomalacia is self-limited and resolves by 18 months of age. Changes in positioning and feeding, treatment of reflux, and, in some neonates, use of monitoring may be necessary. In severe cases, surgical intervention with either a supraglottoplasty (surgical division with or without partial resection of the aryepiglottic folds) or a tracheostomy may be necessary.

Tracheobronchomalacia is defined as collapse of the tracheobronchial airway. It may be congenital or acquired (from long-standing intubation and infection) and may be segmental or involve the entire tracheobronchial tree. Depending on the extent and location, symptoms include low-pitched biphasic or expiratory stridor and signs of respiratory compromise. The diagnosis is usually made with endoscopy, although fluoroscopy of the airway may often demonstrate it. Treatment ranges from observation in most cases to airway management with a tracheostomy tube and positive-pressure ventilation in severe cases. Tracheomalacia may be localized, especially when associated with esophageal atresia, and aortopexy is occasionally the treatment of choice if due to extensive compression from vessels (see Chapter 69). Tracheal stents have also been used for more extensive tracheomalacia.

Vocal fold paralysis is the second most common congenital laryngeal anomaly (after laryngomalacia) and may be unilateral or bilateral. Congenital vocal fold paralysis may be caused by neurologic abnormalities (hydrocephalus, Arnold-Chiari malformation), birth trauma, or, rarely, in association with neoplasms of the larynx or neck. Acquired vocal fold paralysis may result from trauma or from neoplasms of the chest or neck, or it may be iatrogenic, typically after surgery of the neck, esophagus, or arch of the aorta. The risk of vocal cord paralysis is higher in premature babies who have surgery before they reach normal birth weights. Neonates with bilateral involvement typically present with high-pitched inspiratory or biphasic stridor but a good cry. Respiratory compromise and feeding difficulties may accompany the stridor because the vocal cords cannot abduct and the resultant airway is narrow. However, compensatory extralaryngeal muscles can help adduct the cords to produce a strong voice. In infants with unilateral involvement, the airway may be adequate because the affected vocal cord remains partly lateralized at rest. Unlike the case of bilateral vocal cord paralysis, the extralaryngeal muscles cannot cause the cord to adduct upon vocalization or during a swallow. As a result, these infants are at increased risk of aspiration and often have breathy, weak voices. The diagnosis of unilateral or bilateral vocal fold paralysis is confirmed with flexible or rigid endoscopy. Additional studies in the evaluation of patients with vocal fold paralysis include lateral neck and chest radiography, barium swallow, and CT or MRI of the head and neck. Most children with unilateral involvement can be observed. As they grow, they may be candidates for vocal cord medialization procedures, whereby, agents such as Gelfoam or Teflon are injected lateral to the cord to improve vocalization. Another treatment option is ansa cervicalis–to–recurrent laryngeal nerve anastomosis to reinnervate the affected cord. This increases the tone, bulk, and tension of the cord, but does not restore normal mobility.[34] Infants with bilateral vocal fold paralysis often require a tracheostomy. In addition, infants with associated feeding difficulties may need a gastrostomy. In older children (4 or 5 years of age) with bilateral vocal cord paralysis, a more permanent solution, such as a cordotomy or arytenoidectomy, can be considered to improve the glottic airway and to allow for decannulation of the tracheotomy tube.

Congenital subglottic stenosis is the third most common congenital laryngeal anomaly and is defined as a neonatal larynx in a term baby without a history of prior instrumentation or intubation who fails to admit a 3.5-mm endotracheal tube (Fig. 55-13). The underlying abnormality is a cricoid cartilage that is either small or deformed. Children with Down syndrome are at higher risk for this condition. Infants with congenital subglottic stenosis present with inspiratory

**FIGURE 55-13** Subglottic stenosis. Congenital and acquired stenosis create airway obstruction, depending on the severity and type of stenosis. Various forms of reconstruction are available (see Chapter 65).

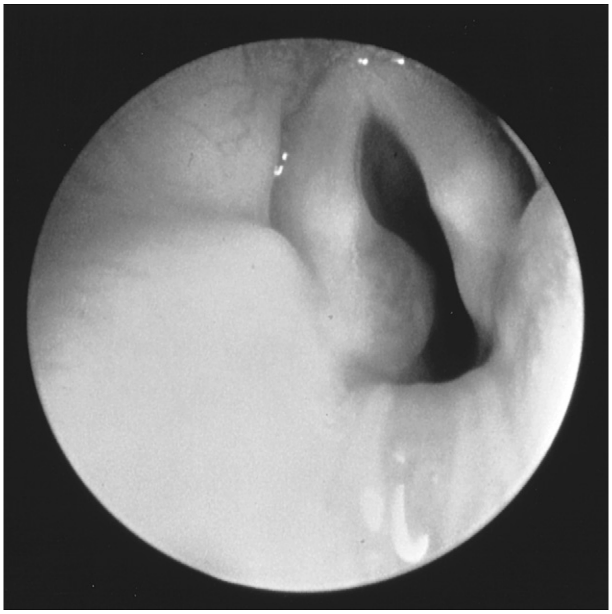

**FIGURE 55-14** Subglottic hemangiomas typically arise from the posterior lateral aspect of the larynx. Small lesions may be managed conservatively, whereas lesions with aggressive growth patterns that do not respond to propranolol or steroids require tracheotomy to bypass the laryngeal obstruction.

or biphasic stridor, barking cough, and other symptoms of airway obstruction. The diagnosis is often suggested by narrowing of the subglottis on a lateral neck radiograph and confirmed by endoscopy. Treatment depends on the severity of symptoms and ranges from observation to laryngeal reconstruction to tracheostomy.

A child with a subglottic hemangioma presents with the onset of progressive stridor during the first few months of life (Fig. 55-14). Hemangiomas are proliferative endothelial lesions that can form in the submucosa of the posterior and lateral subglottis. Occasionally, they may involve the subglottis in a circumferential pattern. Associated cutaneous hemangiomas may be found in approximately 50% of patients, but only 1% of patients with cutaneous lesions have airway lesions. Symptoms are dependent on the amount of airway compromise and include biphasic stridor, barking cough, difficulty feeding, and other symptoms and signs of airway obstruction. The diagnosis may be suggested on a lateral neck radiograph but is confirmed with endoscopy. Nonsurgical management of infants with a subglottic hemangioma includes observation or treatment with systemic corticosteroids or propranolol. Surgical therapy includes laser excision, open excision through a laryngofissure, or a tracheostomy.

A laryngocele is an air-filled dilatation of the saccule of the larynx that communicates with the laryngeal airway. It may present internally into the posterior superior false cord region or externally through the thyrohyoid membrane. A saccular cyst is fluid filled and protrudes between the true and false vocal folds. The diagnosis of this lesion is confirmed endoscopically, and CT of the larynx is helpful in assessing its extent and if it is fluid or air filled. Treatment is with endoscopic marsupialization or excision through a laryngofissure.

## INFLAMMATORY DISEASE OF THE UPPER AIRWAY

Laryngotracheobronchitis (viral croup) is an inflammation of the subglottic airway caused by a variety of parainfluenza and influenza viral agents. The infection may involve the entire glottis and extend into the trachea and bronchi. Affected children fall typically into the 1- to 3-year-old group; males are more commonly affected than females. Symptoms and signs of viral croup include biphasic stridor, barking cough, and hoarseness, often in association with a prodromal viral upper respiratory tract infection. The diagnosis of croup is made clinically, but endoscopic examination may help to exclude other pathologic processes. Care should be taken not to instrument the subglottis, causing more swelling and inflammation and precipitating acute obstruction. Lateral neck radiography demonstrates subglottic narrowing, whereas anteroposterior neck films show a "steeple sign," the result of subglottic edema. Treatment of viral croup is typically supportive with humidification. Treatment with nebulized racemic epinephrine in the emergency department or hospital setting often relieves symptoms; however, rebound of signs may occur several hours later, and children should be monitored accordingly. A meta-analysis of randomized controlled trials has shown treatment with glucocorticoids is effective in improving symptoms within 6 hours, for up to 12 hours, with significant improvement in croup scores, shorter hospital stays, and less use of epinephrine.[35] Severely affected children may require intubation for respiratory failure (less than 5% of affected patients). A smaller than normal tube should be chosen to avoid edema and scarring. In rare cases, a tracheostomy may be required if the inflammation fails to resolve.

A child younger than 1 year of age with recurrent bouts of "croup" should be suspected of having either congenital subglottic stenosis or a hemangioma. Spasmodic croup is the recurrence of crouplike symptoms in a child who is otherwise well. Fever is rarely present, and the attacks frequently occur at night. Gastroesophageal reflux disease has been suggested as a possible inciting process. Treatment of spasmodic croup is usually observant, although corticosteroids or antireflux medications may prove beneficial.

Supraglottitis (epiglottitis) is an infectious disease that involves the supraglottic larynx. In children, the most common pathogen is *Haemophilus influenzae* type B (HIB), followed by *S. pneumoniae* and *S. aureus*. The incidence of supraglottitis in children has diminished markedly since the introduction of the conjugated HIB vaccine in the early 1990s.[36] However, HIB-related supraglottitis continues to occur in children who have been vaccinated, with a reported 2% vaccine failure rate. Alternatively, *S. pneumoniae, S. aureus,* and viruses are more likely to cause supraglottitis in adolescents and adults.

Children who develop supraglottitis are somewhat older than those seen with croup in the 2- to 6-year-old group. Symptoms and signs have a rapid onset, progress quickly to frank airway obstruction, and include stridor, dysphagia, fever, muffled voice, and signs of systemic toxicity. Affected children frequently sit and assume the "sniffing" position in an attempt to maximize their airway. Intraoral or endoscopic examination should be avoided in suspected patients because of concern for precipitating complete obstruction. Lateral neck radiography demonstrates a classic "thumbprint sign" of the epiglottis but should only be obtained if facilities are present in close proximity to secure the airway.

Prompt airway management is essential in children with supraglottitis. In severe cases, the child's airway should be secured in either the emergency department or operating room with team members, including a pediatrician, anesthesiologist, critical care physician, otolaryngologist, or pediatric surgeon or others familiar with the pediatric airway. After inducing the child with general anesthesia, the airway should be intubated. Examination of the supraglottis may be made, and cultures of the larynx and blood are obtained. Equipment to perform a tracheostomy should be readily available. The child should remain intubated for 24 to 72 hours and should be supported with intravenous fluids and antibiotics that treat antibiotic-resistant *H. influenzae, S. pneumoniae*, and *S. aureus* (third-generation cephalosporins or ampicillin-sulbactam).

Bacterial tracheitis (membranous croup) often occurs as a complication of another infection, such as measles, varicella, or other viral agents. The most common organisms include *S. aureus,* GABHS, *M. catarrhalis,* or *H. influenzae*. It can occur in any age child and present with stridor, barking cough, and low-grade fever. Symptoms and signs then progress to include high fever and increasing obstruction and toxicity. The diagnosis may be suspected by diffuse narrowing of the tracheal air shadow on chest radiograph but is confirmed by endoscopic examination in the operating room. Purulent debris and crusts can be removed at this time. Cultures of secretions and crusts may be helpful in guiding intravenous antibiotic therapy that should be aimed initially at the usual pathogens. The airway should be secured with an endotracheal tube or, rarely, a tracheostomy. Repeat endoscopic examination of the airway may be warranted to continue debridement and to determine the feasibility of extubation.

## CHRONIC AIRWAY OBSTRUCTION

The chronic management of subglottic stenosis and other prolonged airway disorders is discussed in Chapter 65.

## BENIGN LARYNGEAL NEOPLASMS

Recurrent respiratory papillomatosis (RRP) is the most common benign neoplasm of the larynx in children. Squamous papillomas involve the larynx and, occasionally, the trachea and lower respiratory tract as exophytic lesions. Because of its recurrent nature, RRP causes morbidity and, rarely, mortality resulting from malignant degeneration. Patients may be almost any age, but the disease is more aggressive in children. Human papillomavirus (HPV) subtypes 6, 11, 16, and 18 have all been identified within papilloma tissue. The first two subtypes have been associated with genital warts, whereas the latter two have been associated with cervical and laryngeal cancers. The exact mechanism of HPV infection in the larynx remains unknown. In most cases, transmission of virus to the child is thought to occur via vaginal birth in a mother with cervical HPV infection or warts. However, children can still get RRP even when born by cesarean section.

Children afflicted with RRP present initially with hoarseness but may also have symptoms and signs of airway obstruction, including stridor. Lateral neck radiography may suggest laryngeal involvement, but the diagnosis is confirmed by direct laryngoscopy and biopsy (Fig. 55-15). In addition to the trachea and bronchi, squamous papillomas may also be found in the oral cavity.

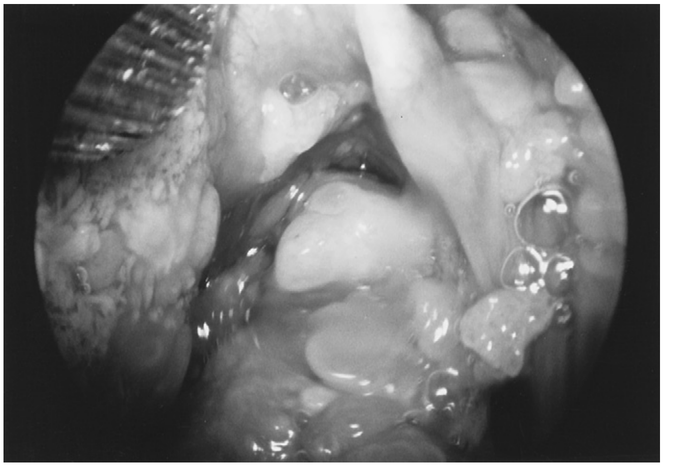

**FIGURE 55-15** Recurrent respiratory papillomatosis. Severe papillomatosis may completely obstruct the larynx. Papillomas are characterized by malignant degeneration and aggressive growth patterns.

Surgical excision is the mainstay of therapy in patients with RRP. In the past, papillomas were excised using the carbon dioxide laser. More recently, the laryngeal microdebrider has become the preferred method of excision in many centers. In aggressive cases with swift recurrence and accompanying airway obstruction, tracheostomy may be necessary for airway management, although tracheostomy has been implicated in the spread of disease to the trachea and lower respiratory tract. Medical adjuvant therapy that has been used with mixed results includes interferon, photodynamic therapy with dihematoporphyrin ether, indole-3-carbinol, or antiviral agents such as cidofovir.

Other benign laryngeal neoplasms are rare and include connective tissue tumors such as chondromas or fibromas, neurogenic tumors such as neurofibromas, or granular cell tumors and other cell types such as hamartomas or fibrous histiocytomas. Malignant tumors of the larynx are also rare and include squamous cell carcinoma and a variety of epithelial and connective tissue malignancies, such as spindle cell carcinoma, rhabdomyosarcoma, mucoepidermoid carcinoma, and chondrosarcoma. Metastatic tumors and lymphoma may also rarely involve the larynx in children. Diagnosis is suspected by the sudden appearance of stridor, hoarseness, and airway obstruction and confirmed by biopsy. Treatment is dependent on cell type and may include surgical excision, radiation therapy, and/or chemotherapy.

# Neck

## ANATOMY

The surgical anatomy and embryology of the neck is discussed in Chapter 59.

## CLINICAL EVALUATION

The initial examination of a disease or disorder of the neck begins with a thorough history. A detailed history can often serve to focus the differential diagnosis of a neck disorder. The age of the child is an important first consideration. The appearance of a neck mass in an infant often suggests a

congenital disorder, whereas the sudden appearance of a mass in an adolescent might suggest a malignant process. Inflammatory diseases of the neck may occur in any age group but typically mirror the incidence of upper respiratory tract infections in children. Growth and temporal relationships are often important clues to a diagnosis. Neck masses that grow rapidly suggest either an inflammatory or malignant process, whereas slow-growing masses are typically benign. A history of systemic infection elsewhere in the body or recent travel or exposure to farm animals often points to an infectious origin. A history of trauma to the neck may explain the sudden appearance of a neck mass. Likewise, changes in the size of a neck mass with eating may suggest a salivary gland origin. Vascular lesions enlarge with straining or crying. Finally, systemic symptoms of fever, weight loss, night sweats, or fatigue in association with the sudden development of a neck mass may indicate a malignant process.

The physical examination of a child with a neck mass should begin with a comprehensive examination of the entire head and neck. Because the vascular, neural, and lymphatic patterns of the head drain into the neck, the source of neck disorders may be found in the head. Depending on the differential diagnosis, a physical examination of the entire body, including an assessment of lymph nodes in the groin and axillae and the presence of an enlarged spleen or liver, is essential. Palpable lymph nodes in the neck of children are a common finding, but lymph nodes larger than 2 cm fall outside the range of normal hyperplastic nodes and should be either monitored or investigated. The sudden appearance of large nodes in either the posterior cervical or supraclavicular regions may suggest a malignancy, especially if unilateral.[37] The consistency of a neck mass is also important in narrowing the differential diagnosis. Hard masses tend to be associated with either infection or malignancy. Fixation of a neck mass to skin or nearby structures is also suggestive of a malignancy. Cysts or abscesses tend to have a characteristic feel on palpation and are usually ballotable, and the overlying skin may be inflamed if infected. Depending on the differential diagnosis after a history and physical examination, radiologic studies may be useful. A lateral neck radiograph may demonstrate an abnormality of the nasopharynx, retropharynx, or cervical spine. Likewise, a chest radiograph may identify a malignancy, sarcoidosis, or tuberculosis. Infection or a neoplastic process in the sinuses may appear on a sinus series. CT and MRI are useful in the evaluation of a neck mass. Demonstration of hypodensity on CT suggests an inflammatory or necrotic process. Ring enhancement of a hypodense region on a contrast CT scan is indicative of an abscess. MRI is excellent for distinguishing fine detail within soft tissue and in the evaluation of vascular lesions of the neck. Finally, ultrasonography is helpful in distinguishing solid and cystic masses and may be the only imaging modality required in the assessment of neck masses. Use of ultrasonography preoperatively in patients with a thyroglossal duct cyst is also a simple and economic way to assess the presence of normal thyroid tissue when it is not easily felt. Ultrasonography should be used in the assessment of any thyroid mass, while thyroid scanning is now thought to be of limited value in the pediatric age group.

Selected laboratory studies may be helpful in the evaluation of a child with a neck disorder. A complete blood cell count with differential may identify patients with either a malignancy or systemic infection. Serologic testing for EBV or cytomegalovirus infection, toxoplasmosis, or cat-scratch disease may be diagnostic. Thyroid function testing is essential in any child with a suspected thyroid disorder. Finally, collection of urine for catecholamine metabolites (vanillylmandelic acid) may assist in the diagnosis of neuroblastoma.

If the diagnosis remains in doubt at this point, incisional or excisional biopsy may be indicated. Biopsy provides material for pathologic examination, culture, and other more sophisticated testing if necessary. Fine-needle aspiration of a neck mass in children for suspected malignancy is not as reliable as in adults.

## CONGENITAL TRACTS AND CYSTS

Congenital sinuses and cysts are discussed in Chapter 59.

## INFLAMMATORY AND INFECTIOUS MASSES

Viral adenitis is the most common infectious disorder to involve the neck in children. Enlarged or hyperplastic lymph nodes are frequently the result of viral upper respiratory tract illnesses. Common pathogens include rhinovirus, adenovirus, and enterovirus, but measles, mumps, rubella, varicella, EBV, and cytomegalovirus may also cause lymphadenopathy. The diagnosis is often suspected by other findings in the history or physical examination and can be confirmed by serologic testing. Acute human immunodeficiency virus infection may present, as do other viral syndromes, with fever, headache, malaise, gastrointestinal symptoms, and a neck mass.

The usual source of bacterial cervical adenitis is the pharynx. Causative organisms are often streptococcal or staphylococcal species. Patients present with systemic symptoms of fever and malaise in addition to a neck mass that is diffusely swollen, erythematous, and tender. In contrast to viral adenitis, which is frequently bilateral, bacterial infections of the neck are usually unilateral. CT with contrast medium enhancement may be helpful in the evaluation of large infectious neck masses that may contain an abscess cavity (Fig. 55-6, *B*), although ultrasound examination can provide similar information without radiation. Needle aspiration of suspected infectious masses may provide material for culture and decompress the mass.

Most children with bacterial cervical adenitis respond to oral antibiotics chosen to cover group A streptococci and *S. aureus,* but those who fail to improve require IV antibiotics. The initial choice of antibiotic is important. A recent study has shown a predominance of *S. aureus* (63%) compared with *Streptococcus* group A isolates (22%) obtained from those abscesses requiring surgical drainage. Of those with *S. aureus* infections, 27% were methicillin-resistant *Staphylococcus aureus* (MRSA), and all of these were sensitive to clindamycin and trimethoprim-sulfamethoxazole. Of the methicillin-sensitive *Staphylococcus aureus* (MSSA) isolates; 100%, 86%, and 82% were sensitive to trimethoprim-sulfamethoxazole, clindamycin, and ciprofloxacin, respectively.[38]

Cat-scratch disease is caused by *Bartonella henselae* infection. The clinical picture includes the sudden appearance of unilateral lymphadenopathy after a scratch from a cat. Fever and malaise may be accompanying symptoms in many cases. Serologic testing for antibodies to *Bartonella* is diagnostic. Cat-scratch disease is usually self-limited, although some

benefit has been described with the use of erythromycins and other antibiotics.[39]

In the past, most mycobacterial infections have been caused by atypical organisms, such as *Mycobacterium avium-intracellulare, M. scrofulaceum, M. bovis,* or *M. kansasii*. These organisms are commonly found in the environment in dirt, dust, water, and sometimes in food. In the past decade or so, mycobacterial tuberculosis has made a resurgence as the pathogen responsible for a neck infection. A chest radiograph should be obtained if *M. tuberculosis* is suspected. *M. tuberculosis* is usually associated with abnormal chest radiograph and the presence of a positive tuberculous skin test. Tuberculosis should be treated with appropriate antituberculous chemotherapy.

Children with nontubercular (NTM) or atypical mycobacterial infections have weakly positive or negative skin tests and present with a typical indolent course consisting of slowly growing, nontender nodes in the preauricular, intraparotid, submandibular, or posterior triangle regions that do not respond to antibiotics. Systemic symptoms are rare. After several days to weeks, the skin overlying the node typically assumes a violet color, and the area may become fluctuant and tender to palpation. The diagnosis is mainly clinical, because the organism will often take several weeks to grow in culture, and acid-fast bacilli are not always demonstrated. The treatment is surgical and consists of excision of the involved node(s). Combination therapy using clarithromycin and rifabutin may be effective but requires a prolonged course; it is generally reserved for recurrences or nodes that are not safely accessible by surgical approach.

Rarely, the neck may be involved with infections such as tularemia, brucellosis, actinomycosis, plague, histoplasmosis, or toxoplasmosis. Inflammatory disorders that may affect the neck include Kawasaki syndrome, sarcoidosis, sinus histiocytosis (Rosai-Dorfman disease), Kikuchi-Fujimoto disease, and PFAPA syndrome (periodic recurrent fever).

## MALIGNANT NEOPLASMS

Thyroid malignancies are discussed in Chapter 58, and malignant lymphadenopathies in Chapters 38 and 57.

Neurofibromatosis is a benign disorder that in some forms (plexiform) may infiltrate surrounding tissues. For this reason, CT and/or MRI are vital in the preoperative evaluation of these lesions. When the tumors are multiple and extensive, surgical resection is reserved for symptomatic lesions, because complete excision is usually impossible without compromising neurovascular structures. Neuroblastoma is a malignancy that develops from neural crest cells and may present as a solitary tumor or as lymphadenopathy. Clinical staging determines the mode of therapy that includes surgery, chemotherapy, and radiation therapy.

Rhabdomyosarcoma rarely presents as a primary tumor in the neck, more often being found as a primary tumor in the orbit, temporal bone, or nasopharynx. The diagnosis is made by biopsy, and patients are staged according to involvement. Treatment includes surgery, chemotherapy, and radiation therapy.

Malignancies of almost any type and location in the body can metastasize to the neck. The most common are thyroid malignancies. In adolescents, carcinomas, especially those arising in the nasopharynx, may spread to the neck lymphatics.

*The complete reference list is available online at www.expertconsult.com*.

CHAPTER 56

# Salivary Glands

Douglas Sidell and Nina L. Shapiro

Salivary gland disorders are rare in children. They often present as a painful or, less commonly, a painless swelling in the affected gland. Disease processes may be of infectious, inflammatory, systemic, autoimmune, congenital, neoplastic, or traumatic origin.[1] Treatment is guided by the medical or surgical nature of the specific disease process.

## Classification

Salivary glands may be divided into major and minor categories. The former category includes the parotid, submandibular, and sublingual glands, all of which are paired structures with their own well-defined anatomy, including blood supply and ductal drainage. Their function is augmented and facilitated by the minor salivary glands, which include the mucus-secreting tissues in the buccal mucosa, palate, mucosal surfaces of the lips, and floor of the mouth.

## Embryology

In the sixth week of gestation, solid epithelial buds of ectoderm from the developing mouth invaginate into the surrounding mesenchyme. A groove from this invagination develops into a tunnel, which subsequently forms branches of salivary ductal tissue. The mesenchymal tissue forms the capsule and connective tissue of the salivary glands. This process is similar for all of the major salivary gland embryogenesis.[2] During early gestation, the parotid ductules begin to grow around the facial nerve and its branches. This is of great clinical and surgical significance, because the facial nerve may be compressed or invaded by parotid gland lesions, or its branches may be injured during parotid gland surgery.[3]

## Anatomy and Physiology

The parotid gland is located in the space between the external auditory canal and the mandible. Its main duct (Stensen duct) crosses the masseter muscle and opens in the buccal mucosa at the level of the second maxillary molar. The deep lobe of the parotid gland lies medial to the facial nerve branches and the mandible. Deep lobe parotid gland masses may extend to the parapharyngeal space and present as intraoral growths. The parotid gland is the only salivary gland containing lymph nodes, which may become apparent during certain pathologic processes, such as atypical mycobacterial adenitis (see Chapter 57). Accessory parotid tissue is present in some children and in approximately 20% of adults. It can occur superficial to the masseter and is often mistaken for a neoplasm.[4] The submandibular gland is located in the submandibular triangle of the neck. The main submandibular duct (Wharton duct) exits the gland at a right angle and enters the mouth just lateral to the midline lingual frenulum. The sublingual gland is located at the lateral aspect of the floor of the mouth.[1]

The salivary glands serve to lubricate the mouth for hygiene, speech, and deglutition; to moisten food for taste and mastication; and to initiate early starch digestion with $\alpha$-amylase.[1] These processes may be initiated by various stimuli, including cerebral, visual, olfactory, or gustatory.

## Pathology

The majority of salivary masses in children are congenital vascular lesions, with hemangiomas seen in 50% to 60% of salivary gland masses and lymphatic malformations in approximately 25%.[5] Acquired lesions are of inflammatory, infectious, autoimmune, traumatic, or neoplastic origin. Salivary gland swelling is characteristic of nearly all glandular pathologic processes, and may be accompanied by pain, tenderness, or abnormal ductal discharge.[4] Advanced stages of disease may lead to cranial nerve involvement with resultant paresis or paralysis.

## Diagnosis

### HISTORY

A careful history should focus on the duration of the lesion, its bilateral or unilateral presentation, and whether there is any symptom fluctuation associated with eating. A complete medical history is essential, because the salivary glands may be involved in several systemic conditions.

### PHYSICAL EXAMINATION

The physical examination should include careful inspection of the overlying skin, both local and distant, to evaluate for any cutaneous hemangiomas, as well as of the intraoral mucosa to

evaluate for intraoral extension of the mass. Longitudinal duct massage will assess for duct obstruction or purulent material in the saliva. Benign salivary lesions tend to be mobile, soft, and spongy, whereas malignant and infectious lesions are more often fixed and firm on palpation.

## DIAGNOSTIC IMAGING

Plain radiographs of the salivary glands are helpful in detecting salivary duct calculi or diffuse glandular calcification.[1] Sialography is useful in identifying strictures, sialectasis, calculi, or saccular dilatation (Fig. 56-1).[6] High-resolution ultrasonography is a useful, noninvasive technique in the diagnosis of sialectasis and salivary gland calculi.[7] The addition of color-flow Doppler imaging can provide accurate information regarding the consistency of the lesion and its vascular pattern (Fig. 56-2).[8]

### Computed Tomography

Computed tomography (CT) is an excellent diagnostic modality for assessing both the pathology and anatomy of the salivary glands. It can aid in distinguishing intrinsic or extrinsic lesions. Use of an intravenous contrast agent can help detect an abscess or delineate the vascularity of congenital and acquired vascular lesions.[1] These features help in both medical and surgical planning.[9,10]

### Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) provides the best soft tissue detail of the salivary glands, and it is the only imaging technique that can delineate the facial nerve anatomy within the parotid glands. Signal intensity variations (T1- and T2-weighted images) provide additional valuable information regarding the nature of the mass.[11,12]

FIGURE 56-1 Sialogram shows saccular sialolithiasis of the parotid gland.

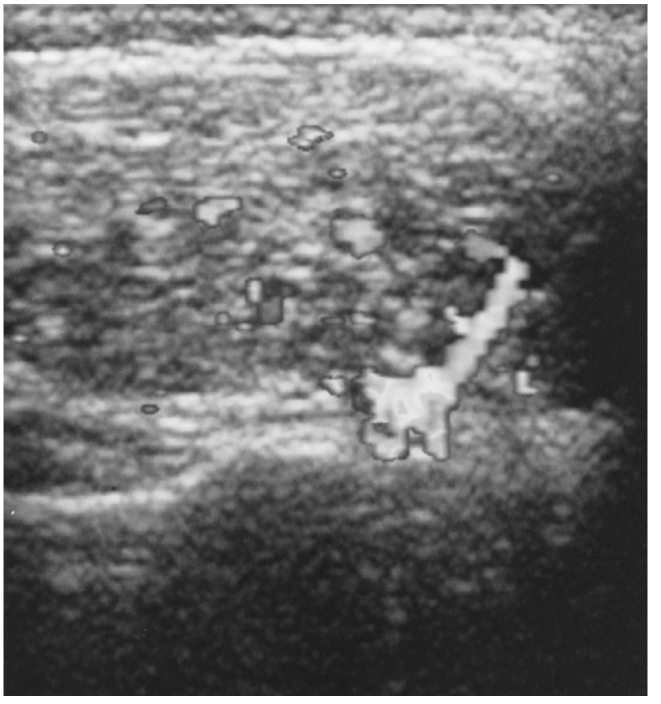

FIGURE 56-2 Doppler ultrasound study shows vascular pooling in a parotid hemangioma.

## BIOPSY

Fine-needle aspiration (FNA) biopsy is an excellent tool in the diagnostic evaluation of salivary gland masses.[13,14] The overall diagnostic accuracy is 84%, with a sensitivity and specificity approaching 92% for parotid lesions.[15–17] Obtaining an adequate needle biopsy specimen may preclude the necessity for surgical therapy or aid in surgical planning. Understandably, the accuracy and dependability of FNA rely heavily on the expertise of the cytopathologist and may vary based on institution or clinical setting.[13] For deeper salivary gland tumors, fine-needle aspiration may be performed under image guidance. Open excisional biopsy is the definitive tool for investigation and may be curative. If the size and location of the lesion are favorable, the entire tumor may be resected intact with a clear surrounding cuff of normal tissue. The diagnosis of Sjögren syndrome may be obtained by incisional biopsy of the minor salivary glands of the labial mucosa, or, alternatively, of the parotid gland.[18]

## SIALENDOSCOPY

Sialendoscopy involves semirigid endoscopy and microinstrumentation to evaluate and treat certain disorders of the parotid and submandibular glands. Although relatively new, this technique is increasing in popularity and has been demonstrated to effectively classify and treat ductal lesions, such as stricture and calculi. Sialendoscopy has been reported to produce a greater sensitivity in detecting salivary calculi than conventional radiography, MRI, or ultrasonography. Duct marsupialization and intraductal calculi retrieval have been demonstrated, allowing for the early treatment of some lesions without the requirement for open surgery.[19,20]

# Inflammatory Disease

## VIRAL SIALADENITIS

Acute inflammation of the salivary glands may be viral in up to 85% of cases, and the majority of viral sialadenitis involves the parotid glands. Viral infections are characterized by a benign self-limiting course over 2 to 3 weeks. Antipyretics, analgesics, and anti-inflammatory agents may be given for relief of symptoms. Causative organisms include coxsackievirus A and echovirus. Before the nearly universal implementation of the mumps vaccine in 1967, mumps virus (paramyxovirus) was the most common cause of acute parotid inflammation in children.[21–24] Other potential causes include cytomegalovirus (CMV), which is most commonly seen as a component of disseminated CMV infection in infants and young children,[25] and Epstein-Barr virus (EBV), which in healthy children is associated with infectious mononucleosis and in chronically ill children may be associated with human immunodeficiency virus (HIV) infection.[26,27]

## BACTERIAL SUPPURATIVE SIALADENITIS

Acute suppurative sialadenitis most often presents as rapidly developing pain, swelling, and occasional ductal discharge, with associated fever and poor oral intake. It is primarily seen in the parotid glands and less commonly in the submandibular or sublingual glands. The causative organisms are usually *Staphylococcus aureus* and *Streptococcus viridans*.[28] Acute sialadenitis often occurs in dehydrated patients because of decrease in salivary flow and dry oral mucosa.[29] Most cases will respond to antistaphylococcal antibiotics, with careful attention to hydration, oral hygiene with mouthwashes, warm local compresses, and sialogogues, such as sour lemon drop candies, to stimulate salivary flow. Rarely, despite treatment, the infected tissue will coalesce to form an abscess. Treatment of a salivary gland abscess includes intravenous antibiotics and surgical drainage.[30] If an abscess develops in the parotid gland, fascial incisions parallel to the course of the facial nerve are made to drain the abscess. If the facial nerve is paretic preoperatively, abscess drainage will usually facilitate resolution of nerve function.[1]

## CHRONIC SIALADENITIS

Chronic sialadenitis is the most common cause of inflammatory salivary gland disease in children and may lead to structural changes in the gland and acinar destruction (Fig. 56-3). There are obstructive and nonobstructive causes of this condition. Obstruction is caused by ductal stenosis, which may be congenital, caused by a stone, or result from chewing or biting the ductal opening. In such cases, the duct should be probed and stented for continuous drainage. Nonobstructive chronic sialadenitis may occur in conjunction with metabolic disorders, such as Sjögren syndrome, or chronic granulomatous disease, such as sarcoidosis, tuberculosis, or atypical mycobacterial disease.

The treatment of obstructive sialadenitis is initially conservative, with warm compresses and anti-inflammatory medications. Ductal dilatation or marsupialization may be necessary for recalcitrant disease. Gland excision is rarely required.

Sialolithiasis (salivary gland or duct calculi) is rare in children and occurs in the submandibular gland in 80% of cases. When the stone is located at the distal salivary duct, it may be excised by a simple incision at the ductal orifice. Temporary stent placement may be necessary. Rarely, a large calculus will be located in the proximal salivary duct or salivary gland parenchyma and may require complete gland excision with the stone-containing duct.

# Cystic Disease

Cystic disease may be acquired, congenital, or traumatic. Congenital cystic disease may occur in the salivary glands, but it is not of salivary gland origin. Work type I and type II first branchial cleft cysts may present as parotid gland masses, and depending on the orientation of the tract, may have accompanying otorrhea.[31,32] Congenital lymphatic malformations may also present in the parotid, submandibular, or sublingual glands. Large, bilateral intraparotid lymphoepithelial cysts are characteristic of HIV infection.[1] Small mucous retention cysts may present in the minor salivary glands of the labial or buccal mucosa; these cysts usually result from single or

**FIGURE 56-3** **A,** Sialogram of patient with history of recurrent parotid swelling. Note normal ductal system with early diffuse punctate sialectasis. **B,** Parotid gland swelling between acute attacks of inflammation.

**FIGURE 56-4** Floor of mouth ranula with posterosuperior lingual elevation.

repeated local trauma to the minor salivary glands and may lead to recurrent local mucosal swellings. If they do not resolve spontaneously, they will require complete excision. Local drainage or marsupialization will result in recurrence.

## RANULA

A ranula is a mucus extravasation cyst of the sublingual gland. Initial presentation is a bluish, cystic mass at the floor of mouth, which may lead to lingual elevation or difficulty with deglutition. They may extend to the neck through the mylohyoid (plunging ranula) (Fig. 56-4). Surgical management is controversial and ranges from simple transoral marsupialization to combination transoral-transcervical approaches.[33,34] Despite controversy, recurrence rates as high as 67% have been described with marsupialization alone. Recent evidence, derived from the largest review to date, suggests that the excision of the ipsilateral sublingual gland produces the lowest incidence of recurrence.[35] During sublingual gland excision, care must be taken to avoid Wharton duct injury, and it can be avoided by placing a lacrimal probe in the duct intraoperatively. The lingual nerve must also be meticulously dissected just deep to the sublingual gland.

# Neoplasms

Salivary gland neoplasms are extremely rare in children and comprise less than 1% of all pediatric neoplasms.[5,28,36,37] Less than 5% of salivary gland neoplasms occur in patients younger than 16 years of age.[38,39] However, when present, a pediatric salivary tumor must be assessed to rule out malignancy.[40–42] In the pediatric population, greater than 90% of salivary neoplasms occur in the parotid gland.[43] Caution should be exercised when evaluating adolescents, because imaging characteristics change over time as the gland is replaced with fat. Occasionally, this can cause benign disease to be mistaken for an infiltrative tumor on CT.[4]

## BENIGN NEOPLASMS AND MALFORMATIONS

Benign neoplasms account for 60% of salivary tumors in children and are most commonly vascular in origin.[5] Vascular lesions include hemangiomas and lymphatic malformations, which are both congenital in origin (Fig. 56-5).

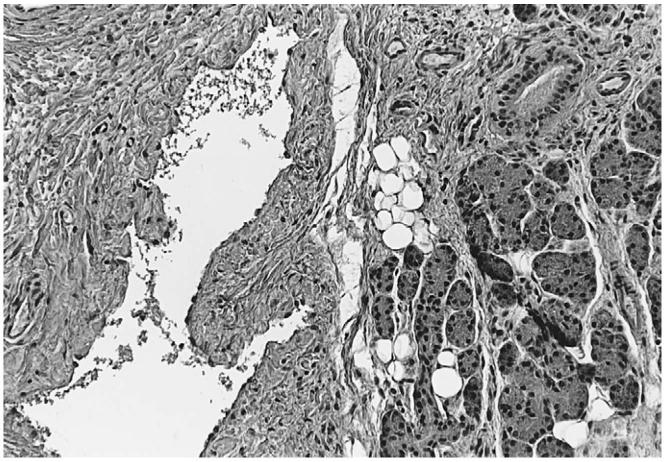

**FIGURE 56-5** Vascular malformation of the parotid gland, showing large, irregular vascular spaces. (Hematoxylin-eosin stain, ×50.)

### Hemangiomas

Hemangiomas are one of the most common salivary (primarily intraparotid) neoplasms in children, with infantile hemangiomas comprising greater than 90% of all salivary lesions in children less than 1 year of age.[4] Hemangiomas usually present in infancy as a soft, nontender parotid swelling, with or without associated pigmented cutaneous lesions.[44] Diagnosis is usually confirmed with ultrasonography, which demonstrates a lobulated, hypervascular mass, with arterial and venous signals visible on color-flow Doppler.[4,45] MRI may also be useful but is rarely required. Parotid hemangiomas often resolve spontaneously and do not require treatment. If they are rapidly growing or are causing functional impairments, such as facial nerve weakness, external auditory canal obstruction, or cutaneous breakdown, systemic therapy such as corticosteroids, propranolol, or interferon alfa-2a or alfa-2b are viable options to inhibit vascular growth and promote involution of the tumor.[46–49]

### Lymphatic Malformations

Lymphatic malformations are less common than hemangiomas. They do not undergo spontaneous involution, are usually present at or soon after birth, and grow with the growth of the child.[44] They are not true salivary lesions, but they are commonly seen in the submandibular and parotid region in infants and young children.[50] Lymphatic malformations are susceptible to infection, with potential for cellulitis, intralesional bleeding, abscess formation, or lymphangiomatous extension to the floor of mouth or trachea with airway compromise. Treatment modalities have been an area of much investigation. Surgical resection must be complete to obviate recurrence. This is often difficult, because of the fragility of the tumor lining, its infiltrative nature, and its proximity to major vessels and branches of the facial nerve.[51,52] In an effort to avoid surgical morbidity, success with intralesional sclerotherapy has been demonstrated, resulting in reduction in tumor size and minimal scarring or recurrence.[53]

### Pleomorphic Adenoma

Pleomorphic adenomas (benign mixed tumors) are the most common nonvascular benign salivary tumors in children (Fig. 56-6).[42,54] They present as firm, rubbery masses, most often in the parotid gland, with an average age at presentation of 9.5 years within the pediatric population.[54,55] The tumor

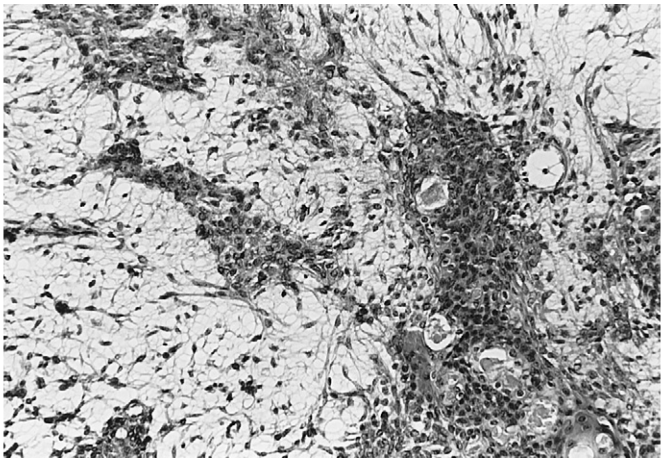

FIGURE 56-6 Pleomorphic adenoma (mixed tumor) of the parotid gland. Epithelial areas are mixed with myxomatoid and chondroid stroma. (Hematoxylin-eosin stain, ×50.)

presents as a painless, slowly growing mass and is rarely infiltrative.[56] They have variable echogenicity on imaging, with increased heterogenicity seen in larger lesions secondary to necrosis or cystic changes.[4] Treatment of superficial lobe tumors includes superficial parotidectomy with facial nerve dissection and preservation. Recurrence rates have been reported to be up to 40%; so, long-term follow-up is recommended.[57,58] Simple excisional biopsy should be avoided, because it is associated with a higher recurrence rate. Rarely, recurrent pleomorphic adenomas may undergo malignant degeneration.[59]

### Monomorphic Adenomas

Monomorphic adenomas are rare in children. Histologically, they may resemble adenoid cystic carcinoma, a highly aggressive malignant salivary tumor.[60] Treatment includes complete surgical resection and close long-term follow-up.

### Papillary Cystadenoma Lymphomatosum (Warthin Tumor)

These tumors are most commonly seen in men and are often bilateral parotid lesions. They may rarely present as benign parotid tumors in children.[1] Treatment is similar to that for pleomorphic adenomas.

## MALIGNANT NEOPLASMS

Malignant salivary neoplasms are rare in children. When present, they are often low-grade lesions, located most commonly in the parotid gland, and have a female preponderance.[54] Diagnostic evaluation should include CT or MRI and fine-needle aspiration biopsy. Treatment is surgical, with complete tumor excision with clear margins. Invasive malignancies may require sacrifice of the facial nerve branches. Postoperative radiation therapy is recommended for high-grade lesions.[61,62]

### Mucoepidermoid Carcinoma

Mucoepidermoid carcinoma is the most common pediatric salivary malignancy and is most commonly low grade and located in the parotid gland. Surgery is usually curative.[39,63] For high-grade mucoepidermoid carcinomas, or those involving the submandibular or minor salivary glands, concomitant neck dissection and adjuvant radiation therapy is recommended by many institutions.[36,64,65]

### Acinic Cell Carcinoma

Acinic cell carcinomas present in a similar fashion as mucoepidermoid carcinomas. They tend to be low grade, and treatment is similar to that of mucoepidermoid carcinoma (Fig. 56-7).

### Adenoid Cystic Carcinoma

Adenoid cystic carcinoma is a rare, high-grade salivary gland tumor. Perineural invasion may result in cranial nerve deficits. There is a high incidence of regional nodal metastases, as well as distant metastases to the lungs, liver, and bone. Treatment includes wide surgical resection, neck dissection, and adjuvant radiation therapy.[61]

### Rhabdomyosarcoma

Rhabdomyosarcoma may present as a parotid mass. Histologic variants include undifferentiated and embryonal types (Fig. 56-8). Treatment and outcomes depend on tumor stage and may include wide local surgical resection with radiation and chemotherapy.

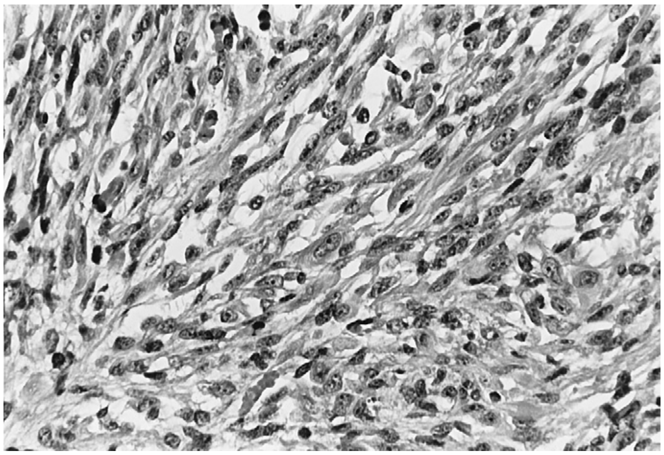

FIGURE 56-8 Rhabdomyosarcoma of the parotid gland showing spindle cell sarcoma with myogenous differentiation. (Hematoxylin-eosin stain, ×100.)

# Surgical Considerations

## PAROTID GLAND

An S-shaped incision is made, beginning in the preauricular crease and extending in a curvilinear fashion to the postauricular region, followed by an inferior extension to 2 fingerbreadths below the angle of the mandible (Fig. 56-9). Skin flaps are elevated, and the greater auricular nerve and posterior facial vein will be identified and may need to be sacrificed to expose the posterior border of the parotid gland. Blunt dissection along the tragal pointer and mastoid process, following the posterior belly of the digastric muscle, will allow visualization of the main trunk of the facial nerve as it emerges from the stylomastoid foramen. Meticulous dissection along the facial nerve branches in an anterior direction will elevate

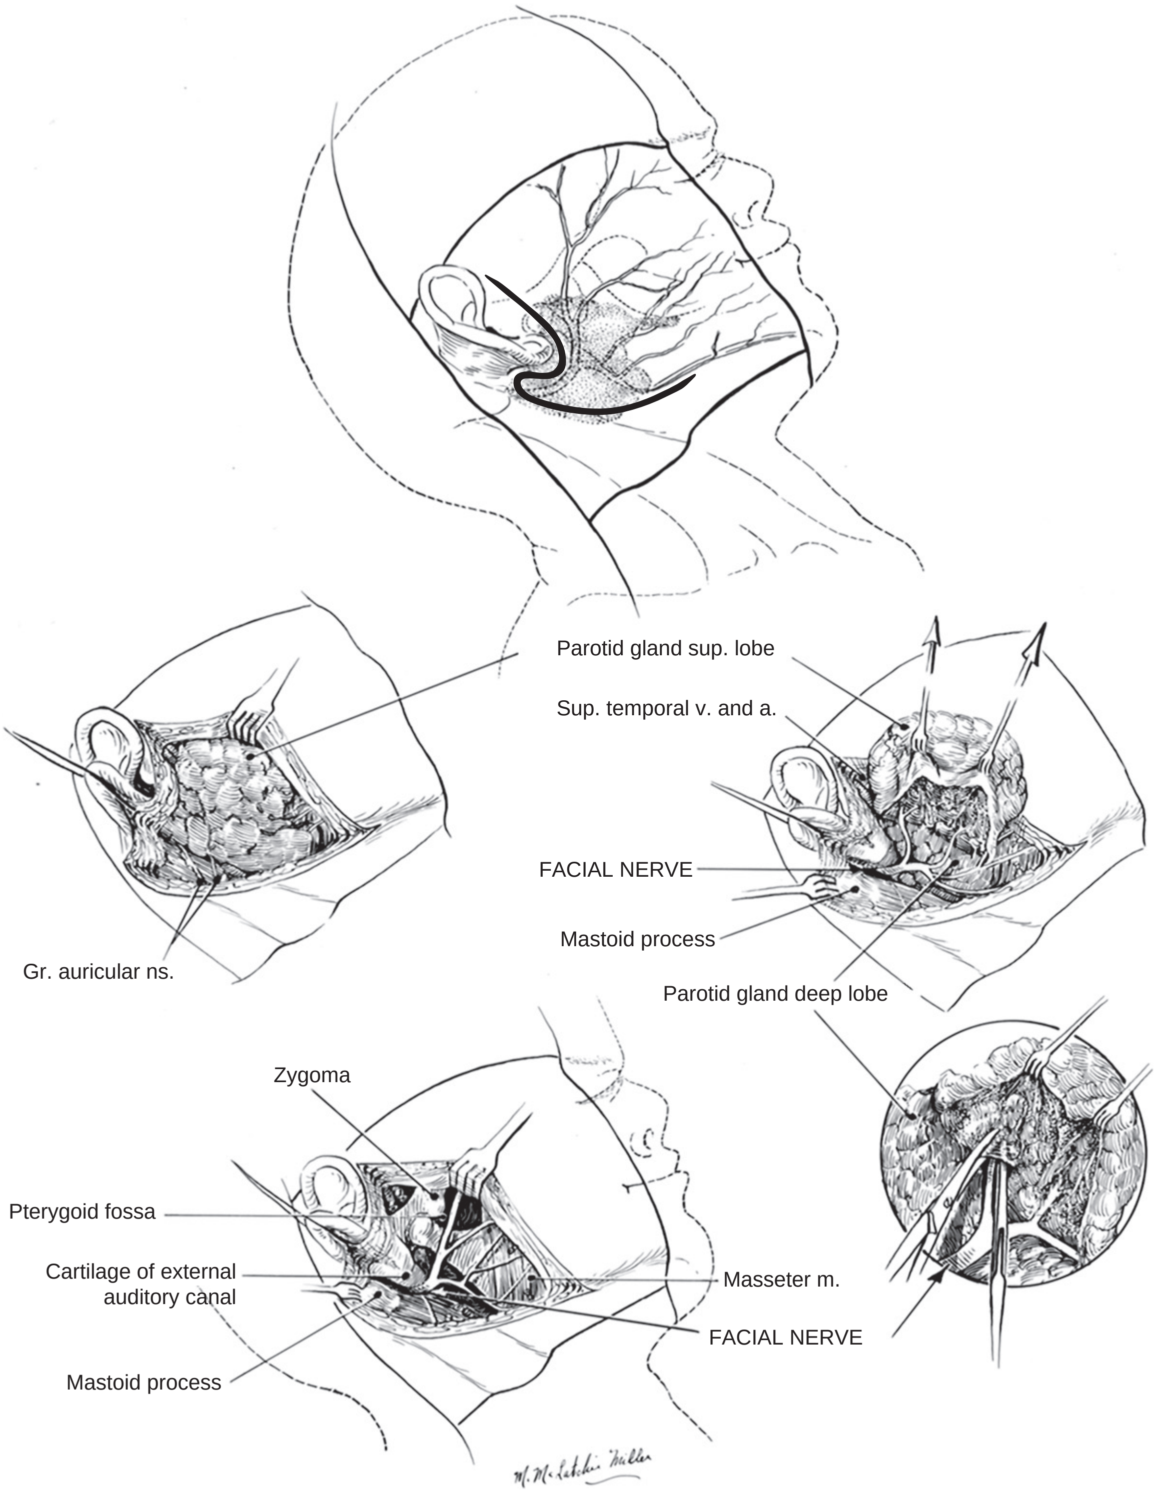

**FIGURE 56-9** Technique for parotidectomy.

the superficial lobe of the parotid gland. Careful blunt dissection, with use of the bipolar cautery and facial nerve monitor, will maximize excellent surgical results with minimal morbidity.[64,67]

### SUBMANDIBULAR GLAND

For submandibular gland resection, a horizontal skin incision is made in a natural skin crease approximately two fingerbreadths inferior to the body of the mandible. The dissection plane is carried to the investing fascia of the submandibular gland. Exposure should reveal the mylohyoid muscle anteriorly, the sternocleidomastoid muscle posteriorly, and the digastric muscle inferiorly. Identification and division of the anterior facial vein, just deep to this fascia, will facilitate protection of the facial nerve. Anterior retraction of the mylohyoid muscle and downward retraction on the submandibular gland will enable identification of the lingual nerve and Wharton duct. Division of the duct will free the lingual nerve from the gland and allow complete blunt dissection of the gland.[66]

## Conclusion

Although salivary gland disorders are rare in childhood, knowledge of the anatomy of the major salivary glands and understanding of both systemic and neoplastic physiology is critical. Neoplasms of the salivary glands are very rare in children and are commonly benign.[31,68] Evaluation and management should be tailored to the specific entity. A multitude of diagnostic tools are available and may include radiologic or pathologic studies.

Inflammatory and infectious disorders are often treated medically, whereas neoplastic disorders require surgical intervention. Patients and families must be counseled regarding potential short-term and long-term complications of facial nerve injury.

Despite the rigorous demands of parotid and submandibular gland surgery, in experienced hands, with adequate monitoring and meticulous dissection and hemostasis, surgical results are excellent.[67]

CHAPTER 57

# Lymph Node Disorders

Faisal G. Qureshi and Kurt D. Newman

Lymphadenopathy is defined as an enlargement or a change in the character of a lymph node. Pathologic lymphadenopathy is usually a symptom of infectious, noninfectious conditions, or, in rare cases, malignant disease. Lymphadenopathy, especially cervical lymphadenopathy, is quite common in childhood, with a reported prevalence of 28% to 55% in otherwise normal infants and children.[1,2] In addition, children have palpable nodes in most of the superficial lymphatic basins, including cervical, axillary, and inguinal regions that are nonpathologic; there is progressive increase in lymphoid mass from birth until early adolescence. This lymphoid tissue then normally diminishes throughout puberty.[3]

Many lymph nodes are palpable in children, and generally, cervical nodes less than 2 cm, axillary nodes less than 1 cm, and inguinal nodes less than 1.5 cm are considered physiologic in young children. Palpable epitrochlear and supraclavicular nodes should, however, be viewed with suspicion and trigger investigations.

The primary goal of a consulting surgeon is to determine the need for a tissue diagnosis. A key consideration is to resolve the family's fears of malignancy in an efficient and cost-effective manner. This chapter focuses primarily on lymphadenopathy in the cervical region. Some comments are made about other regions.

## Anatomy

The regional lymph node groups of the head and neck are shown in Figure 57-1. The precise borders for these groups have been classified by the American Head and Neck Society and are shown in Figure 57-2.[4] Drainage to lymphatic basins usually follows predictable, anatomic routes, with the nomenclature reflecting the site of the lymph nodes. The face and oropharynx drain predominantly to the preauricular, submandibular, and submental nodes; the posterior scalp drains to the occipital nodal group; and the mouth, tongue, tonsils, oropharynx, and nasopharynx drain to superficial and deep chains of the anterior cervical nodes. Significant lymphatic collateralization exists.

## Differential Diagnosis

Most lymphadenopathy is benign in nature and is generally associated with a short duration of symptoms. Table 57-1 shows a list of differential diagnoses. Generalized lymphadenopathy is defined as enlargement of more than two noncontiguous lymph node groups.

### MALIGNANCY

Malignancy accounts for 11% to 24% of the diagnoses, depending on the nature of the group reporting their result. The higher rates are reported in series from oncology practices.[5,6] Malignant processes are more common in the age group of 2 to 12 years old and very rare in the age group of less than 2 years old. Malignancy as a cause is also more common in children with chronic generalized lymphadenopathy, nodes greater than 3 cm in diameter, and nodes in the supraclavicular region. Associated symptoms of night sweats, weight loss, and hepatosplenomegaly also increase the chance of malignancy. Finally abnormal laboratory and radiologic evaluation are associated with increased malignancy rates.[7] Soldes and colleagues reviewed predictors of malignancy in children with peripheral lymphadenopathy and determined that increasing node size, increasing number of sites of adenopathy, and age were associated with an increasing risk of malignancy ($P < 0.05$).[8] In addition, supraclavicular adenopathy, an abnormal chest radiograph, and fixed nodes were all significantly associated with malignancy.

The most common malignancies as a cause of lymphadenopathy are Hodgkin and non-Hodgkin lymphomas, leukemia, and metastatic disease.

## Evaluation

A careful history, physical examination, appropriate laboratory evaluation, and targeted imaging will usually help in deciding the need for tissue sampling. Persistent or progressive new-onset lymphadenopathy of greater than 4 to 6 weeks duration usually triggers a workup by the referring pediatrician. Indeed, most children with acute lymphadenopathy are rarely ever evaluated by pediatric surgeons. Most will improve with antibiotic therapy initiated by their pediatrician or the lymphadenopathy will resolve spontaneously when related to viral illnesses.

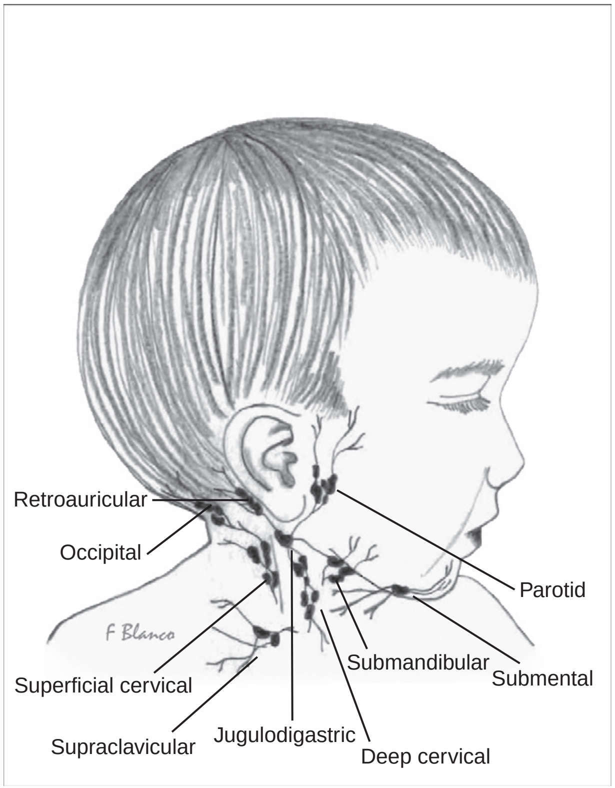

**FIGURE 57-1** Regional lymph node groups of the head and neck.

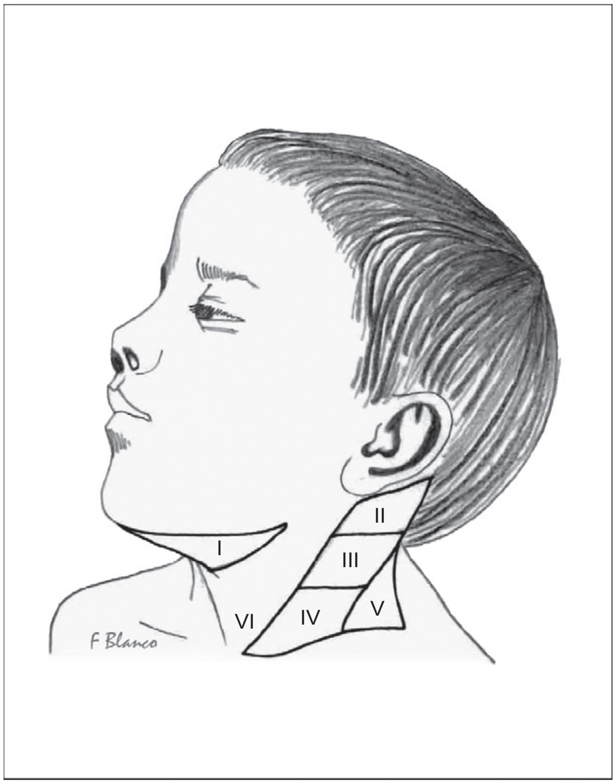

**FIGURE 57-2** Lymphatic node levels of the neck. Level I: submental and submandibular; level II: superior jugular; level III: middle jugular; level IV: inferior jugular; level V: supraclavicular or posterior; and level VI: central or anterior.

**TABLE 57-1**

**Differential Diagnosis of Lymphadenopathy in Children**

| | |
|---|---|
| Generalized lymphadenopathy: infectious | Viral: CMV, HIV, rubella, varicella, measles, EBV, herpes, hepatitis<br>Bacterial: typhoid, tuberculosis, mycobacterial, syphilis, LGV, leptospirosis, brucellosis<br>Protozoal: for instance, toxoplasmosis, leishmaniasis<br>Fungal: for instance, coccidioidomycosis, *Cryptococcus*, histoplasmosis<br>Other: syphilis, Lyme disease |
| Generalized lymphadenopathy: malignant | Lymphoma, leukemia, neuroblastoma, thyroid tumor, metastasis (e.g., osteosarcoma, glioblastoma) |
| Generalized lymphadenopathy: others | Autoimmune disorders: for instance, JRA, SLE, drug reactions, CGD, lymphohistiocytosis, LCH, dermatomyositis<br>Storage disorders: for instance, Gaucher disease, Niemann-Pick disease<br>Miscellaneous: Addison disease, Castleman disease, Churg-Strauss syndrome, Kawasaki disease, Kikuchi disease, lipid storage disease, sarcoidosis |
| Localized lymphadenopathy: infectious | *Staphylococcus aureus,* group A *Streptococcus* (e.g., pharyngitis), anaerobes (periodontal disease), acute bacterial lymphadenitis, cat-scratch disease, tularemia, bubonic plague, diphtheria, chancroid, viral URI, mononucleosis, tuberculosis/atypical mycobacterium |
| Localized lymphadenopathy: malignant | Lymphoma, leukemia, neuroblastoma, rhabdomyosarcoma, parotid tumor, nasopharyngeal tumor, solid tumor metastasis |
| Localized lymphadenopathy: site specific | Cervical: Kawasaki disease<br>Occipital: tinea capitis, pediculosis capitis<br>Preauricular: cat-scratch disease, chronic eye infections<br>Supraclavicular: histoplasmosis, coccidioidomycosis<br>Mediastinal: sarcoidosis, cystic fibrosis, histoplasmosis,<br>Axillary: local infection, brucellosis, immunization reactions, JRA<br>Inguinal: syphilis, LGV, diaper rash |
| Localized cervical masses: non-nodal masses | Mumps, thyroglossal duct, branchial cleft cyst, sternocleidomastoid tumor, cervical ribs, lymphatic malformation, hemangiomas, laryngocele, dermoid cyst |

CGD, chronic granulomatous disease; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HIV, human immunodeficiency virus; JRA, juvenile rheumatoid arthritis; LCH, Langerhans cell histiocytosis; LGV, lymphogranuloma venereum; SLE: systemic lupus erythematosus; URI, upper respiratory infection.

Once a child is referred to a surgeon, important historical questions include duration, progression, location, and associated symptoms, such as pain, fever, weight loss, and night sweats. Additional clinical information includes recent illnesses, especially upper respiratory tract symptoms, infections, trauma, bites, and dental problems. Drug use and sexual activity are important questions, especially in adolescents. Recent immunizations, especially bacillus Calmette-Guérin (BCG) should be evaluated. Social history, including recent travel, animal exposure, and exposure to tuberculosis and tropical diseases should be sought.

Once a general physical examination is completed, including a search for organomegaly, specific evaluation of the enlarged lymph nodes and other nodal basins should be performed. The skin and subcutaneous tissue that is drained by the affected lymph nodes should be evaluated; the characteristics of the lymph node should be noted. Normal nodes are usually soft, mobile, small, and nontender. Lymphadenopathy secondary to infections is also usually soft and can be mobile. However, on occasion, bacterial invasion of lymph nodes can result in erythema, tenderness, and fluctuance. With time, infected nodes can become adherent and have no inflammatory signs. Firm, fixed, nontender rubbery nodes can indicate a neoplastic process in older children.[8]

A thorough history and physical examination usually help separate local from generalized processes and help guide further evaluation, including laboratory and radiologic evaluation.

## INVESTIGATION

### Laboratory Studies

Most patients have had a laboratory evaluation prior to referral to surgery. These tests usually include a complete blood count (CBC) with manual differential, sedimentation rate, and C-reactive protein. However, these are not always helpful in determining the specific etiology of the disease process. Pancytopenia can be seen in leukemia; lymphocytosis is seen with mononucleosis, cytomegalovirus (CMV), and toxoplasmosis.

Based on the history and physical examination, more specific tests for Epstein-Barr virus (EBV), CMV, toxoplasmosis, brucellosis, histoplasmosis, syphilis, bartonellosis, and coccidioidomycosis should be considered. Tests for human immunodeficiency virus (HIV) should also be considered, based on the history as well as the tuberculin skin test.

Serum lactate dehydrogenase should be assayed when suspecting leukemia or lymphoma as a byproduct of high cell turnover.

### Radiologic Evaluation

Diagnostic imaging can be used to determine the characteristic of the lymphadenopathy, identify potential sources of infection, identify mediastinal and abdominal masses, and to help differentiate enlarged lymph nodes from other pathology. Chest radiographs, ultrasonography with Doppler, and computer tomography have all been used in the evaluation of adenopathy.

In children with long-term lymphadenopathy, a two-view chest radiograph is helpful to rule out mediastinal masses that may compress the airway with or without significant symptoms. A chest radiograph should be performed prior to any operative intervention, including biopsies done under general anesthesia. Patients with large mediastinal masses compressing the airway should not undergo general anesthesia, because this could result in airway collapse (see Chapter 38).[9]

Ultrasonography (US) is helpful when the nodes are difficult to palpate and to help differentiate nodes from other structures, such as thyroglossal duct cysts and dermoid cysts in the neck, and undescended testis and inguinal hernias in the groin, US may also be helpful in determining the characteristics of the node. Fluctuance and abscess formation will help guide therapies such as needle aspiration or incision and drainage.

Attempts have been made to use ultrasonography and Doppler characteristics to differentiate neoplastic from non-neoplastic etiologies. Reactive lymphadenopathy is associated with central necrosis, central hyperechogenicity, long to short–axis ratio (>2.0), hilar vascularity, and low pulsatility index.[10–14] However, these modalities are not sensitive or specific enough to primarily rule out neoplastic processes. The decision to delay biopsy diagnosis should not be dependent on US/Doppler findings.

Computed tomography (CT) is useful in patients with mediastinal masses and suspected intra-abdominal malignancies. Airway compromise may be best evaluated by chest CT. Interventional radiologists sometimes use CT scans to help guide biopsies from mediastinal masses.

### Diagnostic Procedures

The decision to proceed with obtaining tissue from the involved lymph node is made in conjunction with the referring physician and after appropriate physical, laboratory, and radiologic evaluation as required. Often, the child has been observed for several weeks prior to referral to a surgeon. Small, soft, mobile nodes should not undergo biopsy, because these are most likely benign unless they are in the supraclavicular region. Tissue diagnosis is helpful when lymph nodes persist or enlarge after adequate antibiotic therapy, when they are associated with signs or symptoms of malignancy, and, finally, if the diagnosis is questioned.

Most authors recommend waiting at least 4 to 6 weeks before obtaining tissue samples. Earlier biopsy should be considered for nodes in the supraclavicular or epitrochlear region, nodes greater than 3 cm in diameter, and for children with a history of malignancy, weight loss, night sweats, fever, or hepatosplenomegaly. Similarly, physical characteristics of the lymph node may also indicate earlier biopsy.[15,16]

***Fine-Needle Aspiration*** Fine-needle aspiration (FNA) has been used extensively in adults, with practical advantages, including its simplicity, speed in the outpatient setting without sedation, as well as its cost effectiveness. In addition, the sensitivity and specificity reaches more than 90%.

The use of FNA in children has increased, especially in countries where tuberculosis is prevalent.[17–20] Aspirates should be sent for Gram stain, acid-fast stain, and cultures for aerobic/anaerobic bacteria, mycobacteria, and fungi.

However, the use of FNA in children has not become universal, because the aspirate usually provides a small sample, which limits the ability to perform flow cytometry, chromosomal analysis, and electron microscopy. Most pediatric hematologists and pathologists prefer excisional biopsy, because it allows the assessment of nodal architecture and permits

the use of special stains. In addition, some children will not permit FNA without some sedation, which negates a primary benefit of FNA. Aspirates may also have a higher rate of false-negative rates in the diagnosis of Hodgkin disease, a common malignant condition in children. Finally, the risk of seeding the needle site tract with malignant cells, although small, is a legitimate concern of physicians and parents alike.[21]

***Excisional Biopsy*** Excisional biopsy provides enough tissue to perform flow cytometry, chromosomal analysis, electron microscopy, and the use of special stains. Indications for an excisional biopsy include

1. Lymph nodes that are hard/matted
2. Lymph nodes fixed to surrounding tissue
3. Progressively enlarging nodes without response to antibiotic therapy
4. Presence of abnormally enlarged nodes after 4 to 6 weeks
5. Supraclavicular, epitrochlear lymph nodes
6. Hepatosplenomegaly
7. Mediastinal or hilar masses
8. Laboratory anomalies, especially anemia, leukocytosis, leucopenia, and thrombocytopenia
9. Symptoms such as fever, weight loss, and night sweats
10. Suspicion of atypical mycobacterial adenitis
11. Diagnostic dilemma

Most excisional biopsies are done under general anesthesia or sedation and, very rarely, under local anesthesia. The biopsy should be coordinated with pathology so that the lymph node can be sent as a fresh specimen. The nodes should not be fixed in formalin. As discussed earlier, a chest radiograph should be obtained to rule out a mediastinal mass that may compromise the airway prior to exposing children to general anesthesia or sedation.

In a recent review, Oguz et al. reviewed their experience with 457 children (2 months to 19 years old) with lymphadenopathy who were referred to their oncology group; 346 (75.7%) had benign processes, and 111 (24.3%) had malignant disease. Of these, 134 patients underwent excisional biopsy for indications highlighted previously. Table 57-2 highlights the findings on excisional biopsy and compares them to findings by other authors.[7]

**TABLE 57-2**
**Excisional Biopsy Results**

| ***Excisional Biopsy Results*** | ***Oguz et al, 2006[7] (n = 134)*** | ***Moore et al, 2003[5] (n = 1332)*** | ***Yaris et al, 2006[21a] (n = 38)*** |
|---|---|---|---|
| Malignant | 79.8% | 11.8% | 50% |
| Hodgkin lymphoma | 40.2% | 6% | |
| Non-Hodgkin lymphoma | 29.1% | 2.1% | |
| Nasopharyngeal cancer | 3.7% | | |
| Thyroid cancer | 2.2% | | |
| Miscellaneous | 4.2% | 3.9% | |
| Benign | 20.1% | 88.2% | 50% |
| Chronic lymphadenitis | 5.9% | 11.3% | |
| Hyperplasia | 5.9% | 47.8% | 25% |
| Tuberculosis | 2.9% | 25% | 15.7% |
| Reactive | 2.2% | | |
| Miscellaneous | 3.2% | 4.1% | |

As can be seen, the pathologic diagnosis varied depending on the reporting group and the associated referral pattern, with higher malignant rates documented by oncology groups[7,21a] and higher infectious rates reported by authors in developing countries.[5]

# Management of Adenopathy

Darville and colleagues have suggested a helpful algorithm for the management of cervical lymphadenopathy (Fig. 57-3).[22] This algorithm is a useful tool to help surgeons determine their role in the management of enlarged lymph nodes. As suggested elsewhere in this chapter, most of the medical evaluation and management has usually been performed by the referring physician; however, it is the surgeon's responsibility to review each case prior to intervention.

## SURGICAL MANAGEMENT

Surgical management is usually limited to diagnostic FNA, excisional biopsy, incision and drainage, and total excision. Further details are provided under the specific conditions discussed later.

## ACUTE LYMPHADENITIS

The most common cause of self-limiting, acute, inflammatory lymph node is a viral infection.[23] Acute bilateral cervical adenopathy is most often caused by a viral respiratory tract infection (rhinovirus, parainfluenza virus, influenza virus, respiratory syncytial virus, coronavirus, adenovirus, reovirus) and is usually hyperplastic in nature.[24] Viral-associated adenopathy does not suppurate and usually resolves spontaneously.

Unilateral lymphadenitis is usually caused by streptococcal or staphylococcal infection in 40% to 80% of the cases.[25] These are usually large (>2 cm), solitary, and tender in the preschool child.[26] The submandibular, upper cervical, submental, occipital, and lower cervical nodes are affected in decreasing order of frequency.[27] Suppurative adenitis is associated with group A streptococcal or penicillin-resistant staphylococci. *Staphylococcus* infection leading to lymphadenitis seems to occur more commonly in infants.[28] Other less frequent causal organisms include *Hemophilus influenzae* type B, group B streptococci, and anaerobic bacteria. Community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) is now more commonly being isolated from superficial abscesses and suppurative lymphadenitis in children. Clindamycin is an appropriate agent to use under these circumstances.[25,29]

Suppurative lymphadenitis presents with local inflammatory signs, including unilateral tender adenopathy involving the submandibular or deep cervical nodes draining the oropharynx. Erythema, fever, malaise, and signs of systemic illness may occur. The primary infection in the head and neck regions should be looked for with careful attention to the oropharynx and middle ear. Appropriate treatment should be started, usually an empirical 5- to 10-day course of an oral β-lactamase–resistant antibiotic. Intravenous antibiotics should be started if systemic signs are present or in very young infants. A response should be observable within 72 hours, and failure of therapy usually necessitates additional diagnostic testing. This is usually fine-needle aspiration or ultrasonography.

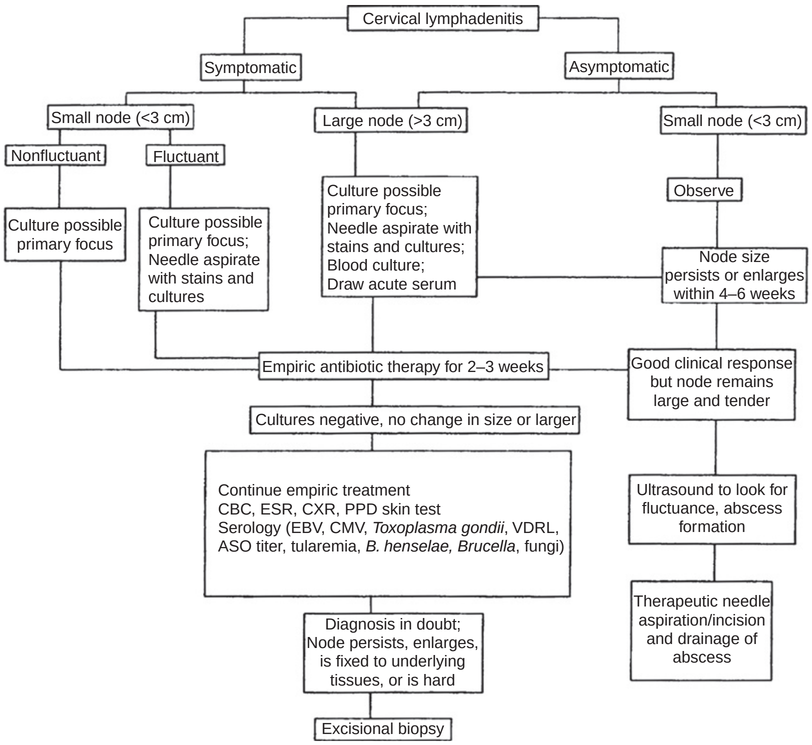

**FIGURE 57-3** Evaluation and treatment algorithm. ASO, antistreptolysin titer; CBC, complete blood count; CMV, cytomegalovirus; CXR, chest radiograph; EBV, Epstein-Barr virus; ESR, erythrocyte sedimentation rate; PPD, purified protein derivative; VDRL, Venereal Disease Research Laboratory. (Reprinted with permission from Elsevier.[22])

Aspirate culture by FNA can guide further organism-specific antibiotic treatment, including clindamycin if MRSA is encountered. If no fluid is aspirated, sterile saline can be injected and then aspirated to obtain material for culture.[26] In addition, repeated aspiration together with antibiotics is an effective treatment for fluctuant lymphadenitis.[30] As stated previously, however, FNA may require sedation or anesthesia in young children.

Ultrasonography may help to differentiate between solid and cystic masses and can identify fluid that may require operative drainage. Incision and drainage is a more definitive surgical approach to suppurative fluctuant lymphadenitis. Gauze packing has been used to prevent early skin closure and achieve hemostasis; however, the use of minimal incisions, with vessel loops functioning as drains, has been gaining wider acceptance recently.[31]

## PERSISTENT LYMPHADENITIS

Persistent lymphadenitis that does not resolve despite 2 to 4 weeks of appropriate therapy warrants additional diagnostic workup. Some common causes of persistent lymphadenitis are discussed in this section.

### Atypical Mycobacterial Adenitis

The genus *Mycobacterium* is characterized on light microscopy to be bacilli distinguished by their dense lipid capsules. The lipid capsules resist decolorization by acid alcohol after staining and thus are termed *acid-fast bacilli*. In the United States, 70% to 95% of mycobacterial lymphadenitis cases are caused by atypical mycobacteria (nontuberculous strains). The most common agents include *M. avium-intracellulare, M. scrofulaceum, M. fortuitum,* and *M. chelonei*.[32] In contrast to tuberculous adenitis, atypical (or nontuberculous) mycobacterial adenitis is generally considered a local infectious process, without systemic involvement in immunocompetent hosts. Disseminated disease is more commonly observed in patients with underlying acquired or congenital immunodeficiency states. Atypical mycobacterial adenitis is not contagious, and the portal of entry in otherwise healthy children is the oropharynx.[33]

Atypical mycobacterial adenitis usually occurs in young children between 1 and 5 years of age. The common clinical presentation is focal, unilateral involvement of the jugulodigastric, preauricular, or submandibular nodal group. There is rapid onset of nodal enlargement, and the skin gradually develops a pink or red hue; with time, the overlying skin becomes thin.[26] In contrast to acute suppurative lymphadenitis, there is no response to first-line antibiotics, and the clinical course is described as indolent, with the involved nodal group being minimally tender, firm, and rubbery to palpation, well circumscribed, and sometimes adherent to underlying structures. Although remarkably nontender, these lesions develop a draining sinus tract in 10% of patients.[34,35] Signs of systemic illness or inflammation are usually minimal or nonexistent. Chest radiographs are usually normal.

Differentiating atypical mycobacterial and mycobacterial tuberculous cervical lymphadenitis can occasionally be challenging, based purely on epidemiologic and clinical features. Age (<5 years), race (white), place of residence (rural), bilaterality (rare) all point toward atypical mycobacterial infection. Purified protein derivative (PPD) skin testing in

children with atypical mycobacterial lymphadenitis can result in an intermediate reaction because of cross reactivity, usually less than 15 mm. Blood interferon-gamma release assay is emerging as the discriminating test of choice; it was originally described for pulmonary disease but is now being used for nodal disease as well.[36] Other criteria that point toward a diagnosis of tuberculous lymphadenitis are (1) a positive PPD, (2) abnormal chest radiograph, and (3) contact with a person with infectious tuberculosis. Spyridis and colleagues have shown that fulfilling two of three criteria results in diagnosis of tuberculous lymphadenitis with a 92% sensitivity.[37]

Unlike tuberculous adenitis, atypical mycobacterial adenitis generally does not respond to chemotherapy. The treatment of choice is complete surgical excision with primary wound closure. In a literature review of the surgical treatment of atypical mycobacterial cervicofacial adenitis in children, excision, incision and drainage, curettage, and needle aspiration were compared across 16 studies. The cure rates were 92%, 10%, 86%, and 41%, respectively.[38] Incision and drainage should be avoided, because it often results in a chronically draining sinus. There have been reports of adequate medical treatment of atypical mycobacterial lymphadenitis; however, in a recent multicenter randomized trial comparing surgical excision and antibiotics, surgical excision was superior, with a 96% cure rate compared with 66% with antibiotic therapy.[39] Multidrug antibiotic therapy, usually including clarithromycin and rifabutin, may be used as an adjunct for unresectable or recurrent disease.[40] Surgical treatment should include elliptic excision of the overlying skin when it is thinned out, debridement of subcutaneous granulation tissue, and complete excision of the involved node(s) with closure of the overlying skin; formal lymph node dissection is not required. Curettage is recommended only if surgical excision is not possible because of unacceptable cosmetic outcomes or risk of injuries to adjacent nerves. A nerve stimulator may be helpful for lesions at the angle of the mandible to avoid injury to branches of the facial nerve.

### Mycobacterial Adenitis

In developed countries, tuberculous adenitis or scrofula is almost exclusively caused by *M. tuberculosis*. Before control of bovine tuberculosis, the predominant cause of tuberculous adenitis was *M. bovis*. Occasional cases of *M. bovis* are observed from underdeveloped regions in which consumption of contaminated raw meat occurs. Patients proven to have human tuberculous adenitis often report previous exposure to a known carrier of tuberculosis, but most patients do not have active disease on a chest radiograph.[37] Differentiation between tuberculosis and atypical mycobacterial adenitis has been highlighted previously. Tuberculous adenitis is considered to be a local manifestation of a systemic disease and not an initial primary focus of tuberculous infection.[41]

Clinically, children with tuberculous adenitis are usually older and present with nonsuppurative lymphadenitis, which may be bilateral.[42] A retrospective review of 24 immunocompetent children with tuberculous lymphadenitis showed that no patient had bilateral disease, and the submandibular (29%) and the anterior cervical (71%) sites were the only areas of involvement.[37] However, posterior triangle nodal involvement does occur.

The diagnosis of tuberculous adenitis can be made on the criteria established by Spyridis and colleagues[37] and positive acid-fast bacteria on stain or culture of nodal tissue. Diagnostic confirmation may be aided by FNA with aspirate culture and cytologic examination.[43] Rapid diagnosis of tuberculous adenitis by DNA amplification of nodal material using polymerase chain reaction (PCR) has been reported.[44] Blood testing and PPD are also used. A negative tuberculin PPD test essentially excludes the diagnosis of tuberculous adenitis. If a diagnostic dilemma persists, surgical excisional biopsy is warranted. Incisional biopsy or incision and drainage should be avoided to prevent development of chronic, draining sinus tracts.[23,45] Fistula and cheloid formation can be seen in up to 100% of patients who undergo incision and drainage of tuberculous infected lymph nodes.[37]

Tuberculous adenitis generally responds to medical management that consists of multiple-agent chemotherapy. The World Health Organization recommends directly observed short-course therapy, including isoniazid, rifampin, ethambutol, and pyrazinamide for the first 2 months, followed by isoniazid and rifampin for an additional 4 months.[46] Nodal regression usually occurs within 3 months. Although antituberculous chemotherapy remains essential, the role of complete surgical excision of involved nodes is more controversial.[47] Complete excision of involved nodes is prudent when biopsy is required for diagnosis, when a chronically draining sinus tract evolves during medical treatment, or when optimal medical management fails.

## CAT-SCRATCH DISEASE

Cat-scratch disease is a common cause of lymphadenitis in children, with an estimated incidence in the United States of 9.3 per 100,000 ambulatory pediatric and adult patients per year.[48] The highest age-specific incidence is among children younger than 10 years of age.[2] Current microbiologic and PCR-directed DNA analysis demonstrates that the pleomorphic, gram-negative bacillus *Bartonella henselae* (formerly *Rochalimaea)* is the causative organism of cat-scratch disease.[49] Most cases can be directly related to contact with a cat, and the usual site of inoculation is an extremity. Subsequent adenitis occurs at regional lymphatic drainage basins (inguinal, axillary, epitrochlear nodes) 5 days to 2 months later.[50] Similarly, cervical lymphadenopathy is observed with scratches in the head and neck region. Although the primary manifestation of *Bartonella henselae* infection is lymphadenopathy, some series report up to 25% of cases resulting in severe systemic illnesses.[51]

Initial infection occurs at the portal of entry in the skin, such as a scratch or bite. Papule formation may be observed at the site of inoculation in 3 to 5 days, with development of subacute lymphadenopathy at regional nodal drainage beginning within 1 to 2 weeks. Early systemic symptoms of fever, malaise, myalgia, and anorexia are commonly reported.

Although most cases involve the lymph nodes of limbs, approximately 25% of cases involve the cervical nodes.[50] Diagnosis is based on a history of exposure to cats, presence at a site of inoculation, and regional lymphadenopathy. Identification of *Bartonella henselae* from involved lymph nodes using Warthin-Starry silver impregnation stain has

traditionally been used for diagnosis, but the stain has been found to be unreliable and lacking specificity. PCR for *Bartonella henselae* using paraffin sections from lymph nodes or other tissue is more reliable and specific.[52] To confirm diagnosis without obtaining tissue, many centers use serologic testing, which has been available for several years; it has a low sensitivity but is highly specific.[53]

Lymphadenitis associated with cat-scratch disease is usually benign, self-limiting, and resolves within 6 to 8 weeks without specific treatment.[54] Antibiotic treatment has thus been controversial, although azithromycin has been associated with rapid resolution of the adenitis.[55] Suppuration is unusual; however, if it occurs, needle aspiration may provide symptomatic relief. Excisional biopsy is generally unnecessary but may be warranted if a draining sinus tract develops or if the diagnosis is uncertain and the potential for malignancy cannot be excluded.

## MISCELLANEOUS LESIONS

Various other infectious and inflammatory conditions can produce lymphadenopathy in infants and children. Most patients with these disorders do not require surgical management or, in particular, excisional biopsy of the lesions. A systematic approach to evaluation of these patients, as outlined previously, generally leads to the correct diagnosis. Surgical management of these lesions should be directed to patients who present diagnostic dilemmas and have nodal disease in suspicious areas, or have persistent adenopathy despite adequate medical therapy.

### Infectious Lymphadenopathy

Lymphadenopathy caused by infectious agents include toxoplasmosis (caused by *Toxoplasma gondii*), tularemia (caused by *Francisella tularensis),* and mononucleosis (caused by Epstein-Barr virus). Infection with *Actinomyces israelii* in the head and neck may lead to cervicofacial actinomycosis that is characterized by a woody indurated cervical mass and development of chronic, draining fistulas. Direct involvement of the lymph nodes is uncommon, but the induration can make the clinical differentiation difficult.[56] Infection with HIV can produce general lymphadenopathy in infants and children.[57]

### Inflammatory Disorders

Inflammatory disorders include Kawasaki disease, Kikuchi disease, Castleman disease, and Rosai-Dorfman disease.

*Kawasaki disease,* or mucocutaneous lymph node syndrome, is a febrile disorder of childhood that is characterized in part by the abrupt onset of erythematous changes in the oropharyngeal mucosa, acute vasculitis, and extensive nonsuppurative, nontender cervical adenopathy.[58] Diagnosis is made on clinical grounds, and the resolution of the nodal disease occurs relatively quickly in the course of the disease.

*Kikuchi disease*, or histiocytic necrotizing lymphadenitis, may present as cervical lymphadenopathy that resolves spontaneously. It typically presents in the older child with bilateral, painful cervical nodes. There are associated fevers, night sweats, splenomegaly, leucopenia with atypical lymphocytosis, and elevated erythrocyte sedimentation rate (ESR). This disease can be clinically confused with malignant disease, and the patients often appropriately undergo excisional biopsy for definitive diagnosis.[59]

*Castleman disease,* also called angiofollicular or giant lymph node hyperplasia may also occasionally present as a solitary, enlarged cervical lymph node. The enlarged node appears hypervascular on US/Doppler or CT scan. Surgical excision is curative in the localized form.[60] The multicentric form of the disease, often accompanied by visceral involvement, is considered a type of lymphoproliferative disorder and requires systemic therapy.

*Rosai-Dorfman disease,* or sinus histiocytosis with massive lymphadenopathy, is a rare disorder affecting predominantly African-American children in the first decade of life. Disease progresses from unilateral cervical adenopathy to massive bilateral cervical involvement and extension to other nodal groups or extra nodal sites. The disorder is benign but has a slow rate of resolution spanning 6 to 9 months. Excisional biopsy may aid diagnosis.[61]

## MALIGNANT DISORDERS

Although lymphoma is the most common malignant disorder manifested by cervical adenopathy, neuroblastoma and thyroid carcinoma are other childhood cancers that can present as enlarged cervical lymph nodes.

*Lymphomas* are one of the more common malignant conditions in children. They may present as primary neck adenopathy that does not resolve with antibiotics or is enlarging. Patients with congenital or acquired immunodeficiency states, including HIV infection, are at greater risk for developing malignant lymphoproliferative conditions. Excisional biopsy is often used to help diagnose lymphomas.

In *neuroblastoma,* adenopathy is usually bilateral. These patients often have stage 4 disease, and if the primary is not evident on examination and radiologic evaluation, excisional biopsy is performed for initial diagnosis of neuroblastoma.

*Metastatic thyroid carcinoma* may present with unilateral cervical lymph node enlargement that should not be mistaken for ectopic thyroid gland. If a thorough neck examination does not reveal a thyroid nodule, and a history of neck irradiation or other high-risk factors is obtained, thyroid ultrasonography should be performed as part of the evaluation of neck lymphadenopathy.

# Summary

Most adenopathy in children is nonpathologic and spontaneously resolves. Pathologic lymphadenopathy has a large differential diagnosis, with viral lymphadenitis being the most common. Surgical consultation is often obtained when the lymph nodes do not spontaneously resolve, if there is concern for malignancy, or if there is a diagnostic dilemma. Most of the investigation is usually performed prior to surgical consult, but the surgeon must be aware of an adequate workup prior to intervention. The surgeon's role is usually limited to excisional biopsy, incision and drainage, and, rarely, aspiration in children, depending on the pathology suspected. FNA for diagnosis has a more limited role in children but may be useful in selected cases.

CHAPTER 58

# Childhood Diseases of the Thyroid and Parathyroid Glands

Hannah G. Piper and Michael A. Skinner

Diseases of the thyroid and parathyroid glands are relatively uncommon in the pediatric population. The incidence of thyroid nodules is estimated to be 20 per 1000 children, and the incidence of hyperparathyroidism is approximately 4 per 100,000 children.[1,2] However, although rare, there is a wide range of pathology, both benign and malignant, with which pediatric surgeons must remain familiar. Surgery plays a central role in the management of many of these disorders, including thyroid nodules, parathyroid adenomas, and, occasionally, goiter and hyperthyroidism.

## Thyroid Embryology and Physiology

The thyroid begins to form 24 days after fertilization and is both the first and the largest of the endocrine glands in the developing embryo. The thyroid commences as an endodermal outpouching on the floor of the primordial pharynx and becomes the thyroid diverticulum. This diverticulum then descends from the pharynx, passing anterior to the hyoid bone and maintains a connection to the base of the tongue, known as the thyroglossal duct. The migration is usually complete by 7 weeks of gestation, at which point the thyroglossal duct is obliterated. Initially, the thyroid diverticulum is hollow but then becomes solid cellular parenchyma with both a right and left lobe. The cells are arranged in spherical units called follicles, which are filled centrally with proteinaceous colloid. Parafollicular cells, or C cells, derived from neural crest cells, are found between the follicles and are the source of calcitonin. In approximately 50% of people, a pyramidal lobe extends superiorly from the isthmus. Infrequently, there will be an ectopic thyroid gland found along the normal route of descent. A lingual thyroid is the most common ectopic location, representing 90% of cases.[3] When present, a lingual thyroid is usually the only thyroid tissue and can sometimes be mistaken for accessory thyroid tissue or a thyroglossal duct cyst. Ectopic tissue will often produce insufficient amounts of hormones and can become secondarily enlarged; therefore care must be taken to avoid inadvertent removal of the only viable thyroid tissue.[4,5] Accessory thyroid tissue can also be found anywhere along the normal pathway of thyroid descent, as seen in Figure 58-1, but these remnants are usually insufficient in size to have any normal function.

Thyroid follicular cells are responsible for the synthesis of thyroid hormones. This begins when tyrosine molecules within thyroglobulin are iodinated to form monoiodotyrosine (MIT) and diiodotyrosine (DIT), neither of which is biologically active. Active hormone synthesis occurs when either two DIT molecules couple to form thyroxine ($T_4$), accounting for 90% of excreted hormone, or one DIT and one MIT molecule combine to form triiodothyronine ($T_3$), accounting for about 9% of excreted hormone. Thyroid-stimulating hormone (TSH) is the main stimulus for hormone production and release and is produced by the anterior pituitary gland. TSH release, in turn, is controlled by thyrotropin-releasing hormone (TRH) produced in the hypothalamus. Circulating thyroid hormone is reversibly bound to carrier proteins, most commonly thyroxine binding globulin (TBG) and has a wide range of physiologic effects. Children with congenital hypothyroidism are at risk for significant neurologic impairment, delayed bone development, and decreased metabolism. In contrast, infants and children with hyperthyroidism may have tachycardia with increased cardiac output, excessive sweating, weight loss, and tremors.

The parafollicular cells produce calcitonin, a 32–amino acid polypeptide. Calcitonin lowers serum calcium and phosphate by inhibiting bone resorption and likely plays a role in calcium deposition after a postprandial serum rise. Interestingly, there are no known definitive complications in humans from either excess or deficient calcitonin.

## Evaluation of the Thyroid Gland

Proper evaluation of a child with potential thyroid disease begins with a focused history inquiring about symptoms of hyperthyroidism or hypothyroidism as well as any family history of thyroid disease or multiple endocrine neoplasia. This is followed by a detailed examination of the neck. The thyroid should be palpated to evaluate size, consistency, symmetry, and whether there are any nodules or associated enlarged

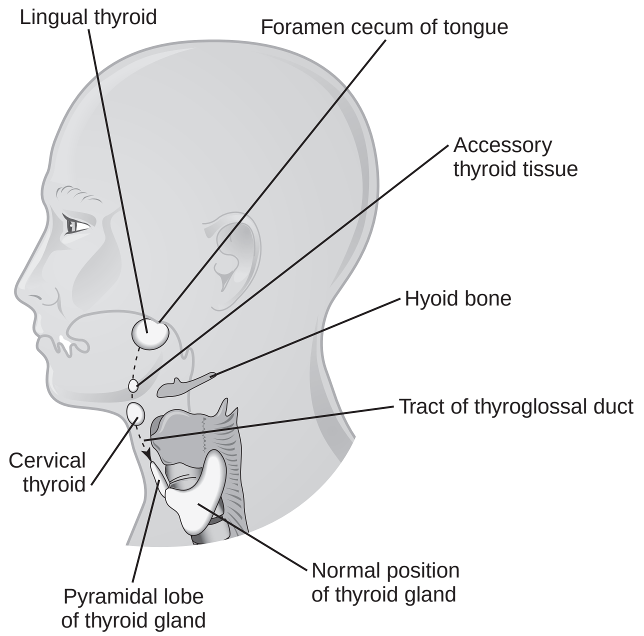

**FIGURE 58-1** Usual sites of ectopic thyroid tissue. The broken line demonstrates the path of normal thyroid descent. (Reprinted from The Pharyngeal (Branchial) Apparatus: In Moore K, Persaud TVN: The Developing Human: Clinically Oriented Embryology, ed 6. Philadelphia, WB Saunders, 1998, p 233; with permission from WB Saunders.)

lymph nodes. Certain features on physical exam are suggestive of specific disease processes. For example, diffuse enlargement can be seen in Graves' disease and Hashimoto and endemic goiter. A tender gland can be found with an acute inflammatory process, multiple nodules are more common in a metabolic or inflammatory process, and a single nodule is more likely to be neoplastic. Other worrisome signs suggestive of a neoplasm are rapid growth, hardness, fixation to surrounding structures, and enlarged cervical nodes.

Useful laboratory tests include measurement of TSH, which when elevated, suggests hypofunction and when suppressed suggests elevated hormone circulation. To estimate circulating thyroid hormone, a plasma free $T_4$ level can be measured. Plasma total $T_4$ and $T_3$ can be measured along with thyroglobulin to properly calculate unbound, active hormone.

Finally, thyroid imaging may be necessary. Ultrasonography (US) can be used to evaluate cysts and nodules and can be helpful in following these lesions over time. In addition, US can be used to help guide FNA for diagnostic purposes. Features on US suggestive of malignancy include hypoechogenicity, microcalcifications, irregular margins, and hypervascularity.[6] Radionuclide scintigraphy is also occasionally useful for thyroid imaging. In patients with suppressed TSH iodine-131 ($^{131}$I) or technetium-99m ($^{99m}$Tc) can be used to identify hyperfunctioning areas of the thyroid gland. Scintigraphy can also be used to assess for recurrent disease or metastatic disease in the setting of malignancy. An emerging imaging technique is single-photon emission computed tomography (SPECT), which gives a more three-dimensional view of increased uptake. This can also be combined with traditional CT (SPECT/CT) to add anatomic detail, increasing both the sensitivity and specificity over conventional scintigraphy,[7] as seen in Figure 58-2.

# Non-neoplastic Thyroid Conditions

## GOITER

A goiter is an enlargement of the thyroid gland that can be diffuse or nodular in nature, and patients can be euthyroid, hypothyroid, or hyperthyroid. The most common cause worldwide is iodine deficiency, resulting in hypertrophy secondary to substrate deficiency. However, in locations with

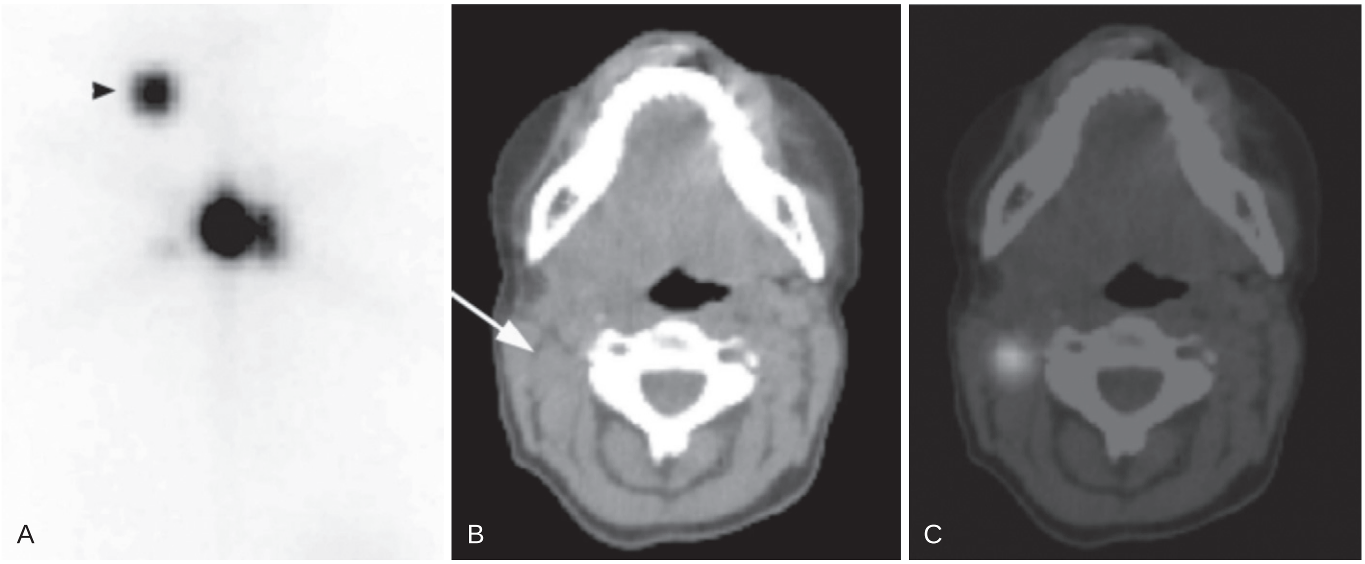

**FIGURE 58-2** SPECT/CT for nodal localization: cervical nodal metastasis in a 12-year-old girl. **A,** Planar image shows a single focus in the right upper neck *(arrowhead)* and two foci of activity in the central neck. **B** and **C,** Computed tomography (CT) and fused single-photon emission computed tomography (SPECT)/CT localizes the right upper neck focus to an enlarged lymph node *(arrow)*. (Reprinted from Wong KK, Zarzhevsky N, Cahill JM, et al: Hybrid SPECT-CT and PET-CT imaging of differentiated thyroid cancer. Br J Radiol 2009;82:860-876, 2009; with permission from the British Journal of Radiology.)

adequate dietary iodine intake, most patients will have simple colloid goiter and maintain normal thyroid function. For the most part, this type of goiter requires no specific therapy, because the rate of regression is no different whether or not the patient is treated with hormone suppression.[8] Surgery is indicated if the goiter grows so large that there is significant airway compression or if there is a nodule that is concerning for possible malignancy.

## THYROIDITIS

Inflammation of the thyroid gland can have several different etiologies, including autoimmune, viral, bacterial, or an infiltrative fibrous process. The most common type of thyroiditis in children is chronic lymphocytic or Hashimoto thyroiditis. Hashimoto thyroiditis is an autoimmune process in which antibodies against thyroid antigen are produced, resulting in a lymphocytic infiltrate within the gland. It often occurs in association with other autoimmune disorders, such as type I diabetes, Addison disease, systemic lupus and juvenile arthritis, as well as in children with Down and Turner syndromes. Initially, patients may be euthyroid or hyperthyroid, but this can be transient, and eventually hypothyroidism may ensue. Usually, the management is expectant with about 30% of patients, demonstrating resolution over time. Exogenous thyroid hormone should be provided to patients who are hypothyroid but does not seem to have any meaningful effect on reducing the size of the goiter or decreasing progression of disease in euthyroid patients.[9]

Other forms of thyroiditis, although rare, can also be seen in children, as listed in Table 58-1. Subacute thyroiditis is thought to be viral in nature, and patients often present with fever and gland tenderness in the setting of a recent upper respiratory infection. Initially, there may be excessive hormone release, followed by transient hypothyroidism. About 10% of patients develop permanent hypothyroidism. In most cases, nonsteroidal anti-inflammatory medication or low-dose corticosteroids is the only treatment required. Acute suppurative thyroiditis is bacterial in origin, can present with hard nodules, and be diagnosed on ultrasonography or with fine-needle aspiration (FNA). Treatment is with antibiotics, drainage if necessary, and, very rarely, thyroid lobectomy. Many cases formerly called acute suppurative thyroiditis are the result of a third or fourth branchial pouch remnant, also called pyriform sinus fistula. This should be suspected, especially when the infection presents in the left superior pole (see Chapter 59). Ideally, treatment is with antibiotics, followed by excision of the fistula tract to the pyriform sinus.[10]

## HYPOTHYROIDISM

The primary cause of congenital hypothyroidism is abnormal thyroid gland development rather than from a problem with the hypothalamic-pituitary-thyroid axis. Most commonly, it is secondary to either thyroid dysgenesis or agenesis and, less commonly, from defects in thyroid hormone synthesis or from the transfer of maternal thyroid blocking antibodies. Dietary iodine deficiency in utero can also lead to hypothyroidism, and in those cases, a palpable goiter may be appreciated. $T_4$ is essential for myelinization of the central nervous system during the first 3 years of life. Deficiencies in $T_4$ can lead to intellectual disability, which is completely preventable if recognized.[11] Newborn screening for hypothyroidism is essential and involves measuring TSH. Some states also require measuring $T_4$, which will allow for rare cases of central hypothyroidism to be detected. However, if these tests are normal but symptoms persist, it is important to maintain a high index of suspicion, because up to 50% of cases of central hypothyroidism will have a normal newborn screen.[12] In older children with acquired hypothyroidism, presenting signs and symptoms include a decline in linear growth, fatigue, constipation, and poor school performance. Preteens or teenagers may complain of dry skin, thin hair, weight gain, and menstrual irregularities. The most common causes of pediatric hypothyroidism can be seen in Table 58-2.

## HYPERTHYROIDISM

Graves' disease, or diffuse toxic goiter, is the most common cause of hyperthyroidism in children, with an incidence of 0.02%,[13] and it is approximately 5 times more common in girls than in boys. Thyroid gland hypertrophy occurs because antibodies against the TSH receptor bind and mimic the effect of TSH. Patients usually present with a firm, smooth goiter and symptoms of hyperthyroidism. Occasionally, there can be fibroblast deposition in the eyes, leading to exophthalmos, or in the skin, leading to pretibial myxedema, although these findings are less common in children. Severe hyperthyroidism is sometimes seen with associated hyperthermia and tachycardia, referred to as thyroid storm, and initial treatment includes active cooling and propanolol.

Usually, first-line therapy for Graves' disease is antithyroid medication (methimazole or propylthiouracil), and improvement in symptoms can occur within 1 month of treatment. Treatment is maintained for 12 to 18 months, during which time thyroid function is monitored routinely.[14] Remission is achieved in 30% of children after the first course of medication, and risk factors for relapse include young age and severe

**TABLE 58-1**
**Types of Thyroiditis**

| *Histopathology* | *Eponym* | *Etiology* | *Goiter* | *TSH* | *$T_4$* | *Thyroid Function* |
|---|---|---|---|---|---|---|

biochemical hyperthyroidism at the time of diagnosis.[15,16] Because of the relatively low remission rate, some advocate the use of radioactive iodine ($I^{131}$). The radioactive iodine is ingested and then incorporated into the thyroid. The radiation to thyroid cells leads to gland ablation over the following 6 to 18 weeks. However, this is not recommended for children less than 5 years of age, and most patients will be made hypothyroid after treatment requiring hormone replacement therapy.

Surgery is also an option for some children with Graves' disease, usually for those who have very large goiters, are unable to take antithyroid medication, or cannot tolerate radioactive iodine. Surgery is also the treatment of choice if there is any concern of underlying malignancy in the gland. The preferred operation continues to be debated. In a large meta-analysis looking at more than 7000 adult patients, there were no cases of recurrent disease after total thyroidectomy versus an 8% recurrence rate after subtotal thyroidectomy. The incidence of other complications, including injury to the recurrent laryngeal nerve or hypoparathyroidism, did not differ between the two groups.[17]

# Neoplastic Thyroid Conditions

## MANAGEMENT OF THYROID NODULES

Thyroid nodules are less common in children than in adults, with an incidence of 1% to 2%.[2] However, when found, there is a 16% to 27% chance that the nodule will be malignant, which is far greater than the estimated 5% in the adult population.[18,19] In general, discrete lesions that are distinct from the surrounding thyroid tissue and are equal to 1 cm should be investigated. This begins with a history and physical exam, as well as measuring serum $T_4$ and TSH levels. The utility of imaging is less clear, especially in children. Some advocate that if a nodule is functional on scintigraphy, no further workup is required; however, this must be practiced with caution because, although rare, functional nodules can still harbor malignancy. Ultrasonography can be useful for measuring the size of a nodule, determining if it is solid or cystic, and locating it within the gland. Certain features on ultrasonography can raise or lower the suspicion of malignancy; for example, an entirely cystic lesion has a very low probability of being malignant. However, ultrasonography cannot definitively make the diagnosis of a malignancy.[6] The use of FNA for cytologic evaluation is now the most accurate diagnostic intervention in adult patients[20] and is standard in the workup of a thyroid nodule. FNA is also commonly used in children and adolescents, with the goal of trying to reduce diagnostic thyroid surgery for benign lesions. The question that is raised is whether this test has a low enough false-negative rate to justify its use in the pediatric population. Most would agree that for adolescents FNA can be used reliably, because it has an accuracy of at least 90%, and any potential delay in diagnosis will not likely result in decreased survival. Because younger children have a higher incidence of malignancy in any thyroid nodule, there has been some reservation in relying on FNA.[21] However, FNA results are useful for planning a resection (thyroidectomy versus hemithyroidectomy) in this population. A recent meta-analysis supporting the use of FNA included 12 studies collectively reviewing 183 patients with malignant nodules and 347 patients with benign nodules, the age range being 1 to 21 years. The analysis found that FNA has a sensitivity of 94% and specificity of 81% for detecting malignancy.[22] A selection of individual studies included in the analysis can be seen in Table 58-3.[18,23–27] In part, FNA is not very specific because when the cytology reveals follicular cells, malignancy cannot be determined because the diagnosis hinges on the presence of capsular invasion, which can only be seen on histology.[28,29] Overall, FNA is a useful tool in the workup of pediatric patients with thyroid nodules but should not overshadow other important clinical information, such as a history of radiation or prior malignancy; the family history; enlarging, fixed nodules; or associated cervical lymphadenopathy.

If FNA is performed, the results are reported as benign, malignant, or indeterminate. Resection is indicated for malignant or indeterminate nodules, or for benign nodules that continue to grow or have other worrisome features on follow-up.

## WELL-DIFFERENTIATED THYROID CARCINOMA

Well-differentiated thyroid cancer (WDTC) includes papillary and follicular cell tumors, accounting for approximately 1% of malignancies in prepubertal children and up to 7% in

adolescents, making it the most common endocrine cancer in the pediatric population.[13] Thyroid cancer occurs at least 4 times as often in females as males and is most common in white patients.[30] The overall incidence does appear to be increasing in children at a rate of approximately 1.1% per year. This is potentially because of a rise in the use of radiotherapy for other malignancies.[31] Head and neck radiation has been widely recognized as a significant risk factor for the development of WDTC. Patients exposed to as little as 50 cGy prior to the age of 4 years have presented 10 to 30 years later with thyroid cancer.[32] Malignancies with the strongest correlation with a secondary thyroid cancer include Hodgkin and non-Hodgkin lymphoma, neuroblastoma, and Wilms' tumor.[33] It is therefore important to provide careful follow-up for children who have been successfully treated for cancer.

On a molecular level, there is increasing evidence that the *RET* (rearranged during transfection) proto-oncogene plays a role in WDTC. The *RET* proto-oncogene is a tyrosine kinase receptor that, when exposed to radiation, can fuse to another gene to form a hybrid oncogene (*RET/PTC*), resulting in increased tyrosine kinase activity.[34] Even more common is for WDTC to be caused by an activating mutation in the B isoform of the Raf kinase (BRAF). These cancers tend to be larger at the time of presentation and may have a poorer prognosis.[35]

Papillary cancer is the most common type of thyroid cancer seen in children but also has the best survival, with estimates of 98% at 5 years. Follicular cancer is about 6 times less common, with approximately 96% survival at 5 years.[30,36]

In general, the treatment of WDTC in children is similar to that of adults. However, it must be taken into consideration that children often present with larger tumors, are more likely to have metastatic spread to cervical nodes, have a higher recurrence rate, and have a longer overall survival.[37] The primary therapy is surgical resection of the gland with or without lymph node dissection, depending on whether there is clinical evidence of nodal disease.[38] There continues to be some debate regarding how much of the gland should be resected. The surgical options include total thyroidectomy, near-total thyroidectomy (leaving less than 1 g of tissue near the ligament of Berry), subtotal thyroidectomy, and hemithyroidectomy. The argument for more aggressive resection revolves around decreased recurrence rates, the ability to treat residual disease with radioiodine ablation therapy, and the ability to assess for recurrence by following thyroglobulin levels. In addition, some surgeons prefer total or near-total thyroidectomy in the setting of malignancy, because at least 50% of children will have bilateral or multifocal disease.[39] In a retrospective review of 68 children who were less than 19 years of age and undergoing thyroid surgery for malignancy, 75% had a total thyroidectomy, 9% had a lobectomy, and 6% had a subtotal thyroidectomy. Forty-four percent of patients who had less than a total thyroidectomy needed further surgery for recurrence compared with only 12% of patients who had a total thyroidectomy, which was a significant difference.[36] Similarly, a larger, recent review of 215 children with papillary thyroid cancer also found that recurrence rates were significantly higher in children having undergone lobectomy compared with total or near-total thyroidectomy (35% vs. 6%).[40] However, mortality from thyroid cancer in children is very low, with 98.8% overall survival at 10 years, and therefore it is unclear whether the increased recurrence rate affects mortality.

Support for less-than-total thyroidectomy is based upon minimizing potential morbidity from the operation. Estimates of complications after total thyroidectomy vary widely, depending on the series and the time frame of the study, ranging anywhere from 12% to 20%.[36,41,42] Two of the most significant complications are injury to the recurrent laryngeal nerves and permanent hypoparathyroidism. For an experienced surgeon, the incidence of recurrent laryngeal nerve injury is less than 1%, and it is less than 2% for permanent hypoparathyroidism.[43] However, a recent study found that incidental removal of parathyroid glands occurs in up to 21% of thyroid surgeries and is not clearly dependent on the extent of resection.[44] A retrospective review of 1200 children undergoing thyroid and parathyroid surgery found that hypocalcemia accounted for 68% of the complications, and voice disturbances accounted for another 6%. Interestingly, they also found that the complication rates were age dependent: 22% in children less than 6 years, 15% in children aged 7 to 12 years, and 11% in children aged 13 to 17 years, and these differences were statistically significant.[45] It does appear that surgeons with more experience and a higher case volume of thyroid surgery have fewer complications. In a study by Tuggle and colleagues,[46] surgeons were classified as high volume (>30 cases per year), pediatric (>90% of cases were children), or other. A total of 607 patients were included in the study, and the authors found that high-volume surgeons, on average, performed 72 thyroid procedures per year, pediatric surgeons performed 2 thyroid procedures per year, and other surgeons performed 7 thyroid procedures per year. The complication rates were 8.7%, 13.4%, and 13.2%, respectively.

One strategy to reduce the incidence of hypoparathyroidism is to autotransplant one or two of the glands into the sternocleidomastoid, which can be done immediately during the dissection if the blood supply is thought to be compromised.[47] To minimize injury to the recurrent laryngeal nerve, intraoperative nerve stimulation can be used, which can help identify its course during dissection.[48,49]

Unfortunately, the recurrence rate for thyroid cancer in children after surgical resection is up to 32% when followed for 40 years.[40] For this reason, long-term follow-up for these children is required. Current recommendations for children who have had a total or near-total thyroidectomy include a $^{131}$I whole-body scan 6 weeks after thyroid resection to assess for any residual disease, and treatment with the radionuclide can be administered as needed, at this time, for remnant ablation.[50] These children can then be monitored for recurrence by checking annual plasma thyroglobulin and antithyroglobulin antibody levels, as well as obtaining an annual neck ultrasound scan. Further whole-body radionuclide scanning is unnecessary for children with low-risk tumors, undetectable thyroglobulin levels, and negative neck US. Annual scans can be considered for patients with intermediate- or high-risk tumors but should be done with a low-activity radionuclide.[51]

There is now evidence that radiation exposure from radioiodine remnant ablation (RRA) may predispose children to other malignancies. This potential risk must be carefully considered given the low mortality (<2%) associated with thyroid cancer. In a recent review of 215 patients less than 21 years of age with papillary thyroid cancer, there were no disease-associated deaths within the first 20 years following surgery. In addition, none of the patients with distant metastases died of their disease. It was found that recurrence rates of local and

distant disease were lower in patients treated with RRA, but this did not reach statistical significance. Interestingly, they did report a statistically higher mortality rate from secondary malignancy compared with an aged-matched control group. Of the patients in the study who died of a secondary malignancy, 73% had received RRA. This does not prove the association, but it does raise some concern.[40]

### MEDULLARY THYROID CANCER

Medullary thyroid cancer (MTC) arises from the parafollicular cells of neuroectodermal origin and accounts for approximately 5% of thyroid cancers. MTC that arises sporadically usually involves only one lobe, whereas cases of familial inheritance usually involve both lobes. Inherited MTC includes the multiple endocrine neoplasia type 2 syndromes (MEN2A and MEN2B) as well as familial medullary thyroid cancer. In general, hereditary medullary thyroid cancer begins with parafollicular cell hyperplasia and then progresses to invasive microcarcinoma, followed by macroscopic disease if left untreated. The *RET* proto-oncogene also plays an important role in medullary thyroid cancer, including not only familial but also 40% of sporadic cases,[52–55] and *RET* testing is used to make the diagnosis of MEN2. When there is a germline *RET* mutation, the aberrant protein is expressed in all of the tissues in which it is produced, leading to MEN2 or familial medullary thyroid cancer. Sporadic MTC occurs when there is a somatic mutation with aberrant protein expression only in the thyroid.[56] Although essentially all patients with MEN2A will eventually develop medullary thyroid cancer, MTC in MEN2B tends to develop earlier and is in general more aggressive.[35] Because of this, when families are known to carry the *RET* mutation, genetic testing should be performed before 5 years of age in families with MEN2A and even earlier for MEN2B. Less clear is the age at which to perform prophylactic thyroidectomy. On the one hand, the goal is to perform thyroidectomy well before the onset of metastatic disease, after which point cure can be difficult,[56] but on the other hand it is also important to minimize the risks to the recurrent laryngeal nerve and parathyroid glands, which are at higher risk in smaller children. Determining the ideal age for thyroidectomy has been based upon numerous criteria, including the age of the youngest family member to develop cancer, the mean age of onset for a particular genotype, and yearly neck ultrasound findings.[57–59] It is known that for MEN2A, microinvasive carcinoma can be seen in children as young as 5 years of age.[60] The most current recommendations have been established by the American Thyroid Association (ATA) and are guided by the fact that the risk of developing MTC correlates with specific *RET* mutations where different codons are known to have different clinical behavior.[61] There are four risk categories—ATA-A having the lowest risk and ATA-B through ATA-D almost always resulting in MTC.[62] Specific recommendations based on these risk categories are seen in Table 58-4. In general, a central neck node dissection is not necessary during prophylactic thyroidectomy for children, unless there is evidence of nodal disease.[63] For patients with a suspicion of sporadic medullary thyroid cancer, serum calcitonin levels are useful for screening.[62] Treatment after the diagnosis of established medullary cancer includes total thyroidectomy with central node dissection of all nodal tissue from the hyoid bone to the sternal notch and to the carotid sheaths laterally. Preoperative neck ultrasonography is recommended for all children with medullary thyroid cancer to assess for nodal disease.[64] Children can then be followed with serum calcitonin and carcinoembryonic antigen (CEA) levels, which reliably correlate with disease recurrence. Survival in patients with established medullary thyroid cancer has been most recently reported as 96% at 5 years and 86% at 15 years.[30] Novel therapy in adults with metastatic medullary thyroid cancer includes the use of an oral RET inhibitor that blocks kinase signaling. There is evidence that the inhibitor may halt disease progression in the adult population.[65] To date, similar studies have not been done in children.

## Parathyroid Embryology and Physiology

The parathyroid glands arise from the third and fourth pharyngeal pouches, which are paired endoderm-lined structures between the branchial arches. By the sixth week of gestation, the dorsal aspects of the third and fourth pouches differentiate into the inferior and superior parathyroids, respectively. The ventral aspects of the third pouches form the thymus and the ventral aspects of the fourth pouches develop into the ultimobranchial body, which eventually fuses with the thyroid to supply the parafollicular cells that produce calcitonin. The thymus and parathyroid glands then lose their connection to the pharynx and descend into the neck. Typically the parathyroid glands migrate to the posterior aspect of the thyroid gland, where they obtain their blood supply from the thyroid capsule. However, there is significant variability in the eventual location of the parathyroid glands, as seen in Figure 58-3. They are variable in both location and number and can be found anywhere in the vicinity of the thyroid or thymus. The superior glands tend to be more consistent in their location than the inferior glands.

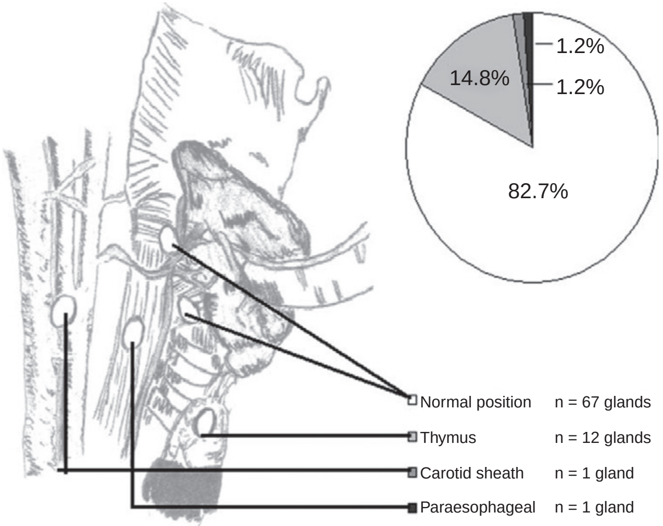

**FIGURE 58-3** Location of parathyroid glands found and removed during primary parathyroidectomy. (Reprinted from Schlosser K, Schmitt CP, Bartholomaeus JE, et al: Parathyroidectomy for renal hyperparathyroidism in children and adolescents. World J Surg 2008;32:801-806; with permission from Springer.)

The parathyroid glands regulate calcium and phosphorous by secreting parathyroid hormone (PTH). PTH is an 84–amino acid protein with a very short half-life that is primarily metabolized by the liver and kidney. PTH secretion is normally stimulated by a drop in circulating calcium and is then inhibited by a negative feedback loop. An increase in serum phosphorus also indirectly stimulates PTH secretion by lowering serum calcium. PTH also acts directly on bones by increasing osteoclast activity, on the kidneys by increasing renal calcium absorption, and on the gastrointestinal (GI) tract by increasing vitamin D activation.

# Disorders of the Parathyroid Glands

## DiGEORGE SYNDROME

DiGeorge syndrome is a congenital disorder characterized by athymia or thymic hypoplasia and absence of the parathyroid glands due to failure of the third and fourth pharyngeal pouches to differentiate. Infants are hypocalcemic and also have increased susceptibility to infection. Additional associated characteristics can include shortened philtrum, low set ears, nasal clefts, thyroid hypoplasia, and cardiac anomalies, especially truncus arteriosum. Treatment is largely symptomatic and includes supplementation with calcium and vitamin D. Emerging therapies include replacement with synthetic PTH[66] and thymus transplantation for children with severe immunodeficiency.[67]

## HYPERPARATHYROIDISM

There are several forms of hyperparathyroidism, all of which lead to excessive PTH secretion. In the case of primary hyperparathyroidism, this results from one or more abnormal parathyroid glands. In secondary hyperparathyroidism, elevated PTH is in response to hypocalcemia, and in tertiary hyperparathyroidism, PTH remains elevated despite correction of the hypocalcemia. Both secondary and tertiary types are seen in the setting of renal disease. Neonatal severe hyperparathyroidism (NSHPT) is a rare disorder that presents with severe hypercalcemia resulting from a homozygous loss-of-function mutation with four-gland hyperplasia. Treatment has traditionally been with a three and one half–gland parathyroidectomy or total parathyroidectomy with autotransplantation. More recently, there has also been some success with medical management with bisphosphonates.[68]

In general, hyperparathyroidism presents clinically with symptoms related to elevated calcium or is suspected when hypercalcemia is found incidentally. However, the differential diagnosis of hypercalcemia in children is quite broad, and this must be kept in mind during the initial evaluation, as outlined in Table 58-5. For example, familial hypocalciuric hypercalcemia is an autosomal dominant condition resulting from a mutation in the calcium sensing receptor. Children have elevated serum calcium but can be distinguished from having hyperparathyroidism by detecting decreased 24-hour urinary calcium levels. PTH levels are often within the normal range. Usually these children are completely asymptomatic, and no specific treatment is required. This condition should be excluded prior to considering parathyroid resection for hypercalcemia.

The incidence of primary hyperparathyroidism in children is estimated to be 2 to 5 per 100,000.[69] In contrast to adults, children may present with more serious effects of hypercalcemia, including renal failure, cardiac arrhythmias, and osteopenia.[2] When suspected, the diagnosis can be confirmed by measuring serum calcium and PTH. Most commonly, there will be a solitary parathyroid adenoma, and there are several localization studies that can be used to identify the abnormal gland. The imaging options include ultrasonography,

$^{99m}$Tc-sestamibi planar scintigraphy, SPECT, SPECT/CT, and/or magnetic resonance imaging (MRI). Because of the rarity of parathyroid adenomas in children, most of the studies used to compare techniques have been done in adults. In one study by Munk and colleagues,[70] ultrasonography and $^{99m}$Tc-sestamibi scans were in agreement 70% of the time and, when in agreement, identified the correct gland in 97% of cases. When these tests were not in agreement, MRI was used, and if consistent with either an ultrasound or $^{99m}$Tc-sestamibi scan, the correct gland was identified 100% of the time. There were six patients (11%) in whom there was no definitive agreement among the three tests. More advanced scintigraphy is now being used (SPECT), which allows for a three-dimensional reconstruction, and this can also be combined with traditional CT (SPECT/CT), allowing for more anatomic detail.[71] However, whether the added detail improves accurate localization is still debated.[72] If localization is successful, a directed resection can then be used instead of the traditional four-gland exploration. However, in the hands of an experienced surgeon, this remains a very reliable approach. To confirm resection of the adenoma, intraoperative PTH measurement can be used. The half-life of PTH is approximately 3 to 4 minutes, and at least a 50% decrease from baseline should be observed to confirm removal of the abnormal parathyroid.[73] An example of a typical decline can be seen in Figure 58-4. It is important to follow the PTH level far enough out to ensure the decline is not temporary, which can be seen with multiple-gland disease.[74] If the PTH remains elevated, a complete cervical exploration should be pursued. If a normal parathyroid is resected or devascularized during thyroid surgery, the gland should be autotransplanted into the forearm or sternocleidomastoid.[75] Hyperparathyroidism is also seen in the setting of multiple endocrine neoplasia and is usually the result of four-gland hyperplasia. The surgical options include resection of only visibly enlarged glands, three and one half–gland parathyroidectomy, or total parathyroidectomy with autografting.[76,77]

Secondary and tertiary hyperparathyroidism are most commonly seen with end-stage renal disease and affect all four glands. Usually, this can be managed with dietary modifications, dialysis, phosphate binders, and vitamin D. However, vitamin D analogs and calcimimetics have not been approved for long-term use in children because of concern for interference with longitudinal growth and the possible impact on timing of puberty.[78] There is some debate as to whether the optimal surgical management is total parathyroidectomy with autotransplantation or subtotal parathyroidectomy, but the preferred management in the United States tends to be the former.[75,79]

# Parathyroid Carcinoma

Parathyroid carcinoma is exceedingly rare in children, with only seven case reports in the literature to date. In all cases, the patients presented with a neck mass and severe hypercalcemia with extremely elevated PTH (3 to 10 times normal). The first step in management is to control the hypercalcemia, followed by surgical excision if appropriate. The recommended resection includes en-bloc hemithyroidectomy, parathyroidectomy, and lymph node dissection. If completely resected, 90% long-term survival can be achieved. However, with incomplete resection, the recurrence rate is up to 50%.[80]

# CHAPTER 59

# Neck Cysts and Sinuses

Craig Lillehei

Cysts and sinuses of the neck represent a wide variety of anomalies, both congenital and acquired. The focus of this chapter is on those of congenital origin. It is a fascinating opportunity to apply our understanding of embryologic development to the spectrum of malformations seen and to guide appropriate management. The most common lesions arise from thyroglossal duct or branchial anomalies (particularly from the second cleft). Nonetheless, one must be cognizant of the range of usual variants as well as the broad differential diagnosis. Lymphatic and vascular malformations will be addressed elsewhere (see Chapter 125). Although present at birth, congenital lesions may not become evident for weeks, months, or even years. However, there are recognizable patterns. Accurate diagnosis guides appropriate intervention. Proper identification is aided by careful history and physical examination. Age at presentation, evolution, anatomic location, and associated drainage are often important diagnostic clues. Radiographic studies, such as ultrasonography or cross-sectional imaging (computed tomography [CT], magnetic resonance imaging [MRI]), may be helpful in selected cases. Although the exact identity is not always evident preoperatively, an awareness of differential diagnostic possibilities will guide the prepared mind and improve prospects for optimal outcomes. The emphasis is total excision of the lesions to minimize the risks of recurrence, infection, or malignancy. Knowledge of the relevant local anatomy and adjacent structures is crucial to safe surgical dissection.

## Embryology

During the fourth week of gestation, neural crest cells migrate into the future head and neck region. A series of six paired branchial or pharyngeal arches begin to develop (Fig. 59-1). In humans the fifth arch, if present, is only very short lived. Their mesoderm is covered externally by ectoderm and lined internally by endoderm. Each arch contains a distinct artery, nerve, cartilage rod, and muscle. These arches are separated by depressions that are referred to as clefts on their external ectodermal surface, and pouches on their internal endodermal surface. These swellings may give rise to normal cervical structures, leave pathologic remnants, or involute entirely. In fish and amphibians, the closing membranes that separate the branchial pouches and clefts regress with the resultant connections forming gills.[1]

Each branchial arch and its components can be traced to the formation of future anatomic structures as outlined in Table 59-1. The first branchial arch forms the mandible and a portion of the maxilla. It is also involved in structures of the inner ear. The first cleft and pouch connect to form the eustachian tube/middle ear, tympanic membrane, and external auditory canal. The other branchial cleft components usually regress. However, it is important to note that during development the second, third, and fourth branchial clefts share a common external opening, the cervical sinus of His (Fig. 59-2, *A*). For this reason the location of the external opening of a persistent sinus or fistula from these clefts cannot be used to distinguish between them.

The remaining pouches give rise to normal glandular structures (Fig. 59-2, *B*). The palatine tonsil and supratonsillar fossa originate from the second pouch. The tonsils are the only structures to remain at their pouch of origin. The third pouch gives rise to the thymus and inferior parathyroid glands, while the fourth pouch is responsible for the superior parathyroid glands. It is believed that the calcitonin-producing cells of the thyroid gland arise from the ultimobranchial body, probably a remnant of the ventral portion of the caudal pharyngeal complex formed by the fourth and vestigial fifth pouch (see Fig. 59-2).

The thyroid gland arises from an endodermal thickening in the floor of the primitive pharynx called the tuberculum impar (see Fig. 59-1). A bilobate diverticulum develops between the anterior and posterior muscle complex of the tongue. As the embryo elongates this anlage descends anterior to or through the eventual location of the hyoid bone and fuses with elements of the fourth and fifth branchial pouches to form the thyroid gland. This descending median thyroid anlage gives rise to the thyroglossal duct, which usually obliterates by the fifth week of gestation.[2] The proximal remnant of this pathway is the foramen cecum at the base of the tongue, whereas the distal remnant is represented by the pyramidal lobe of the thyroid gland (Fig. 59-3). Cystic remnants or accessory thyroid tissue can remain anywhere along this tract (Fig. 59-4).

Note that the second arch grows over the third and fourth arches, thereby burying the second, third, and fourth pharyngeal clefts. **B,** Remnants of the second, third, and fourth pharyngeal clefts form the cervical sinus, which is normally obliterated. Note the structures formed by the various pharyngeal pouches. (From Sadler TW: Head and neck. In Langman J, Sadler TW (eds): Langman's Medical Embryology, ed 7. Baltimore, Williams & Wilkins, 1995.)

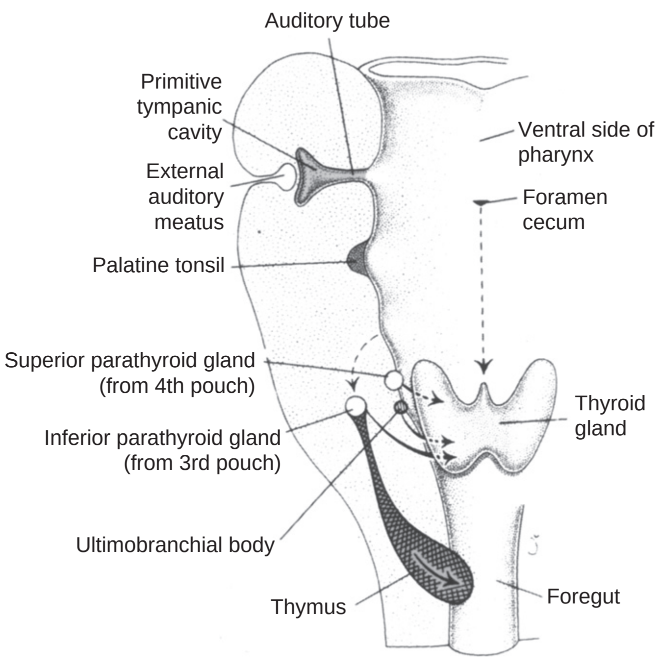

**FIGURE 59-3** Schematic representation of migration of the thymus, parathyroid glands, and ultimobranchial body. The thyroid gland originates in the midline at the level of the foramen cecum and descends to the level of the first tracheal ring. (From Sadler TW: Head and neck. In Langman's Medical Embryology, ed 7. Baltimore, Williams & Wilkins, 1995.)

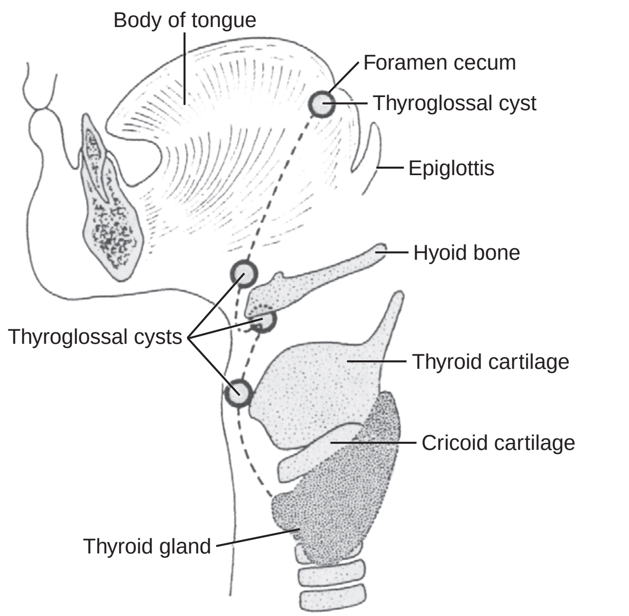

**FIGURE 59-4** Various locations of thyroglossal duct cysts. (From Sadler TW: Head and neck. In Sadler TW (ed): Langman's Medical Embryology, ed 11. Baltimore, Lippincott Williams & Wilkins, 2010.)

Although the exact incidence varies between different pediatric series, thyroglossal duct remnants are typically the more common etiology of congenital neck cysts or sinuses, followed closely by branchial cleft remnants.[3–5] In general, thyroglossal duct lesions lie close to the midline, whereas branchial remnants present more laterally in the neck, although atypical locations have been described.[6]

## Thyroglossal Duct Cysts

Thyroglossal duct remnants are clearly the most common midline congenital cervical anomalies. As described, they occur along the path of thyroid descent from the foramen cecum at the base of the tongue to the lower neck. The remnants usually lie in close proximity to the hyoid bone. Given this relationship one can appreciate why the cysts often move cephalad with swallowing or tongue protrusion. Although classically described as midline, up to 40% may lie just lateral to the midline. Most lesions present as cystic masses, but up to 25% have a draining sinus.[7] Because the thyroglossal duct

does not communicate with ectoderm during development, the sinus is either the result of spontaneous rupture, infection, or a prior drainage procedure. Approximately 60% of thyroglossal duct cysts are adjacent to the hyoid bone, 24% lie above the hyoid, and 13% lie below.[8] The remaining 8% of cysts are intralingual and may pose a risk for acute airway obstruction, particularly in the neonate.[9] Most thyroglossal duct cysts present during the first 5 years of life.[2]

In view of the potential communication with the oral cavity, it is not surprising that the cysts may fluctuate in size or that approximately one third of patients present with an active infection of the cyst or history of prior infection.[2] Some patients may actually report noticing a foul taste. The most common pathogens are *Haemophilus influenzae, Staphylococcus aureus,* and *Staphylococcus epidermidis*.[7,10]

The thyroglossal duct remnants are lined by ductal epithelium and may contain solid thyroid tissue. In fact, in roughly 1% to 2% of patients with presumed thyroglossal duct cysts, the actual lesion is a median ectopic thyroid.[8] It may represent their only functional thyroid tissue in which case excision would be problematic. Further evaluation may be obtained with a screening thyroid-stimulating hormone (TSH) level and neck ultrasonography. If there is evidence of hypothyroidism or the mass appears solid without a visible normal thyroid gland, one might wish to obtain a thyroid scan to determine whether there is any additional thyroid tissue. Such patients are often hypothyroid with an elevated TSH, which is responsible for the hypertrophy of the ectopic tissue. In the setting of hypothyroidism, hormonal supplementation would be appropriate and might promote shrinkage of the hypertrophic thyroid tissue, thereby obviating the need for surgery.

## SURGICAL MANAGEMENT

The primary indication for excision of thyroglossal duct remnants is to avoid problems with recurrent infection. However, malignancy within thyroglossal duct remnants is also well described.[11] Such tumors usually present as papillary carcinoma in adults, but pediatric cases are reported, and multiple cell types have been encountered.[12–14]

Appropriate surgical management of uncomplicated thyroglossal duct disease involves complete resection of the cyst and its tract in continuity with the central hyoid bone, as described by Sistrunk.[15] One should be aware that in young children the hyoid bone may override the thyroid notch, potentially placing the larynx at risk. The patient is positioned supine with the head elevated and neck extended. A transverse cervical incision is used to carefully mobilize the cyst along with its tract. The underlying hyoid bone is divided about 1 cm from the midline on either side after dividing the attachments of the mylohyoid and hyoglossus muscles from its superior border. En-bloc resection is completed with suture ligation of the proximal tract, prior to removal of the specimen (Fig. 59-5). Elegant studies of resected surgical specimens by Horisawa and colleagues, as depicted in Figure 59-6, demonstrate the importance of this strategy to achieve complete excision, thereby reducing the likelihood of recurrence.[16]

In the setting of acute infection, initial efforts are aimed to control the infection. If antibiotics alone are insufficient, aspiration or incision and drainage of the cyst/abscess may be required. Once the infection is well-controlled, the described Sistrunk procedure can be performed using an elliptic skin incision around the cutaneous opening to permit excision of this tract in continuity with the remainder of the specimen.

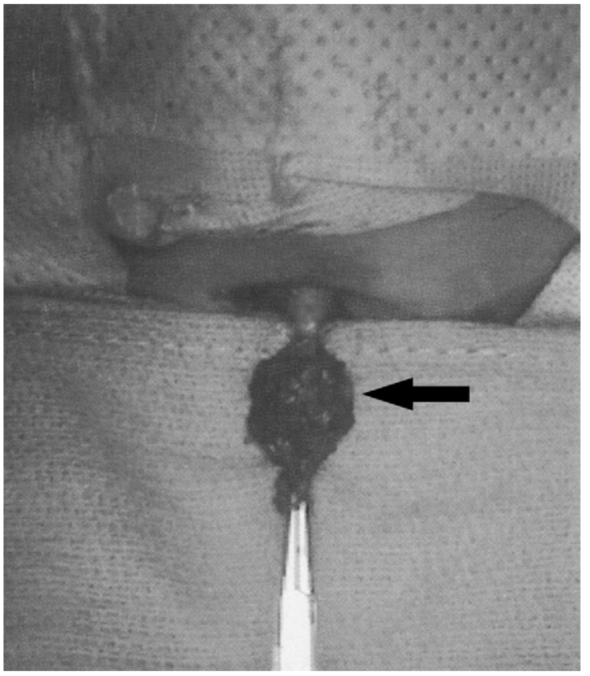

**FIGURE 59-5** Sistrunk procedure: intraoperative photograph of resection of thyroglossal duct cyst in continuity with central hyoid bone *(arrow)*.

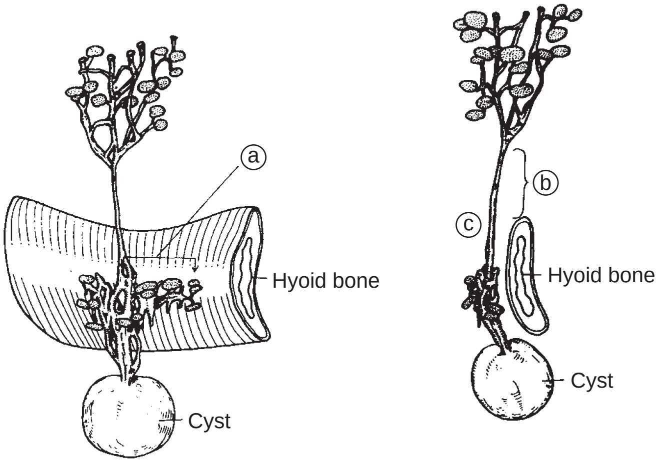

**FIGURE 59-6** Diagram of the common running pattern of the thyroglossal duct based on anatomic reconstruction. *a,* Horizontal distance from midline to the most distant thyroglossal duct; *b,* length of the single duct above the hyoid bone; *c,* point where the diameter of the duct is measured. (From Horisawa M, Niinomi N, Ito T: What is the optimal depth for core-out toward the foramen cecum in a thyroglossal duct cyst operation? J Pediatr Surg 1992;27:710-713.)

Recurrences after thyroglossal duct excisions may occur in up to 10% of cases.[17,18] The most likely cause is incomplete excision of the tract or intraoperative rupture. An association with preoperative infection has been suggested,[19,20] but not confirmed in more recent analyses. Postoperative infection is clearly associated with recurrence, but it is uncertain whether this development represents cause or effect.[18] Excision of a recurrent thyroglossal duct remnant has a 20% to 35% risk of failure.[10,21] Wider resection is recommended, including the pyramidal lobe if present, central strap muscles, additional hyoid bone, and residual tissue up to the foramen cecum.[17,22]

## Branchial Anomalies

Most branchial cleft anomalies arise from the second cleft/pouch, with a much smaller proportion from the first. Remnants of the third or fourth pouches are rare. It is the internal opening of branchial sinuses that best defines their embryologic origin. The anomalies may present as fistulae, cysts, sinus tracts, or cartilaginous remnants and are thought to arise from incomplete obliteration during embryogenesis. To clarify, cysts have mucosal or epithelial lining, but no external openings. Sinuses may communicate either externally with the skin or internally with the pharynx, whereas fistulae connect to both. When an external tract is present, branchial anomalies are usually diagnosed within the first decade of life. However, when there is no external opening the diagnosis may be delayed into adulthood. Up to 10% of these lesions are bilateral as depicted in Figure 59-7.[23,24] The presence of preauricular pits in patients with branchial anomalies should raise the suspicion for the branchio-oto-renal (BOR) and branchio-oculo-facial (BOF) syndromes. Both are autosomal dominant conditions with associated hearing loss, ear malformations, and renal anomalies in the BOR syndrome, while BOF includes eye anomalies, such as microphthalmia and obstructed lacrimal ducts, and facial anomalies consisting of cleft or pseudocleft lip/palate.[24,25]

It is worth mentioning that short sinus tracts, pedunculated skin appendages or subcutaneous cartilaginous remnants are often encountered in the anterior neck and upper chest. These structures are probably branchial remnants, but cannot usually be ascribed to a specific arch. Lesions presenting below the clavicles are more likely epidermoid or dermoid cysts rather than branchial remnants. Most often elective excision is used.

### SECOND BRANCHIAL ANOMALIES

Second branchial cleft anomalies typically lie somewhere between the lower anterior border of the sternocleidomastoid (SCM) muscle and tonsillar fossa of the pharynx. They may be in close proximity to the glossopharyngeal and hypoglossal nerves as well as carotid vessels as the tract travels through the carotid bifurcation and over the nerves to enter the lateral pharyngeal wall as depicted in Figure 59-8.

**FIGURE 59-7** Child with bilateral second branchial cleft sinuses *(arrows)*.

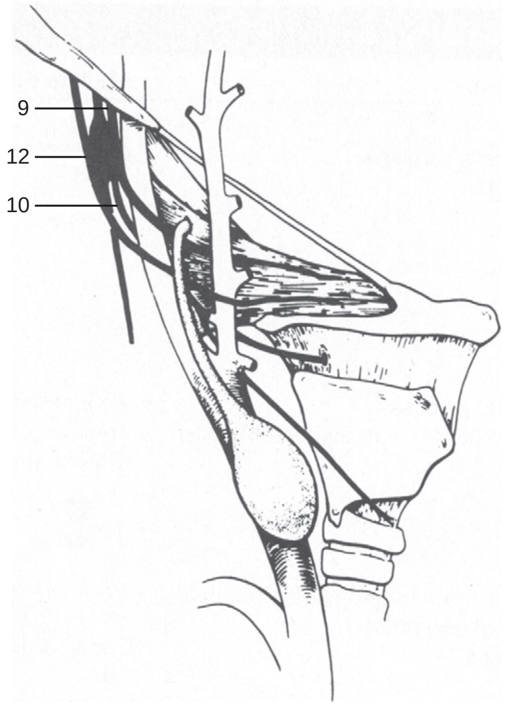

**FIGURE 59-8** Second branchial cleft cyst and sinus tract. (From Donegan JO: Congenital neck masses. In Cummings CW, Fredrickson JM, Harker LA, et al [eds]: Otolaryngology—Head and Neck Surgery, ed 2. St Louis, Mosby-Year Book, 1993.)

The branchial anomalies are lined by epithelium. Overall cystic lesions are more common than fistulae, but usually present later (e.g., second decade).[7] Cysts most often present as nontender soft tissue masses beneath the SCM muscle. However, they may present with acute infection. Change in size during upper respiratory infections is noted in up to 25%.[26] The anomalies have been classified into four types.[5] Type 1 are superficial, but located deep to the platysma and cervical fascia, along the anterior border of the SCM muscle. Type 2 anomalies are the most common. They course deep to the SCM muscle and either anterior or posterior to the carotid artery. Type 3 lesions pass between the carotid bifurcation and lie adjacent to the pharynx. Type 4 lesions are medial to the carotid sheath and in close approximation to the pharynx, usually at the level of the tonsillar fossa.

The most common presentation in infants and young children is a second branchial cleft sinus with drainage from a small cutaneous pit along the anterior border of the lower sternocleidomastoid muscle. On occasion, a subcutaneous tract is palpable more cephalad. Less common symptoms include stridor, dysphagia, odynophagia, or cranial nerve palsies. Branchiogenic carcinoma has been diagnosed in adults.[27]

Given the risks of infection, further enlargement or malignancy, elective excision is recommended once the diagnosis has been made. There is typically no urgency; so, one can defer excision beyond 3 to 6 months of age or to allow treatment of an acute infection. Systemic antibiotics and aspiration are generally preferable to incision and drainage, which might produce more distortion of the surgical planes; however, when diagnosis is unclear, the latter allows biopsy of the cyst wall, which can help to distinguish between an infected branchial cleft cyst and simple bacterial lymphadenitis.

**FIGURE 59-9** Intraoperative photo showing excision of second branchial cleft sinus/fistula using second parallel ("step-ladder") cervical incision.

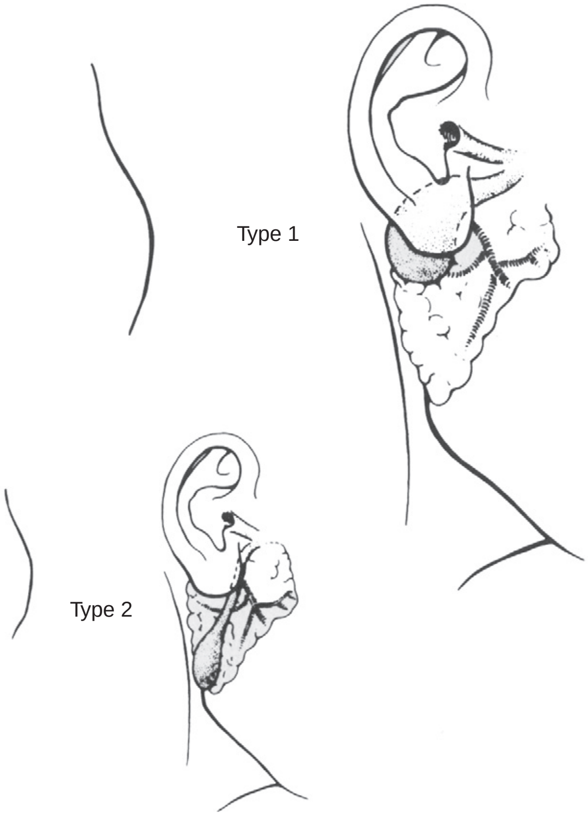

**FIGURE 59-10** Type I and type II first branchial cleft abnormalities. (From Donegan JO: Congenital neck masses. In Cummings CW, Fredrickson JM, Harker LA, et al [eds]: Otolaryngology—Head and Neck Surgery, ed 2. St Louis, Mosby-Year Book, 1993.)

The goal is complete excision of the tract without injury to surrounding nerves or vascular structures. A transverse cervical incision in a skin crease directly over the cyst will aid to optimize the future cosmetic result. In the case of a sinus or fistula, precise identification may be facilitated by gently inserting a probe, catheter, or monofilament suture into the tract. A lacrimal probe dipped in methylene blue has also been used to stain the tract and make it easier to identify should it break during dissection. Excision is best accomplished by dissection directly on the surface of the lesion. The tract may be very thin-walled; so, one must be careful to avoid avulsion with possible loss of the proximal lumen. If the tract is long, exposure may be improved by a second (so-called "stepladder") incision along a skin crease more cephalad (Fig. 59-9). Second branchial anomalies presenting as pharyngeal cysts can be excised by an intraoral approach.[28,29]

## FIRST BRANCHIAL ANOMALIES

First branchial cleft anomalies are rare, but more common in females. Accurate diagnosis is difficult and may be quite delayed.[30] Remnants may persist anywhere between the external auditory canal and submandibular area. They should be distinguished from preauricular pits and sinuses, which arise from failure of the auricular hillocks to fuse. The first cleft anomalies often lie in close association to the parotid gland and facial nerve. In 1972, Work classified first branchial anomalies into types 1 and 2 (Fig. 59-10).[31] Type 1 lesions are rarer and considered duplications of the membranous external auditory canal. They are of ectodermal origin and generally course lateral to the facial nerve. Type 2 lesions contain both ectodermal and mesodermal elements, which may include cartilage. These anomalies pass medial to the facial nerve but may present in preauricular, infraauricular, or postauricular locations. Sinuses may present with external drainage below the angle of the mandible or otorrhea, which may become infected. Cysts present as soft tissue masses in this region which may also become secondarily infected. A communication with the external auditory canal may be present. A careful otologic examination is important to define the pathology.

Complete surgical excision is once again recommended, but great care must be taken given the proximity of the facial nerve. In infants and children, the nerve is probably even more susceptible given that it is smaller and more superficial without well-developed landmarks.[32] Many authors recommend initial exposure of the main trunk of the facial nerve and its peripheral branches with superficial parotidectomy to reduce the risk of facial nerve injury.[33,34] Prior infection may distort accurate tissue dissection planes. It is necessary to excise the involved skin and cartilage of the external auditory canal. Furthermore, if the tract extends medially to the tympanic membrane a second operation may be required to remove this segment.[35,36]

## THIRD AND FOURTH BRANCHIAL ANOMALIES

Third and fourth branchial anomalies are very rare and almost always occur on the left side of the neck. Most present as sinuses or infected cysts rather than congenital fistulae and drain into the piriform sinus. Although sometimes combined

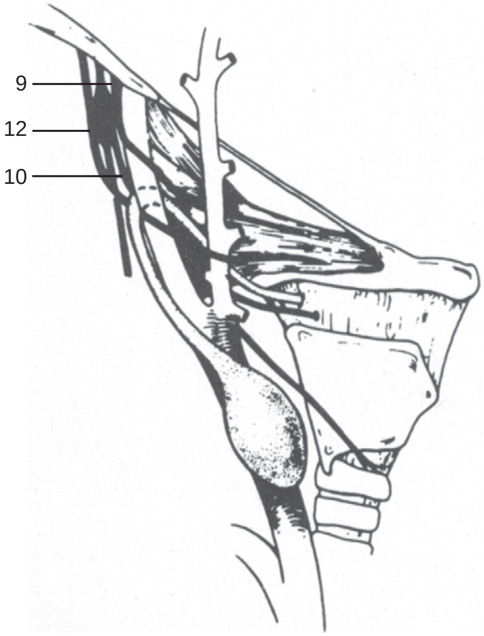

FIGURE 59-11 Third branchial cleft cyst and sinus tract. Note that these occur much more frequently on the left side (approximately 90%); also, during surgery the tract is often seen to go straight up from the left upper thyroid lobe area toward the thyroid cartilage, without passing behind the carotid artery as the embryologic development would suggest. (From Donegan JO: Congenital neck masses. In Cummings CW, Fredrickson JM, Harker LA, et al [eds]: Otolaryngology—Head and Neck Surgery, ed 2. St Louis, Mosby-Year Book, 1993.)

generically as piriform sinus tracts, distinction is possible. As noted in Figure 59-1 the superior laryngeal nerve represents the nerve to the fourth branchial arch. Third pouch anomalies enter the piriform sinus above the superior laryngeal nerve, whereas fourth pouch anomalies enter below this nerve. A third branchial cleft fistula theoretically would extend from the anterior border of the SCM, traversing deep to the internal carotid artery and glossopharyngeal nerve, piercing the thyroid membrane above the internal branch of the superior laryngeal nerve and entering the pharynx at the piriform sinus as depicted in Figure 59-11. A fourth branchial fistula would course around the subclavian artery on the right or aortic arch on the left to ascend back up over the hypoglossal nerve and enter the piriform apex or cervical esophagus (Fig. 59-12). A complete fourth branchial fistula has yet to be identified in humans,[5] and most third branchial fistulae described appear to have been secondary to infection or repeated surgery.[37]

Presentation of piriform sinus tracts may be quite subtle and their diagnosis very challenging. Noncommunicating or noninfected communicating cysts may present as cold thyroid nodules, which may be partly or totally intrathyroid.[37] A history of repeated upper respiratory tract infections and sore throats, hoarseness or pain, and tenderness of the thyroid gland should raise suspicion. Infection may result in suppurative thyroiditis[38]; any thyroid abscess in a child should raise the suspicion of a branchial remnant, particularly if closely related to the left upper pole of the thyroid gland. Acute respiratory compromise in neonates has been described.[39] Needle aspiration may be required to temporarily relieve respiratory symptoms. A contrast esophagogram after resolution of the acute infection may demonstrate the tract from the piriform

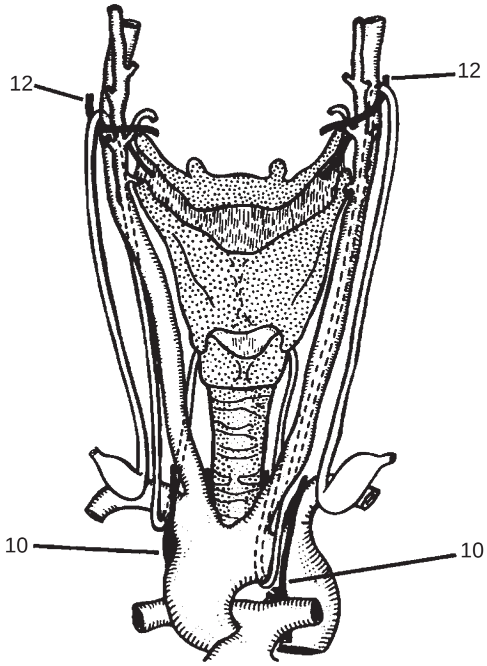

FIGURE 59-12 Anatomic relationships of theoretical course of fourth branchial fistula. Such a complete fistula has never been described in humans. (From Liston SL: Fourth branchial fistula. Otolaryngol Head Neck Surg 1981;89:520-522.)

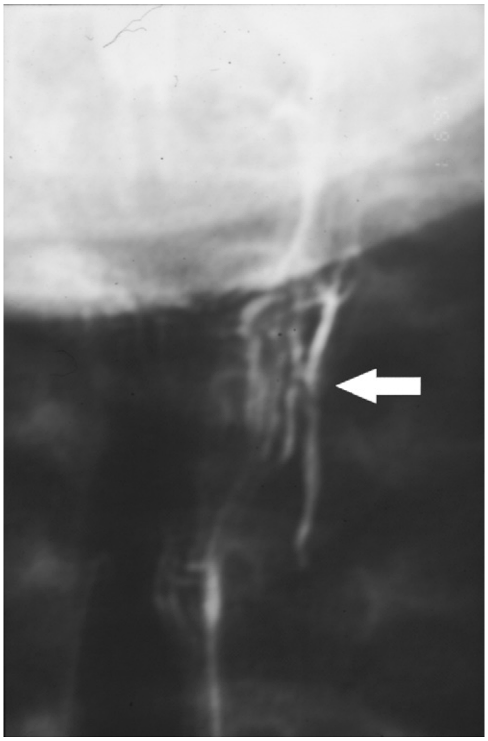

FIGURE 59-13 Contrast esophagogram demonstrating contrast within piriform sinus tract *(arrow)*.

sinus as depicted in Figure 59-13. Other imaging has been successful if air is visualized within the cyst or tract originating from the piriform fossa opening.[40] Combinations of ultrasonography, CT, MRI, and thyroid scan may help in establishing a diagnosis.[37]

Once again, complete excision is necessary to avoid continued difficulties. Often several previous operations have been performed before the correct pathology is recognized.[41,42] Direct laryngoscopy or rigid pharyngoscopy, using a Hopkins rod-lens telescope, is recommended for accurate diagnosis as well as endoscopic cannulation of the opening into the piriform sinus, if possible, to facilitate accurate dissection.[37,43] A standard collar incision is used with identification of the recurrent laryngeal nerve. Partial or total ipsilateral thyroid lobectomy with excision of the tract to the piriform sinus is usually required. Partial resection of the thyroid cartilage may also be necessary to remove the entire tract.[44] Cauterization of the internal opening has been described.[45,46]

## Dermoid Cysts

Cervical dermoid cysts are thought to arise from elements trapped during fusion of the anterior branchial arches. They are composed of ectodermal and mesodermal elements, but in contrast to teratomas, do not contain any endodermal derivatives.[35] These lesions are typically midline and well-circumscribed. They are lined by squamous epithelium and usually contain sebaceous debris, which can become secondarily infected. Although they appear echogenic rather than cystic on ultrasound examination, imaging is useful to differentiate submental dermoids from benign reactive lymph nodes. The overlying skin is often adherent, and a small cutaneous pit may be visible. If the cyst is adherent to the underlying fascia or lies within the strap muscles, it may move with swallowing or tongue protrusion, making the distinction from a thyroglossal duct cyst impossible. Complete excision is appropriate. A yellowish appearance at surgery and the sebaceous cyst content allow distinction from a thyroglossal duct cyst, which more often contains a clear viscous fluid. If the cyst lies adjacent to the hyoid bone and a diagnostic doubt exists, a formal Sistrunk procedure with in continuity excision of the central hyoid bone is recommended to ensure complete removal of the pathology.

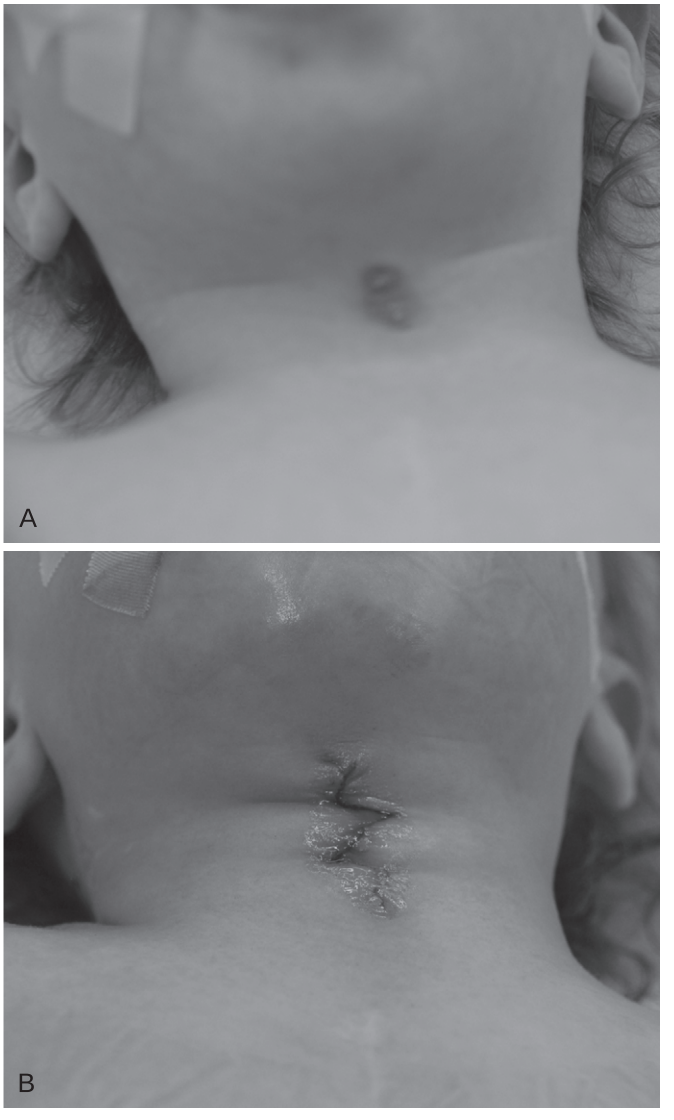

FIGURE 59-14 Photographs of infant with midline cervical cleft (**A**) and Z-plasty reconstruction after excision (**B**).

## Congenital Midline Cervical Clefts

Congenital midline cervical clefts are very rare anomalies thought to arise from failure of anterior fusion of the first two branchial arches.[47,48] They typically present as a longitudinal area of thinned or atrophic skin along the anterior midline of the neck. Characteristically, there are skin tags at the upper end and small sinus tracts at the inferior aspect. Secretions may be noted from accessory salivary glands draining into the cleft.[49,50] Early complete excision is recommended, both for cosmesis as well as to avoid limitations to neck extension and mandibular growth. Wound closure is accomplished using a series of Z-plasties, to avoid a contracting linear scar (Fig. 59-14).[51,52]

## Cervical Thymic Cysts

Thymic cysts are usually seen within the chest and mediastinum. However, given that the thymus arises from the third, and sometimes fourth, branchial pouches, one can appreciate the possibility for a cervical location. Cervical thymic cysts typically present in the anterior triangle, more commonly on the left than the right. They occur more frequently in males, with peak onset at age 5 to 7 years.[53] They may be difficult to distinguish preoperatively from more common cystic lesions, such as branchial cleft cysts or lymphatic malformations. They can be unilocular or multilocular. Extension into the mediastinum is common and accounts for the often-described physical finding of enlargement with a Valsalva maneuver. The precise diagnosis is usually made postoperatively when elements of

thymus are identified within the cyst wall. The fluid within these cysts is typically brownish in color. The lesions are almost always benign. Surgical excision is generally quite straightforward, although one needs to be cognizant of potentially adherent vessels (e.g., carotid artery, jugular vein) or nerves (e.g., phrenic, recurrent laryngeal). Although the aim is to completely remove the cyst, one should be careful in very young children, to avoid removing the entire thymus, which might have untoward immunologic consequences.

Although the focus of this chapter has been congenital lesions, the differential diagnosis for neck cysts and sinuses must be much broader. A wide variety of acquired conditions, including infections and tumors, should also be considered. The distinction between infection of a congenital cervical remnant and a primary cervical infection with the development of an abscess or draining sinus may not always be straightforward. Nonetheless, an awareness of the congenital possibilities and their likely anatomic locations will assist the astute clinician.

CHAPTER 60

# Torticollis

Spencer W. Beasley

There are many causes of torticollis in childhood (Table 60-1), but most are rare. The most common cause of torticollis is tightness and shortening of one sternomastoid muscle, a condition that occurs in about 0.4% of all births. Typically, at about 3 weeks of age, a visible or palpable swelling develops in part or all of the muscle; this swelling is called a sternomastoid tumor. It affects the right side in about 60%,[1] is bilateral in 2% to 8%,[2,3] and often persists for up to 1 year. Older children may present with a fibrotic, shortened sternomastoid muscle, which is presumed in many to be the legacy of a previously unrecognized sternomastoid tumor.

## History

Alexander the Great may have had torticollis, according to Plutarch.[4] Antyllus is said to have performed tenotomies in 350 AD, but the first authenticated division of the sternocleidomastoid was by Minnus in Amsterdam in 1641.[5] A sternocleidomastoid tumor was described by Heusinger in 1826.[6] Torticollis was also a subject of interest to Dupuytren.[7]

## Etiology

Although often referred to as "congenital torticollis," the sternomastoid mass and the torticollis are rarely noticeable at birth. Little is known about the etiology of sternomastoid fibrosis, although several theories have been put forward to explain the condition. It may be due to an idiopathic intrauterine embryopathy[8] or could be the manifestation of an intrauterine positional disorder producing sternocleidomastoid compartment syndrome.[9] The high incidence of obstetric difficulties, such as breech presentation and the need for assisted delivery,[10,11] may be the result rather than the cause of the shortened sternomastoid muscle, as was initially thought. There is no report of a sternomastoid tumor detected by antenatal ultrasonography.[12] Concomitant hip dysplasia is common.[10]

## Pathology

The basic abnormality on histology is fibrous replacement of muscle bundles.[13] The lesion, called fibromatosis colli, is often classified with other types of fibromatoses, such as the Dupuytren contracture and plantar fibromatosis. Jones[8] has described endomysial fibrosis involving the deposition of collagen and fibroblasts around individual muscle fibers that undergo atrophy. The sarcoplasmic nuclei are compacted to form giant cells that appear to be multinucleated. The maturity of the fibrous tissue in neonates suggests that the disease may begin before birth[8,14,15] and may therefore contribute to the frequency of obstetric difficulties during delivery. The reported incidence of breech deliveries is about 20% to 30%[16]—much higher than the normal incidence. About 60% of affected infants are involved in a complicated birth,[16] which suggests that the fibrosis may affect the position of the fetus in utero and perhaps even prevent normal engagement of the head in the maternal pelvis.

The natural history of untreated sternomastoid fibrosis is complete resolution in 50% to 70% of patients at 6 months of age. In about 10%, the tumor and sternomastoid shortening persist beyond 12 months of age.[2,17] The severity and distribution of the fibrosis within the sternomastoid muscle is variable and has led to a variety of classifications based either on a palpable localized sternomastoid tumor or thickening and shortening of the whole muscle or on the basis of ultrasonographic findings.[18,19] The systems of classification have some prognostic significance in that localized lesions within the sternomastoid (clinically or ultrasonographically) are more likely to resolve spontaneously than those involving the whole muscle. In older children with torticollis, the appearance of degenerating fibers is more consistent with disuse atrophy produced by limitation of movement caused by the fibrosis.

## Clinical Features

### STERNOMASTOID TORTICOLLIS

The tumor is a hard, spindle-shaped, painless, discrete swelling usually about 1 to 3 cm in diameter within the substance of one sternomastoid muscle. Almost always, it first becomes evident at about 3 weeks after birth. Obvious head tilt or torticollis tends to develop later.[12] In infants, the head is rotated to the side opposite the tumor, with only slight flexion of the head to the affected side (Fig. 60-1).

In other patients, the sternomastoid tumor is less discrete, and the sternomastoid appears to be thickened and tightened along its whole length. The shortening of the muscle restricts rotation and lateral flexion of the head (Fig. 60-2).

**TABLE 60-1**
**Causes of Torticollis in Infants and Children**

| *Cause* | *Comment* |
|---|---|
| Sternomastoid "tumor" | Common; appears at 3 weeks of age |
| Abnormal position in utero | Tends to improve with age |
| Cervical hemivertebrae | Structural; confirmed on plain radiograph |
| Cervical lymphadenitis/abscess | Acute; usually occurs in first 2 years of life |
| Retropharyngeal abscess[31,58] and pyogenic cervical spondylitis[59] | Acute; signs of toxicity, cervical pain |
| Posterior fossa tumors[61] | A rare cause; headaches, vomiting, and other neurologic signs present[61] |
| Acute atlantoaxial subluxation | May occur after tonsillectomy[30] |
| Atlantoaxial rotatory subluxation | Significance disputed[58,59]; diagnosed on dynamic CT |
| Spasmodic with Sandifer syndrome[59] | Due to gastroesophageal reflux |
| Congenital absence of sternomastoid | Unilateral, extremely rare[60] |
| Postural | Familial |

CT, computed tomography.

**FIGURE 60-1** Appearance of a right sternomastoid tumor in infancy; the head is turned to the contralateral side.

The rotational component of the action of the sternomastoid is easy to measure. It is assessed by standing behind the child's head and passively rotating the head while it is held between both hands. The sternomastoid muscle is stretched to its maximum length by rotation to the side of the affected muscle. Where the muscle is fibrotic, it cannot be stretched to its full length, and rotation to the ipsilateral side is restricted.

Older children with torticollis compensate for the more pronounced tilt by elevating one shoulder to enable the eyes to keep as level as possible (Fig. 60-3). Such compensation is not seen in infants, because there is no need for them to maintain their eyes in a horizontal plane until they stand up.[20] Moreover, older children do not turn their heads to the contralateral side as much, because they tend to compensate by twisting the neck and back to keep their eyes pointing forward.

## DIFFERENTIAL DIAGNOSIS

Initial clinical assessment must establish whether the wry neck is caused by shortness of one sternomastoid muscle or by some other condition. In sternomastoid fibrosis, the anterior border of the muscle stands out as a tight band, although in some small infants in whom the neck is relatively short, the muscle may be difficult to see readily. For this reason, the full length of the muscle must be palpated to determine whether there is an area of thickening or fibrosis along part or all of its length. In about two thirds, there is a definite localized swelling (tumor) in the muscle; in the remainder, the whole muscle appears to be affected. There is no role for plain radiography where the sternomastoid is tight or shortened.[21] Although not required for diagnosis, appearance on ultrasonography may help predict (to a degree) the likelihood of spontaneous resolution.[1,19,22] Inexperienced ultrasonographers, worried by the infiltrative and ill-defined appearance, may recommend

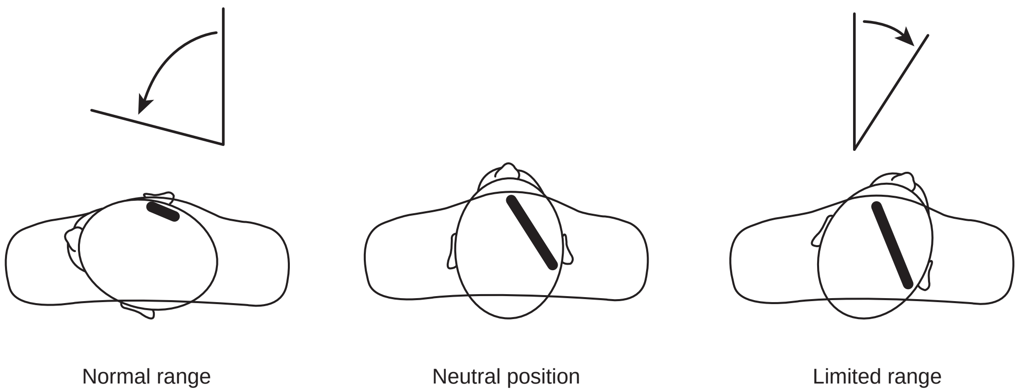

**FIGURE 60-2** Restriction of rotation of the head secondary to shortening of the sternomastoid muscle as viewed from above the head. The black bars represent the right sternomastoid muscle and show that its inability to lengthen limits rotation to that side.

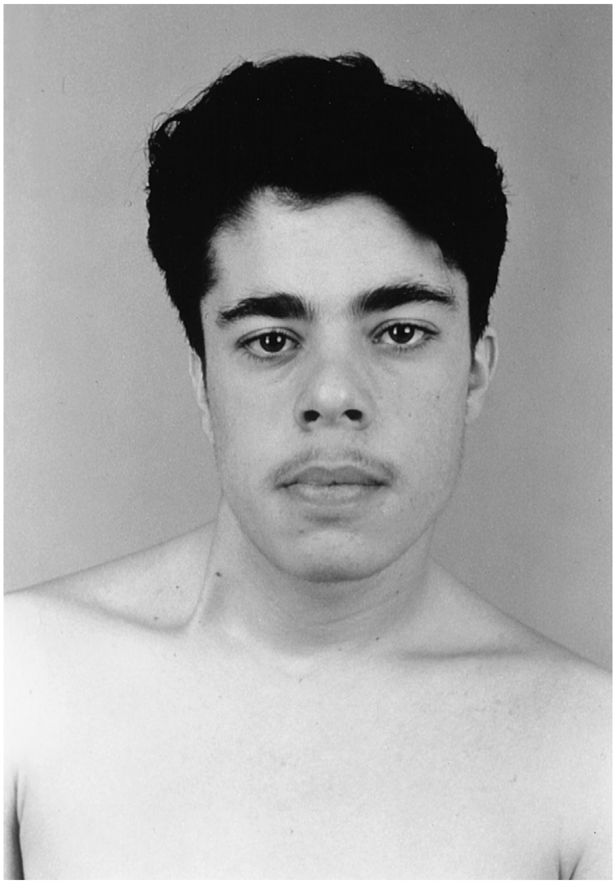

**FIGURE 60-3** Appearance of torticollis as a result of sternomastoid fibrosis in an older child. The eyes are kept horizontal, but the shortened sternomastoid muscle causes compensatory elevation of the shoulder. (From Beasley SW, et al: Pediatric Diagnosis. London, Chapman & Hall, 1994, with permission.)

**FIGURE 60-4** Torticollis caused by atlanto-occipital subluxation after tonsillectomy. Notice that there is no tightness of the sternomastoid muscle on either side. (From Beasley SW, et al: Pediatric Diagnosis. Chapman & Hall, London, 1994, with permission.)

further imaging or biopsy of the "tumor"; this is not indicated in the presence of the typical palpable mass within the sternomastoid and torticollis. It is possible to diagnose a sternomastoid torticollis on magnetic resonance imaging (MRI)[22,23] and computed tomography (CT),[24] but neither alters management and should not be performed routinely.[23,25]

An obvious mass or fibrosis of the muscle may not always be noticeable in idiopathic torticollis, but in such instances, alternative diagnoses must be sought (see Table 60-1 and Fig. 60-4).[20,26]

A squint may cause head tilt from imbalance in rotation of the eyes. The squint may not be obvious at first because the tilt compensates for the abnormal position of the eyes. When the head is straightened passively, the squint becomes apparent. Occasionally, sternomastoid fibrosis may occur coincidentally with ocular torticollis.

Posterior fossa tumors may compress the brainstem at the foramen magnum and produce acute stiffness of the neck that causes it to be held to one side. The neck is frozen in this position and is difficult to move actively or passively. The presence of a central nervous system tumor may be known already, but occasionally, acute torticollis is the first manifestation. Careful neurologic examination may show abnormalities of the lower cranial nerves and cerebellar function, and the causative lesion is demonstrated on CT or MRI.

Hemivertebrae involving the cervical spine may produce a tilt of the head that is evident from birth and does not progress. Vertebral lesions can be identified clinically by inspection and palpation of the dorsal cervical spines and confirmed on plain radiographs of the neck.

Acute torticollis has been attributed to atlantoaxial rotatory subluxation as determined on dynamic CT,[27,28] but others doubt the existence or significance of these findings and suggest that CT scans are not necessary at the initial examination.[29] Atlantoaxial subluxation has been reported after tonsillectomy.[30] Acute torticollis can also result from inflammatory conditions of the neck, including retropharyngeal abscess,[31] and can be a symptom of acute lymphoblastic leukemia.[32]

## Secondary Effects of Torticollis

Table 60-2 lists the secondary effects of torticollis.

**TABLE 60-2**
**Secondary Effects of Torticollis**

| | |
|---|---|
| Infants | Plagiocephaly |
| | Hemifacial hypoplasia |
| Older children | Compensatory scoliosis |

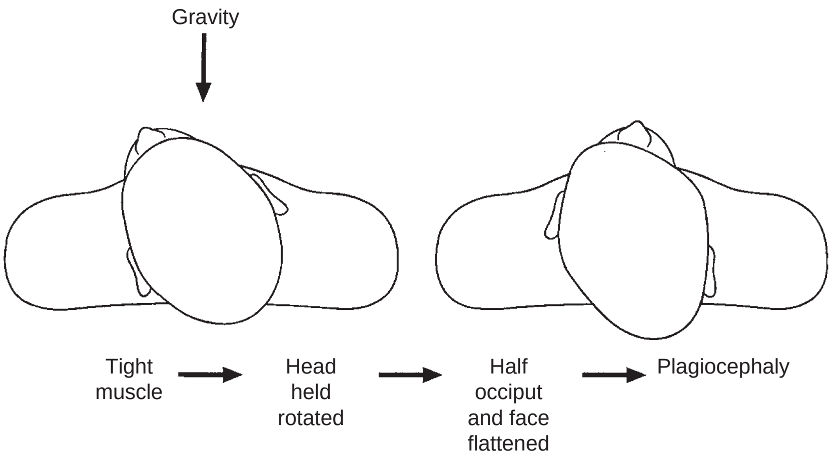

**FIGURE 60-5** Plagiocephaly.

## PLAGIOCEPHALY

In small infants with torticollis and fixed rotation of the head, gravity deforms the relatively soft head as it lies in the same position for a prolonged period. Flattening of one occiput leads to secondary flattening of the contralateral forehead (Fig. 60-5). This asymmetric skull deformity is called plagiocephaly and develops in the first few months of life.[33] It is best observed from above the head. Once the child begins to sit up or the torticollis resolves, the plagiocephaly tends to resolve as well.[34] It may take several years to disappear, and a few children have a slight permanent deformity. It is possible that many children with plagiocephaly have had unrecognized torticollis during infancy.[35]

## HEMIFACIAL HYPOPLASIA

Progressive facial deformity is seen when one sternomastoid muscle immobilizes the face for a long time. The malar eminence on the side of the face limited by the fibrotic muscle grows more slowly than the normal side does[9] and causes progressive asymmetry (Fig. 60-6). This inhibition of growth of the mandible and maxilla embodies an important principle of pediatrics: Normal growth of bones depends on normal muscular movement.

**FIGURE 60-6** Hemifacial hypoplasia on the right side.

The degree of hypoplasia of one side of the face can be determined by the angle between the plane of the eyes and the plane of the mouth. Normally these lines are parallel, but they form an angle to each other when the face is asymmetric. The development of hemifacial hypoplasia is one indication for surgery; division of the tight sternomastoid muscle allows resolution of the skeletal abnormality and subsequent normal growth.[9]

Significant hemifacial hypoplasia takes about 8 months to develop[8] but is more often recognized at about 3 to 4 years of age.[17] It becomes less obvious with ongoing growth once the torticollis has resolved.

## POSTURAL COMPENSATION

When children are old enough to walk, the eyes are kept horizontal to facilitate balance and horizontal eye movement. The child compensates for the short fibrous sternomastoid by elevating the ipsilateral shoulder (see Fig. 60-3). In addition, there may be compensatory cervical and thoracic scoliosis. Adjacent muscles, such as the trapezius, may be wasted because of relative inactivity.[8]

# Conservative Management

Sternomastoid fibrosis resolves spontaneously in the vast majority of infants. Therefore surgery is required only rarely, in those in whom the torticollis has not resolved. The value of manipulation of the head and neck has not been proven,[12] although it is widely used and may have some benefit in the first year of life.[36] Physiotherapy and regular neck exercises appear to be safe[36] and may make the parents feel that "something is being done" for their infant. Unintentional snapping during manipulation has been reported with no apparent deleterious effect on outcome.[37] Some clinicians advocate early institution of intensive passive neck range-of-motion stretching exercises and have reported high rates of resolution,[9,38–40] while others believe that there is no convincing evidence that these measures alter the natural history of the condition.

Others consider it important to encourage parents to place toys and other desirable objects on the ipsilateral side to encourage the infant to turn toward the affected side.[8] Again, this

strategy probably helps the parent more than the infant, but is unlikely to do any harm. Attempts to put the infant to sleep with the head facing toward the affected side tend to fail, particularly if the muscle is tight. Botulinum toxin injection appears to be ineffective in patients presenting in late childhood or adulthood,[41] but results are more encouraging in younger children.[42]

In most cases, reassurance is all that is required. The passage of time is probably as effective as the various manipulations when torticollis is due to sternomastoid fibrosis.

# Operative Treatment

## INDICATIONS FOR SURGERY

Indications for surgery include

1. Persistent sternomastoid tightness limiting head rotation in children more than 12 to 15 months of age[43]
2. Persistent sternomastoid tightness with progressive hemifacial hypoplasia
3. Diagnosis in children older than 1 year[44]

## OPERATIVE TECHNIQUE

The procedure is performed under general anesthesia with laryngeal or endotracheal intubation, according to the expertise and preference of the pediatric anesthetist. The child is placed supine with the shoulders elevated and the neck rotated to the contralateral side. The muscle is best divided at its lower end,[4,9] although division at its upper end,[45] at both ends,[46–48] or in its midportion[8,49] have all been described. Endoscopic tenotomy of the muscle is also feasible[50–53] including through a transaxillary approach.[54,55]

A 3- to 4-cm transverse incision is made in a skin crease about 1 cm above the sternal and clavicular heads of the affected sternomastoid (Fig. 60-7). The platysma is divided with diathermy so that no bleeding occurs in the line of the incision. The external jugular vein can be retracted if it is within the field of view. The tight fibrosis of the two heads of sternocleidomastoid are divided with diathermy near their lower end. Tightness of the cervical fascia between the sternomastoid and trapezius is usually palpable once the sternomastoid has been divided, and this fascia also should be divided (Fig. 60-8). This is done under direct vision to avoid damage to other structures, particularly the spinal accessory nerve and brachial plexus.

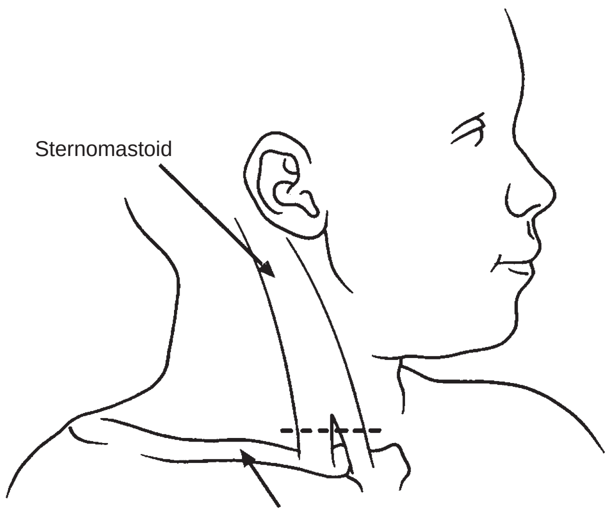

FIGURE 60-7 Skin incision for low division of the sternomastoid muscle.

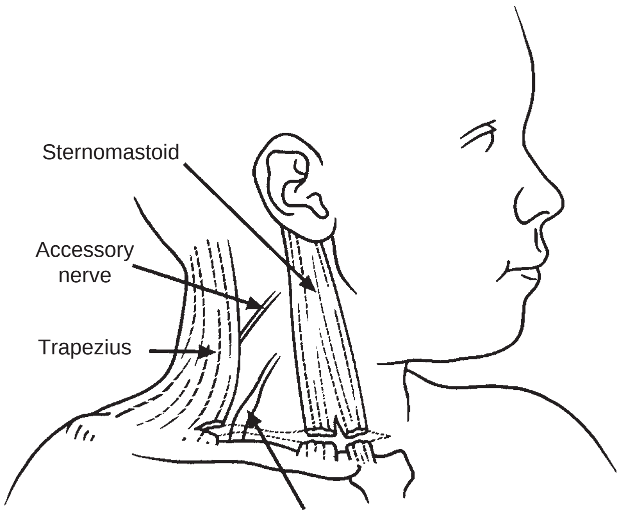

FIGURE 60-8 Division of the sternomastoid and investing cervical fascia to the anterior border of the trapezius.

The wound is infiltrated with bupivacaine or other local anesthetic agent. The platysma is closed with continuous 4-0 absorbable suture and the skin with subcuticular 5-0 Monocryl absorbable suture. No drains are required.

The procedure can be performed as a day case, and no postoperative restriction of movement is necessary. Full range of the neck is normally achieved within 1 week of surgery. Physiotherapy is usually unnecessary, although some advocate an extended period of physiotherapy postoperatively.[46] In older children, restoration of a full range of movement may take longer, and the final cosmetic appearance is less certain.[56]

## COMPLICATIONS

A hematoma may develop if hemostasis was inadequate at the time of surgery. Diathermy dissection keeps blood loss to a minimum. Larger superficial veins may require ligation and division if they cannot be retracted.

Incomplete division of both heads of the sternocleidomastoid muscle or failure to divide the cervical fascia over the posterior triangle of the neck may produce persistent torticollis. Careful inspection and palpation of the neck for residual tightness and bands at the time of surgery should prevent this complication from occurring. Recurrent torticollis is rare after surgical treatment and is seen in less than 3% of patients.[57]

## FOLLOW-UP

Patients should be monitored until (1) the torticollis has resolved completely, (2) there is full range of movement of the head and neck, and (3) the sternomastoid muscle feels normal. In an older child with secondary scoliosis, follow-up, including radiologic studies, if required, should continue until the scoliosis has resolved.

**Notices**

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

# About the Editors

**ARNOLD G. CORAN, MD,** is Emeritus Professor of Surgery at the C. S. Mott Children's Hospital and the University of Michigan Medical School. He was the Chief of Pediatric Surgery and the Surgeon-in-Chief at the C. S. Mott Children's Hospital and Professor of Pediatric Surgery at the University of Michigan Medical School from 1974 to 2006. He is also currently Professor of Surgery in the Division of Pediatric Surgery at New York University School of Medicine. He was one of the editors of the fifth and sixth editions of *Pediatric Surgery* and is the current Editor in Chief of this seventh edition. His expertise in pediatric surgery centers on complex esophageal and colorectal diseases in infants and children. He is the past President of the American Pediatric Surgical Association and the past Chairman of the Surgical Section of the American Academy of Pediatrics. He has been married to Susan Coran for 50 years and has three children and nine grandchildren.

**N. SCOTT ADZICK, MD,** has served as the Surgeon-in-Chief and Director of The Center for Fetal Diagnosis and Treatment at The Children's Hospital of Philadelphia since 1995. He is the C. Everett Koop Professor of Pediatric Surgery at the University of Pennsylvania School of Medicine. Dr. Adzick was raised in St. Louis, received his undergraduate and medical degrees from Harvard, and has a Master of Medical Management degree from Carnegie Mellon University. He was a surgical resident at the Massachusetts General Hospital and a pediatric surgery fellow at Boston Children's Hospital. His pediatric surgical expertise is centered on neonatal general and thoracic surgery, with a particular focus on clinical applications of fetal diagnosis and therapy. He has received grant support from the National Institutes of Health for more than 20 years and has authored more than 550 publications. He was elected to the Institute of Medicine of the National Academy of Science in 1998. Scott and Sandy Adzick have one son.

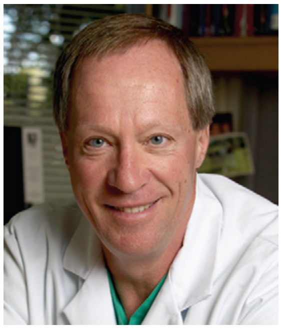
**ANTHONY A. CALDAMONE, MD,** graduated from Brown University and Brown School of Medicine. He was the first graduate of the medical school to become full professor at the institution. He did his residency at the University of Rochester and completed his fellowship under Dr. John W. Duckett at The Children's Hospital of Philadelphia. He is currently Professor of Surgery (Urology) and Pediatrics and Program Director for the Urology Residency at Brown University School of Medicine and Chief of Pediatric Urology at Hasbro Children's Hospital in Providence.

Dr. Caldamone has served as President of the New England Section of the American Urological Association (AUA). He has also served as Secretary-Treasurer and President of the Society for Pediatric Urology. He has been on several committees of the AUA including the Socio-Economic Committee, Publications Committee, and Nominating Committee. He is currently Executive Secretary of the Pediatric Urology Advisory Council. Locally he has served as President of the Rhode Island Urological Society, as President of the Brown Medical Alumni Association, as Chairman of the Board of Directors of Komedyplast Foundation, and as a member of the Board of Regents of La Salle Academy.

Dr. Caldamone has been on several medical missions to the Middle East, South America, and Bangladesh and has been on the Board of Directors of Physicians for Peace.

He was one of the editors of the sixth edition of *Pediatric Surgery.* He is currently an Editor for the *Journal of Pediatric Urology* and is Editor in Chief of the *Dialogues in Pediatric Urology.*

Dr. Caldamone is married to Barbara Caldamone and has two children, Amy and Matthew.



**THOMAS M. KRUMMEL, MD,** is the Emile Holman Professor and Chair of the Department of Surgery at Stanford University and the Susan B. Ford Surgeon-in-Chief at Lucile Packard Children's Hospital. Dr. Krummel has served in leadership positions in the American College of Surgeons, the American Pediatric Surgical Association, the American Surgical Association, the American Board of Surgery, and the American Board of Pediatric Surgery. He has mentored more than 150 students, residents, and postdoctoral scholars. He and his wife, Susie, have three children.

**JEAN-MARTIN LABERGE, MD**, is Professor of Surgery at McGill University and surgeon at the Montreal Children's Hospital of the McGill University Health Centre. He was the Director of Pediatric Surgery at the Montreal Children's Hospital from 1996 to 2008 and Program Director from 1994 to 2008. He is editorial consultant for the *Journal of Pediatric Surgery* and *Pediatric Surgery International* and was guest editor of two issues of *Seminars in Pediatric Surgery.* He has contributed chapters to several textbooks, including previous editions of *Pediatric Surgery,* Holcomb and Murphy's *Ashcraft's Pediatric Surgery,* Taussig and Landau's *Pediatric Respiratory Medicine,* and *Paediatric Surgery: A Comprehensive Text for Africa.* His research has focused on the effects of fetal tracheal occlusion to promote lung growth. His clinical interests include fetal diagnosis and treatment, congenital lung lesions, and anorectal malformations. He was President of the International Fetal Medicine and Surgery Society and is the immediate past President of the Canadian Association of Paediatric Surgeons (2009–2011). He has been married to Louise Caouette-Laberge, a pediatric plastic surgeon, for 34 years and has four children and three grandchildren.

**ROBERT C. SHAMBERGER, MD**, is the Robert E. Gross Professor of Surgery at Harvard Medical School and is Chief of Surgery at Children's Hospital in Boston.

Dr. Shamberger's expertise in pediatric surgery centers on oncology, inflammatory bowel disease, and chest wall deformities. He was Chair of the Surgical Committee for the Pediatric Oncology Group and Children's Oncology Group, as well as a member of the National Wilms' Tumor Study Group. He is the current President of the American Pediatric Surgical Association and Chairman of the Section on Surgery of the American Academy of Pediatrics. He has been married to Kathy Shamberger for 39 years and has three children and one grandchild.

# Preface

In June 1959, a group of five distinguished pediatric surgeons from the United States and Canada formed an editorial board to investigate the possibility of writing an authoritative, comprehensive textbook of pediatric surgery. The five individuals assembled were Kenneth Welch, who served as chairman of the board from Boston Children's Hospital (the original name); Mark Ravitch from The Johns Hopkins Hospital; Clifford Benson from Detroit Children's Hospital (the original name); William Snyder from Los Angeles Children's Hospital; and William Mustard from The Hospital for Sick Children in Toronto, Canada. From 1953 to 1962, the most comprehensive textbook of pediatric surgery was *The Surgery of Infancy and Childhood* by Robert E. Gross. At that time, Dr. Gross had no plans to write a second edition of his book. He was the sole author of the first edition of his book and did not wish to carry out such a monumental task with a second edition. The five editors thought that an updated textbook of pediatric surgery was needed. The first edition was published in 1962 and quickly became recognized as the most definitive and comprehensive textbook in the field. Between 1962 and 2006, six editions of the book were published. During this period, this textbook has been considered the bible of pediatric surgery. The editors and authors have changed during the 44 years that elapsed from the first to the sixth editions. In most cases, the editorial board changed gradually with the deletion and addition of two to three pediatric surgeons with each edition. The editors of the fifth edition also continued as the editors of the sixth edition. In the current seventh edition, the editorial board has been replaced except for Arnold Coran, who has functioned as the Chief Editor of this edition, and Anthony Caldamone, who continues to be the editor for the urology section. A new generation of pediatric surgical leaders has emerged since the last edition, and the editorial board reflects that change. Robert Shamberger from Children's Hospital Boston, Scott Adzick from The Children's Hospital of Philadelphia, Thomas Krummel from the Lucile Packard Children's Hospital and Stanford University Medical Center, and Jean-Martin Laberge from the Montreal Children's Hospital of the McGill University Health Centre represent the new members of the editorial board.

The seventh edition continues its international representation, with authors from several countries contributing chapters. Most of the previous chapters have been retained, but, in several cases, new authors have been assigned to these chapters. Of special interest is the addition of a new chapter (Chapter 16) on patient- and family-centered pediatric surgical care, a relatively new concept in the management of the pediatric surgical patient. Two chapters from the sixth edition, “Bone and Joint Infections” and “Congenital Defects of Skin, Connective Tissues, Muscles, Tendons, and Joints,” have been deleted because currently, most pediatric surgeons do not deal with these problems. A few of the urology chapters have been merged, but all the material from the previous edition is included in these chapters. The chapter “Congenital Heart Disease and Anomalies of the Great Vessels” (Chapter 127) was kept comprehensive because so many of these patients have co-existent pediatric surgical problems or have surgical problems after cardiac surgery. Overall, there are 131 chapters in this edition, all of which are written by experts in the field and represent a comprehensive treatise of the subject with an exhaustive bibliography. In addition, each chapter provides a complete discussion of both open and closed techniques, when appropriate, for the management of the surgical problem.

One of the remarkable things about this edition is that not a single sheet of paper was used by the authors or editors in the creation of the book. Everything from the writing of the chapter to its editing was done electronically. This entire process was overseen by Lisa Barnes, the developmental editor at Elsevier. All the editors wish to thank her for her patience, availability, and efficiency in completing this textbook. Finally, we want to thank all the authors for their outstanding chapters, which will provide definitive and comprehensive information on the various pediatric surgical problems to pediatric surgeons throughout the world and thus improve the surgical care of infants and children worldwide.

CHAPTER 61

# Disorders of the Breast

Mary L. Brandt

Development of the breast begins at around 35 days' gestation, when the ectoderm on the anterior body wall thickens into a ridge known as the milk line, milk ridge, or Hughes line.[1] This ridge of tissue extends from the area of the developing axilla to the area of the developing inguinal canal. The ridge above and below the area of the pectoral muscle recedes around the tenth week of gestation, leaving the mammary primordium, which is the origin of the lactiferous ducts.[2,3] The initial ducts form in the remaining pectoral ridge between weeks 10 and 20 and become interspersed through the developing mesenchyme, which becomes the fibrous and fatty portions of the breast.[2] The breast bud becomes palpable at 34 weeks' gestation.[2] The nipple appears much later at 8 months' gestation. It is initially a depression and later becomes elevated.[3]

Thelarche, or the onset of pubertal breast development, occurs between the ages of 8 and 13 years, at an average 11 to 11.5 years.[4] Lack of development by age 13 is considered delayed thelarche and warrants endocrinologic evaluation.[5] Normal breast development is hormonally mediated.[6] Adipose tissue and the lactiferous ducts grow in response to estrogen. Progesterone stimulation results in lobular growth and alveolar budding.[4,6] The normal development of the breast, which occurs over a period of 2 to 4 years after thelarche, is classified by the Tanner system into five stages (Table 61-1). Menarche usually occurs approximately 2 years after Tanner stage 2.

## Premature Thelarche

Although normal thelarche occurs between 8 and 13 years of age, breast buds can appear in girls as young as 1 to 3 years.[7] Although the vast majority of patients with premature thelarche have no associated medical problems, there are rare cases caused by hypothyroidism.[6] Premature thelarche is often an isolated condition but may be the first symptom of precocious puberty, particularly in girls older than 2 years.[7] Precocious puberty has been reported to occur in up to 18% of girls with premature thelarche who are followed over time.[8] Serial examinations, with particular emphasis on growth velocity and secondary sexual characteristics such as pubic hair and pigmentation of the labia or areola, are usually sufficient to identify precocious puberty in girls with premature thelarche.[2,7] Radiographs to estimate bone age may be indicated in some patients if precocious puberty is suspected.[8] Unless a patient with thelarche has associated signs of precocious puberty, the parents should be reassured and the child followed.[4] Ninety percent of patients with isolated premature thelarche have resolution of the breast enlargement 6 months to 6 years after diagnosis.[9] In asymmetrical premature thelarche, the resolution may also be asymmetric.[7] Long-term follow-up has shown that patients with isolated premature thelarche develop normal breasts at puberty and are at no increased risk for disorders or tumors of the breast.[9]

## Congenital Anomalies of the Breast

### AMASTIA AND HYPOMASTIA

Complete absence of the breast, or amastia, is rare.[3] Amastia, particularly if it is bilateral, can be associated with syndromes of more diffuse ectodermal anomalies such as congenital ectodermal dysplasia.[3,10] It can also be associated with anomalies of the underlying mesoderm, such as the abnormal pectoral muscle seen in Poland syndrome.[3,11,12] Athelia is defined as presence of breast tissue with absence of the nipple and usually occurs in ectopic locations along the milk line.[3] Amastia or hypomastia can also result from injuries sustained during thoracotomy, chest tube placement, inappropriate biopsy of the breast bud, radiotherapy, or severe burns.[2] Because the nipple complex does not normally develop until the eighth month of gestation, it can be difficult to identify in premature infants. As a result, placement of chest tubes or central lines can inadvertently injure the developing breast (Fig. 61-1).

### POLYMASTIA AND POLYTHELIA

Supernumerary breast tissue occurs in approximately 1% to 2% of the population.[1,3,6] Although the most common abnormality is accessory nipples (polythelia), polymastia may also occur (Fig. 61-2) The ectopic tissue is almost universally

located in the axilla or just inferior to the normally positioned breast along the embryonic milk line.[3] The normal axillary extension of breast tissue (the tail of Spence) should not be confused with supernumerary breast tissue. Sixty-five percent of children with supernumerary breast tissue have a single accessory nipple or breast, and 30% to 35% have two.[3] The largest number of reported supernumerary structures is 10.[3] Many studies have suggested an association between polythelia and abnormalities of the urinary tract and congenital heart disease, although this is debated by others.[1,2,10,11,13] True ectopic breast tissue, or breast tissue found outside the normal milk line, is exceedingly rare but has been reported on the face, back, and perineum, and in the midline of the anterior torso.[3,14,15] Polymastia warrants surgical excision in girls to prevent painful swelling during pregnancy. Resection of accessory nipples is usually warranted for cosmetic reasons.

**FIGURE 61-2** Polymastia. This complete breast, with nipple complex, is located in the most common position, just below the normal breast.

## Congenital Anomalies of the Nipple

Inverted nipples may predispose patients to infection, which can usually be prevented by careful attention to hygiene of the recessed area.[6] Surgical correction is possible, but elevation of the nipple inevitably divides the lactiferous ducts and makes future breast-feeding problematic if not impossible.[6] Other anomalies of the nipple that have been described include bifid nipples and intra-areolar polythelia, which is also called dysplastic divided nipples (Fig. 61-3).[6,10]

**FIGURE 61-3** Intra-areolar polythelia, which is also called a dysplastic divided nipple.

# Breast Asymmetry and Hypomastia

Some degree of asymmetry is normal in women and may be more pronounced during puberty while the breasts are developing.[6,8] Significant asymmetry is called hypomastia and may be associated with connective tissue disorders or mitral valve prolapse.[6] Hypomastia is frequently familial.[2] Unilateral hypomastia has been reported in association with a Becker nevus of the breast, which on examination appears as a clear brown stain on the chest wall.[2] Hypomastia can also occur after radiation therapy to the chest wall. Girls with bilateral breast hypoplasia should be evaluated for ovarian dysfunction, hypothyroidism, or androgen-producing tumors.[6] Hypoplastic breast tissue is also associated with a tuberous breast anomaly. In this condition, the base of the breast is limited and the hypoplastic breast tissue "herniates" into the areolar complex.[6,8] Plastic surgery to correct the areolar complex and augment the hypoplastic breast may be indicated.[16]

# Breast Enlargement

## MACROMASTIA

Excessively large breasts are referred to as macromastia. The differential diagnosis of macromastia in adolescents includes juvenile hypertrophy, pregnancy, tumors of the breast, and excessive endogenous or exogenous levels of estrogen or progesterone, or both (Table 61-2).[17] d-Penicillamine and marijuana have also been reported as exogenous causes of macromastia.[17]

## JUVENILE OR VIRGINAL HYPERTROPHY

Spontaneous massive growth of the breast in an adolescent, which may be unilateral or bilateral, is thought to be the result of excessive end-organ sensitivity to gonadal hormones.[2,17] An autoimmune cause has been suggested by some authors because of the occasional association with autoimmune disorders such as Hashimoto's thyroiditis, rheumatoid arthritis, and myasthenia.[2] The breast growth in patients with juvenile hypertrophy is rapid, begins shortly after thelarche, and can be dramatic, resulting in breasts that weigh up to 50 pounds each.[6,8] Spontaneous resolution is very rare.[17] Skin changes, such as peau d'orange and even necrosis, may occur during phases of rapid growth.[17] Treatment depends on whether breast growth is complete. If the patient is still growing, progesterone or antiestrogen medications can be used to control breast growth.[8] If this is unsuccessful, or if breast growth is complete, breast reduction surgery is necessary.[17] Patients should be counseled that lactation may be affected by juvenile hypertrophy, particularly after breast reduction surgery, but there is no increased risk of breast cancer.[17]

# Infections of the Breast

Neonatal mastitis is an uncommon infection that usually occurs in term or near-term infants.[18] It affects female infants twice as often as male infants.[18] A breast abscess develops in approximately 50% of infants with neonatal mastitis.[18] Adolescents may experience nonpuerperal mastitis or a breast abscess as a result of irritation of the skin, a foreign body, or infection of an epidermal cyst.[8] The initial therapy of all breast infections is administration of antibiotics and analgesics.[18] Adolescent girls with mastitis may have symptomatic relief with breast support.[8] Although *Staphylococcus aureus* (often methicillin resistant) is the offending organism in almost all cases, in infants, infections with *Shigella, Escherichia coli,* and *Klebsiella* species have been reported.[18] Gram-negative coverage may be indicated until culture results are obtained, particularly in neonates. Small abscesses are treated by aspiration, using ultrasonographic guidance if necessary, and antibiotic therapy.[8] Larger abscesses may require incision and drainage, although some authors recommend needle aspiration initially, with surgery reserved for failure of aspiration.[8] If incision and drainage are performed, a small periareolar incision is indicated. Probing and disrupting the tissue should be kept to a minimum to avoid injury to the underlying breast bud in a prepubertal child.

# Nipple Discharge

## BLOODY DISCHARGE

The differential diagnosis of bloody discharge in children and adolescents includes mammary duct ectasia, chronic cystic mastitis, intraductal cysts, and intraductal papillomas. Mammary duct ectasia is an anomaly of duct development that results from "pleats" of obstructing epithelium in the lumen of the duct.[2,19] This obstruction can lead to bacterial overgrowth and formation of an abscess, most commonly with *S. aureus.*[4] Infants with mammary duct ectasia typically present with a bloody discharge.[19] Adolescents typically present with a retroareolar, often bluish, mass. There may be a bloody or brownish discharge. All children with bloody discharge should have the discharge cultured and be given appropriate antibiotics.[4] Ductal ectasia often resolves spontaneously.[2,4,20] There may be recurrences but they usually respond to conservative therapy. Surgical excision may be indicated for

persistent or recurrent symptoms or for an associated persistent cyst.[4] In girls the excision should be limited to any identified cyst, with great care taken not to injure the underlying breast bud. In boys with this condition, a simple mastectomy is curative.[4]

Intraductal papillomas are rare subareolar lesions that are often difficult to palpate.[6] They are bilateral in 25% of patients.[6] Cytologic examination of the bloody discharge shows ductal cells.[6] Local excision through a circumareolar incision is curative.[6] Adenoma of the nipple, which is very rare, may also present with erosion of or discharge from the nipple.[21] In adolescent athletes, bloody discharge may be due to chronic nipple irritation (jogger's nipple) or cold trauma (cyclist's nipple).[22]

### GALACTORRHEA

Milky discharge from the neonatal breast is a normal response to fetal prolactin levels, which peak at birth (Fig. 61-4).[23] In an adolescent, nonpuerperal lactation can be classified as neurogenic, hypothalamic, pituitary, endocrine, drug-induced, or idiopathic in origin.[23] Neurogenic lactation occurs as a result of disorders of the chest wall, thorax, or breast. It has been reported after thoracotomy, burns or injuries of the chest wall, herpes zoster, or chronic stimulation of the nipple.[23] Pituitary tumors, especially prolactinomas, are the most common hypothalamic or pituitary cause of galactorrhea.[23] The most common cause of galactorrhea in adolescents is hypothyroidism.[23] A wide variety of drugs has been implicated in causing galactorrhea, including dopamine-receptor blockers and catecholamine-depleting agents.[8,23] Patients with galactorrhea require a careful history and physical examination directed at the possible causes of galactorrhea. Laboratory studies should include serum prolactin, follicle-stimulating hormone, luteinizing hormone, and thyroid function studies.[23]

## Breast Masses

### PREPUBERTAL BREAST MASSES

Neonatal breast hypertrophy is a normal response to maternal estrogen and occurs in both boys and girls in the first weeks of life.[6] Stimulation, such as attempting to squeeze the breast to promote discharge, may result in persistence of the hypertrophied tissue. Neonatal breast hypertrophy resolves spontaneously and no treatment is necessary. There are some data that suggest soy formulas may delay regression of neonatal breast tissue.[24]

Breast development at the onset of thelarche starts with a firm, disklike area of tissue under the areolar complex that can be mistaken for a mass. It is often initially unilateral.[4] Biopsy is contraindicated because of the high risk of injury to the developing breast bud.[5]

Hemangiomas and lymphatic malformations can involve the developing breast (Fig. 61-5). Although hemangiomas may involute after an initial growth spurt, compression of the breast bud during rapid growth may lead to injury and subsequent breast deformity. The diagnosis is usually made on physical examination but can be confirmed with ultrasonography or magnetic resonance imaging (MRI). If there is doubt about the diagnosis, a fine-needle biopsy may be indicated. Rapid growth of hemangiomas may require resection (if technically possible) or treatment with steroids.[4,25] In girls, the risk of injuring the breast bud by resection must be weighed against injury to the breast bud from the enlarging hemangioma or lymphatic malformation. MRI may aid in determining the resectability of the lesion and hence the risk/benefit ratio of surgical resection. Surgical resection of the lesion, with protection of the normal breast tissue, is indicated for complications such as ulceration or hemorrhage.[4]

Other primary or metastatic tumors of the breast are rare but can present in prepubertal children (Table 61-3). The majority of lesions are benign, but if the diagnosis is uncertain, fine-needle or open biopsy may be indicated.[4]

### MASSES IN ADOLESCENT GIRLS

#### Fibroadenomas

Fibroadenomas are the most common breast masses in adolescent girls. They usually occur in late adolescence, but can occur as early as 1 to 2 years before menarche.[6] Fibroadenomas are most often located in the upper outer quadrant of the breast and are more common in African American patients.[4] The average size is 2 to 3 cm, but they can become massive

(Fig. 61-6).[8] Ten percent of patients have bilateral lesions.[8] Up to 25% of patients have multiple fibroadenomas, a condition called fibroadenomatosis.[2,6] The lesions may enlarge slightly during the menstrual cycle.[4] The physical examination is usually diagnostic, as fibroadenomas are well circumscribed, "rubbery," mobile, and nontender. In equivocal cases, ultrasonography may be helpful in making the diagnosis.[26] Mammography is not indicated in adolescent patients because the large amount of fibroglandular tissue makes interpretation difficult and exposes the breast to avoidable radiation.[4]

Fibroadenomas are thought to develop because of a local exaggerated response to estrogen stimulation.[4] The natural history is usually an initial period of 6 to 12 months of growth, during which the mass doubles in size, and then stabilization. Only 5% of fibroadenomas grow more rapidly.[27] Fibroadenomas have been reported to resolve spontaneously.[4,28] This is supported by findings of sclerotic vestiges of fibroadenomas in women older than age 40 years.[29] In 99 women aged 14 to 55 years (median age, 20 years) followed over 7 to 9 years, 38% of 107 clinically diagnosed fibroadenomas resolved spontaneously.[28] One group reported that up to 40% of presumed fibroadenomas in adults decreased in size over a 2-year period.[30] Although these adult data suggest a high rate of spontaneous resolution, there are no data to suggest this is true in adolescents. However, these findings support observation of presumed fibroadenomas as an alternative to early resection. All presumed fibroadenomas smaller than 5 cm can be safely observed for at least one or two menstrual cycles.

**FIGURE 61-6** Giant fibroadenoma, mimicking juvenile hypertrophy, in an adolescent girl.

If there is growth of the lesion or symptomatic tenderness, excisional biopsy is warranted.[30] If the lesion remains stable, there are two options that should be discussed with the patient and family:

1. Observation with or without fine-needle aspiration. Approximately 200 cases of carcinoma of the breast have been reported in adults with fibroadenomas.[31] There are no reports of malignant fibroadenomas in adolescents. The risk of malignancy in an adolescent girl with a typical fibroadenoma on examination is exceedingly low. In the setting of a classic examination and no tumor growth, there is essentially no risk in observation.
2. Excisional biopsy. Many authors recommend excision of all lesions that persist to adulthood, so a case could be made to excise all fibroadenomas that persist during adolescence.[4] Patients should be counseled that the biopsy may result in cosmetic changes to the breast. Persistent local pain after removal of a fibroadenoma has also been reported.[32]

## Giant Fibroadenomas

Fibroadenomas greater than 5 cm are termed giant fibroadenomas. On examination, these may be softer than typical fibroadenomas and may even resemble the normal surrounding breast tissue.[8] There may also be dilated veins over the surface, and the skin overlying the mass may be warm to the touch (see Fig. 61-6).[8] Giant fibroadenomas should be excised because they cannot be distinguished from cystosarcoma phyllodes by physical examination, mammography, or ultrasonography.[33] In addition, giant fibroadenomas have been reported rarely to double in size in as little as 3 months.[6] Fine-needle aspiration and core-needle biopsy should be performed. If the histologic features lead to a definitive diagnosis of cystosarcoma phyllodes, a more radical procedure would be indicated . However, it is very difficult to distinguish between fibroadenoma and cystosarcoma phyllodes by aspiration or needle biopsy, so a negative result should not affect the decision to operate.[33]

The incision for removal of a giant fibroadenoma can be problematic. Whenever possible, a periareolar incision should be used. Large lesions can be removed through a periareolar incision by placing them in a bag and morcellating them before removal.[34] If the mass is close to the inframammary crease, this offers a second, cosmetically appropriate approach. It is best to mark out the inframammary crease with the patient sitting before induction of anesthesia. In either case, plans for a future wide excision should be taken into account when planning the initial excisional biopsy. Excision of large fibroadenomas can result in significant deformity of the breast. Placing a drain is not recommended because this results in adherence of skin to the chest wall. However, leaving the space to fill with serum or blood is also suboptimal, as this may result in contraction of the space and skin adherence. An alternative approach is to distend the space with a mixture of saline and local anesthetic by inserting an intravenous catheter using a "Z" puncture. In theory, this should prevent the rapid influx of serum and decrease the risk of skin adherence.

## Phyllodes Tumors

Phyllodes tumors were first described by Muller in 1838, who coined the term cystosarcoma phyllodes. This term is misleading, however, because these tumors are rarely cystic and do

not have the malignant potential of most sarcomas.[30] For that reason, they are better termed phyllodes tumors.

Phyllodes tumors are stromal tumors that are histologically classified as benign, intermediate, or malignant.[4] The distinction is largely semantic because benign phyllodes lesions can metastasize and may recur locally. The median age of presentation of phyllodes tumors is 45 years; however, they have been reported to occur in girls as young as 10 years.[30,35] These tumors may occur more frequently in African American adolescents.[6]

The diagnosis is difficult to make without a biopsy. On examination, the tumor may resemble a giant fibroadenoma. Large tumors may cause skin stretching, ulceration, and venous distention.[6] If the nipple complex is involved, there may be a bloody discharge.[6] Ultrasonographic findings that are suggestive but not diagnostic of phyllodes tumors include lobulations, a heterogeneous echo pattern, and the absence of microcalcifications.[33]

The treatment of benign phyllodes tumors is total surgical excision with a 1-cm margin of normal tissue.[36] Patients with histologically malignant phyllodes tumors should undergo mastectomy.[33] Some authors have reported that adolescents with malignant phyllodes tumors have a more "benign" course than adults and suggest that the breast can be preserved in these patients.[30] Only clinically palpable nodes, which are present in approximately 20% of patients, should be resected.[37] The role of sentinel node biopsy has not been clarified for this tumor. The majority of nodes are enlarged in response to tumor necrosis and inflammation; metastases occur by hematogenous not lymphatic dissemination.[6] Reexcision is indicated if adequate margins were not obtained at the first surgery.[37] If an adequate margin cannot be achieved on the chest wall, local radiation therapy should be considered.[37]

Local recurrence occurs in up to 20% of patients with phyllodes tumors and is treated with reexcision or mastectomy.[30] Metastatic disease has been reported in 14% to 15% of patients.[37] Metastases can occur in the lung, pleura, soft tissue, bone, pancreas, and central nervous system and usually occur without lymph node involvement.[30,37] There have been isolated reports of palliation from single or multiple chemotherapeutic agents, but in general, adjuvant therapy plays a limited role in the treatment of phyllodes tumors.[30]

The 5-year survival rate in adults with benign, borderline, and malignant phyllodes tumors is 96%, 74%, and 66%, respectively.[30] Overall, the 5-year survival rate for malignant phyllodes tumors in adults is approximately 80%.[30] Because adolescents with phyllodes tumors may have biologically less aggressive tumors than adults, their prognosis may be better.[30]

## Cysts of Montgomery

Montgomery tubercles are the small papular projections on the edge of the areola and are related to the glands of Montgomery, which may play a role during lactation.[8] In adolescents, these glands can obstruct and present with either acute inflammation (62%) or an asymptomatic mass (38%).[38] The diagnosis of these retroareolar cysts is primarily clinical but can be confirmed with ultrasonography, which most commonly demonstrates a cystic lesion, usually unilocular, located in the expected retroareolar location. The most common presentation of patients with retroareolar cysts is acute inflammation with localized tenderness, erythema, and swelling under the areola and extending into the breast tissue.[38] Treatment with oral antibiotics directed at staphylococci and nonsteroidal antiinflammatory agents usually results in resolution of the acute inflammation within 7 days.[38] Only rarely is drainage of a persistent abscess necessary. After this nonoperative treatment, an asymptomatic mass is usually present. Patients with retroareolar cysts may describe a brownish discharge from a Montgomery tubercles, particularly with compression of the mass. In the absence of persistent infection or other complications, retroareolar cysts should be observed with serial physical examinations and, if needed, repeated ultrasonography. More than 80% of these cysts resolve spontaneously, although this can take up to 2 years.[38] Patients should be instructed not to compress the area, as this may delay resolution of the mass. Resection may be indicated if the mass persists or if the diagnosis is in question.[8]

## Fibrocystic Changes

Fibrocystic changes in the breast can result in both localized masses and pain in the breast (mastalgia). Patients should be reassured that fibrocystic changes are normal variants of female physiology, with these changes reported in 50% of women of reproductive age and 90% of women on autopsy.[8] Physical examination alone usually suffices to make this diagnosis because there is usually significant change with serial examinations performed at different points in the menstrual cycle. Ultrasonography may be helpful if the diagnosis is equivocal, but mammography is not indicated. The treatment of mastalgia is a firm brassiere and nonsteroidal anti-inflammatory drugs.[6] Oral contraceptives have been reported to improve symptoms in 70% to 90% of women.[8] Treatment with vitamin E and evening primrose oil and avoidance of caffeine are unproved but popular treatments.[6,8]

## Other Benign Breast Masses

A variety of benign tumors of the breast have been described in adolescents and young adults (Table 61-4). Hamartomas of the breast are rare tumors composed of normal breast components that can present as unilateral macromastia.[39,40] (They have also been called lipofibromas, adenolipomas, and fibroadenolipomas.[39] Only eight cases have been reported in women younger than 20 years.[39] The treatment of hamartomas is total excision.

Adenomas of the nipple are very rare but have been reported to occur in children and adolescents.[41] They are treated by local excision.[21] Tubular adenomas cannot be distinguished from fibroadenomas by history or examination, and the diagnosis is usually made by pathologic evaluation.[29] No further treatment is necessary after local excision.

Erosive adenomatosis is a rare benign tumor that presents with erythema, erosion, and crusting of the nipple.[42] Serosanguineous discharge may occur and a nodule may or may not be palpable.[42] Treatment is local excision of the lesion, which may be delayed until breast growth is complete; successful treatment with cryosurgery has also been reported.[42]

Juvenile papillomatosis is a benign, localized, proliferative lesion usually seen in girls older than 10 years, although it has been reported in prepubertal boys as well.[43] Juvenile papillomatosis usually presents with a mass, similar on examination to a fibroadenoma, in one breast. When resected, this is a well-demarcated mass with multiple cysts separated by fibrous stroma, giving it a “Swiss cheese” appearance.[29] Juvenile papillomatosis is considered a marker for increased breast cancer risk in family members but not necessarily in the patient unless it is recurrent.[43] However, other authors suggest that it does confer an increased risk for the patient as in situ and invasive carcinoma (usually juvenile secretory carcinoma) has been reported in up to 15% of patients with juvenile papillomatosis.[29] The treatment of juvenile papillomatosis is total resection, with preservation of the normal breast.[43]

Trauma can result in lesions that resemble either an infection or a mass in adolescents. In particular, fat necrosis that occurs after trauma can resemble a solid mass in the breast.[6] This has been reported after seat-belt injury and other direct blows to the breast.[44]

### Malignant Tumors of the Breast

Primary carcinoma of the breast has been reported in fewer than 50 pediatric patients.[4,45,46] More than 80% of these patients were diagnosed with juvenile secretory carcinoma, with the remainder having intraductal carcinoma. Juvenile secretory carcinoma has been associated with juvenile papillomatosis.[4] Juvenile secretory carcinoma often has a thick-walled capsule, which may cause the lesion to appear cystic on ultrasonography.[45] The treatment of primary breast cancer in children is complete surgical excision, usually by mastectomy.[4] The role of sentinel node mapping has not been determined in children. Estrogen and progesterone receptors should be assessed. Local recurrence is treated by reexcision or completion mastectomy. Adjuvant therapy for juvenile secretory carcinoma is rarely used, and the prognosis is excellent after local excision. Adjuvant therapy for intraductal carcinoma is based on the node status and hormone receptors, with most oncologists using modified adult protocols for the treatment of children.

Chest wall irradiation, used to treat malignancies such as Hodgkin lymphoma, increases the lifetime risk for breast cancer. This is particularly true for girls who are 10 to 16 years old when they receive radiation therapy, because this is a period of rapid breast growth.[47,48] Girls with Hodgkin disease who require radiotherapy of the chest have a markedly increased risk of breast cancer (estimated at 37 to 82 times normal), with almost 40% of patients ultimately experiencing breast cancer.[47,48] The median time from radiation therapy to diagnosis of breast cancer is 20 years. The risk of breast cancer is also increased if there is a significant family history of breast cancer or known mutations in the *BRCA1* and *BRCA2* genes.[8] Girls who have mutations in one of these genes have a 3.2% risk of breast cancer at age 30 years and an 85% risk by age 70 years.[8] Testing of adolescents for adult-onset disease is controversial, and referral to appropriate specialists for counseling is recommended.[49,50] Sarcoma of the breast is rare in all age groups and exceedingly rare in children. Rhabdomyosarcoma can occur as a primary tumor of the breast, usually in adolescent girls.[51] These tumors are typically rapidly growing mobile masses with no skin involvement; histologically, they are usually alveolar rhabdomyosarcomas.[51] Angiosarcoma of the breast has been reported in adult women after external beam radiation for breast conservation.[35] This rare tumor has also been reported in adolescents.[36] The treatment is mastectomy without routine axillary dissection.[36] Liposarcoma has been reported within a phyllodes tumor of the breast in an adolescent patient.[52] These tumors may appear encapsulated but should be treated by wide local excision.[35] Fibrosarcoma and malignant fibrous histiocytoma are among the most common soft tissue sarcomas of the breast; other rare primary sarcomas of the breast include leiomyosarcoma and osteogenic sarcoma.[35] Primary non-Hodgkin lymphoma of the breast has been reported in children.[53] Treatment of these rare primary malignancies of the breast is based on established protocols for more common tumors of childhood.

Cancer metastatic to the breast has been reported in children with primary hepatocellular carcinoma, Hodgkin lymphoma, non-Hodgkin lymphoma, neuroblastoma, and rhabdomyosarcoma, particularly the alveolar variant.[4,53,54] Other less common tumors that have been reported to metastasize to the breast in children include histiocytosis, medulloblastoma, renal cell carcinoma, and neuroblastoma.[54] Bilateral breast disease occurs in 30% of children with rhabdomyosarcoma metastatic to the breast.[54] Ultrasonography is the diagnostic tool of choice because it may differentiate metastatic lesions from more common benign lesions.[54]

## Gynecomastia

Gynecomastia occurs in up to 70% of boys at the time of puberty.[6,55] The majority of boys have bilateral gynecomastia, with only 10% having unilateral breast enlargement.[56] A history of drug ingestion should be obtained because gynecomastia has been reported to occur secondary to anabolic steroids, digitalis, isoniazid, tricyclic antidepressants, spironolactone, and marijuana.[4] Gynecomastia can be classified using a scale defined by Nydick, which is similar to the Tanner stages of breast development in girls. Stage 1 is limited to the subareolar area but does not reach the edge of the areola; stage 2 extends to the edge of the areola (B2) or beyond the edge (B3). In stages 4 and 5 gynecomastia, the breast assumes the characteristics of a female breast.[56] Examination of the testes is important in boys with gynecomastia to rule out disorders such as Klinefelter syndrome, primary hypogonadism, and androgen resistance (Reifenstein syndrome).[57,58] The combination of gynecomastia with hypogonadism suggests the diagnosis of Klinefelter syndrome. In the vast majority of boys, physiologic gynecomastia resolves spontaneously as puberty progresses, although it may take several years.

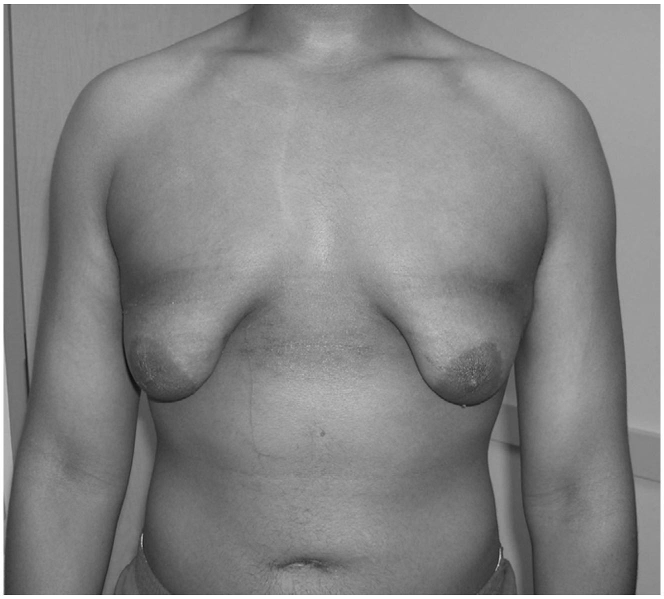

FIGURE 61-7 Stage 5 gynecomastia in an adolescent boy.

The risk of low self-esteem and decreased physical activity is significant in many boys with gynecomastia (Fig. 61-7). Surgery is indicated to allow normal psychological growth and development. In addition, surgery eliminates the small but present risk of carcinoma. [59–61] Liposuction may be adequate treatment for limited gynecomastia, but most patients require a simple mastectomy,[16,62,63] which is performed through a periareolar incision. Nipple reconstruction may be indicated if the areolar complex is large.[64] Drains are often necessary when significant breast tissue has been resected to prevent postoperative seromas, and compression vests are helpful as well. A "pad" of breast tissue should be left underneath the nipple to avoid retraction and adherence of the nipple to the chest wall, as well as subcutaneous tissue with the skin to avoid dermal adherence to the underlying pectoral muscles.[4]

CHAPTER 62

# Congenital Chest Wall Deformities

Robert E. Kelly, Jr. and Robert C. Shamberger

Congenital chest wall deformities are usually divided into five categories: pectus excavatum, pectus carinatum, Poland syndrome, sternal defects, and the miscellaneous dysplasias or the thoracic deformities seen in diffuse skeletal disorders. Most are not life-threatening lesions and produce limited functional abnormalities. Rare lesions, such as thoracic ectopia cordis and Jeune asphyxiating thoracic dystrophy, are, however, almost uniformly fatal.

## Depression Deformities: Pectus Excavatum

Pectus excavatum (funnel chest, trichterbrust, or thorax en entonnoir) is the most common anterior chest wall deformity, involving posterior depression of the sternum and the lower costal cartilages. It occurs more frequently in boys than in girls by a greater than 3:1 ratio. In many cases, it is noted within the first year of life.[1] Although cases of spontaneous resolution occur, they are infrequent, and the advice that a child will "grow out" of the pectus depression should be offered cautiously. Some patients do not develop the depression of the chest wall until the rapid growth of puberty. Children with pectus excavatum, in addition to the central chest depression, are often noted to be tall and lanky, with poor posture, and to have an overall decrease in anteroposterior (AP) chest depth.[2,3] The incidence of the condition was reported to vary from 38 per 10,000 births among white infants to 7 per 10,000 births among black infants, to 20 per 10,000 infants categorized as other than black or white in a 1975 Collaborative Perinatal Project in the United States. In South America, the prevalence of pectus excavatum was 1.275% in a sample of 1,332 11- to 14-year-old students in Brazil.[4] In 1936, Nowak examined 30,000 Austrian school children and found 0.4% affected.[5] A recent report of congenital chest wall malformations in Nigerians, surveying 2,195 autopsied patients, reported one patient with Poland syndrome, one with Cantrell syndrome, and none with pectus excavatum, suggesting that the condition occurs infrequently in that region of Africa. Large numbers of surgically treated patients have been reported in the Far East.[6]

### CAUSE

The cause of pectus excavatum has not been established. Pectus excavatum does occur in animals, and reports of successful surgical treatment in cats and dogs have been published.[7,8] Otters are thought to develop the condition by cracking open shellfish on their chests while floating in the sea.[9] Purported theories in humans include intrauterine pressure, rickets, and abnormalities of the diaphragm resulting in posterior traction on the sternum.[10–12] Some support for this last theory has been provided by reports of pectus excavatum occurring after repair of agenesis of the diaphragm or congenital diaphragmatic hernia.[13] A study of 60 adult congenital diaphragmatic hernia survivors (mean age, 29 years) documented chest asymmetry in 48 and pectus excavatum in 18.[14] The association between pectus excavatum and other musculoskeletal abnormalities, particularly scoliosis (15% incidence) and Marfan syndrome (Table 62-1), suggests that abnormal connective tissue plays a role. Studies have demonstrated abnormalities in the costal cartilage, including decreased levels of zinc and increased levels of magnesium and calcium.[15] Biomechanical analysis has suggested increased flexibility of costal cartilages in individuals with pectus excavatum, but abnormalities in the proteoglycan or collagen distribution between affected individuals and controls were not demonstrated.[16] Fokin and colleagues found that cartilage samples from surgical cases had significantly dysregulated collagen genes, but no clear causative gene was identified.[17] Recent computed tomography (CT) scan studies have thrown considerable doubt on a theory that there is differential growth, with the cartilages growing in length faster than the ribs.[18] A family history of chest wall deformity, identified in 37% to 47% of cases, supports a genetic predisposition.[19] Family studies have shown inheritance by autosomal dominant, autosomal recessive, X-linked, and multifactorial inheritance in different kindreds.[20] An autopsy series study covering 112 years at a major center did not conclusively demonstrate an adverse effect on survival; patients who died before age 56 had shorter survival ($P = 0.0001$), but those who survived past the age of 56 tended to survive

longer than their matched controls.[21] The autopsy reports did not include information to judge the severity of the pectus depression.

## CLINICAL PRESENTATION

Children present with a wide spectrum of depression deformities (Fig. 62-1), from a mildly depressed sternum to a severe case in which the sternum almost abuts the vertebral bodies. The depression is created by two components: (1) posterior angulation of the body of the sternum, generally beginning just below the insertion of the second costal cartilage, and (2) posterior angulation of the costal cartilages to meet the sternum. In older teenagers and adults, posterior angulation of the most anterior portion of the osseous ribs occurs. The depression may be deeper on one side than the other, more frequently on the right than the left, and the sternum may be rotated as well producing an asymmetric depression.[22] The AP depth of the ribs may be different between the two sides as well, and in many children, the AP depth of the chest is narrower than normal.[2] Children may have a broad, shallow defect or a narrow central pocket. A long trench may extend from the area just below the clavicles to the costal margin. Mixed protrusion of the costal cartilages on one side of the sternum (pectus carinatum) and depression on the other side (excavatum) occurs with significant frequency. Currarino-Silverman deformity, a variant of pectus *carinatum*, produces protrusion of the sternomanubrial joint and depression of the lower sternum; patients with this problem are often referred for evaluation of pectus excavatum. An asthenic build and slumped posture are frequently associated with pectus excavatum. Congenital heart disease was identified in 1.5% of children undergoing chest wall correction in one series, and the frequency of chest wall deformities among children with congenital heart disease was 0.17%.[23]

Many methods of assessing the severity of the depression have been developed. Most include the distance between the sternum and the spine as a primary factor. Willital[24] and Klinke and colleagues[25] used a ratio between the depth of the depression and the AP diameter of the chest. Welch used a ratio of the sternovertebral distance divided by the AP depth of the chest at the angle of Louis and added additional increments of severity if the cardiothoracic ratio was greater than 50% or the rib angles were greater than 25 degrees

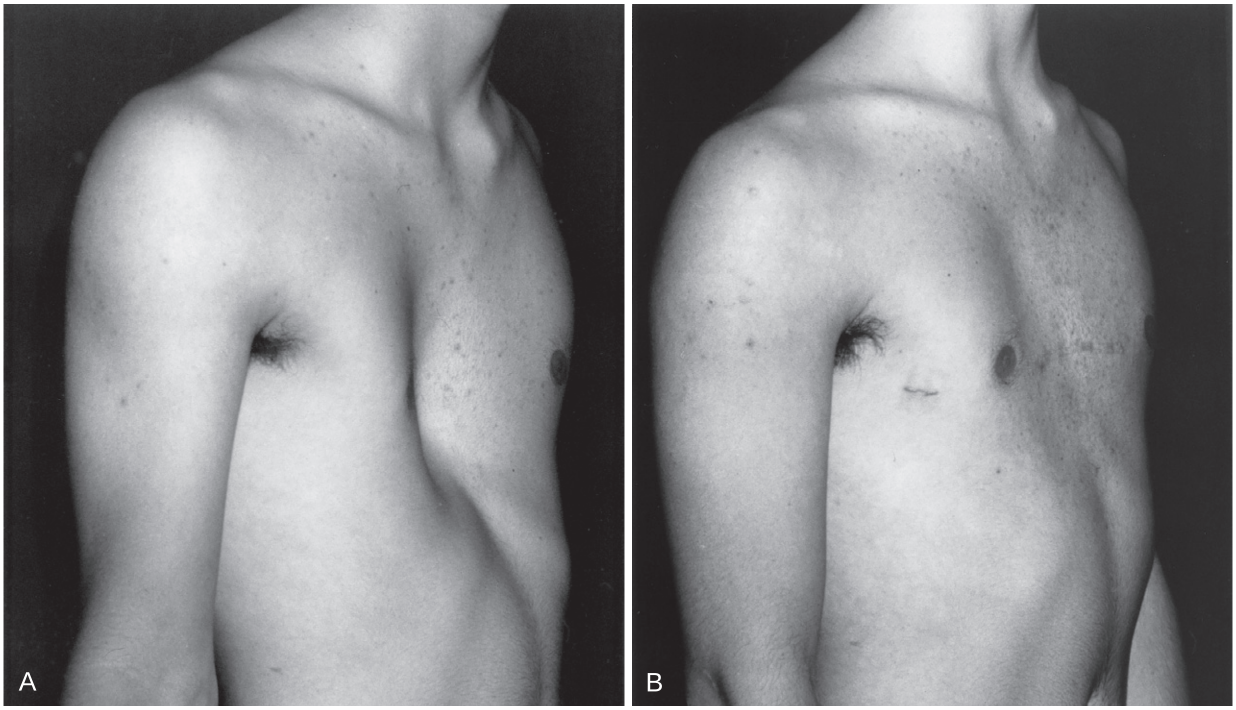

**FIGURE 62-1** **A,** Preoperative clinical photograph of a 14½-year-old boy with a symmetric pectus excavatum deformity. **B,** Postoperative clinical photograph a year after open repair using retrosternal struts shows full correction of the deformity. from horizontal.[26] Backer and colleagues used a ratio between the vertebral body diameter and the distance between the xiphisternal junction and the posterior border of the vertebral body to express the severity of the depression.[27] Haller and colleagues proposed a method of grading that uses transverse and AP measurements obtained from computed tomographic scanning of the chest, but similar measurements can be obtained from standard chest radiographs.[28] Recently, magnetic resonance imaging (MRI) scans have been used to assess both the anatomy of the chest wall and the performance of the heart.

Pectus excavatum is well tolerated in infancy and childhood. Chronic upper airway obstruction because of tonsillar and adenoidal hypertrophy may accentuate the depression in an infant with a flexible chest but is not causative. Older children may complain of pain in the area of the deformed cartilages or of precordial pain at rest or after sustained exercise. Occasionally, palpitations occur, which presumably are the result of transient atrial arrhythmias and may be associated with mitral valve prolapse. A systolic ejection murmur is frequently identified in individuals with pectus excavatum. It is attributed to the close proximity between the posterior aspect of the sternum and the pulmonary artery, which results in transmission of a flow murmur.[29] The physiologic impact of pectus excavatum has been the topic of many reports and much debate. Some authors contend that no cardiovascular or pulmonary impairment results from pectus excavatum. This position contrasts with the clinical impression that many patients have increased stamina and exercise tolerance after surgical repair. The cardiopulmonary impact of pectus excavatum has been extensively studied, with variable results. Despite 6 decades of work in the field, no consensus has been achieved on what degree of cardiopulmonary impairment, if any, this common chest wall deformity produces. Early pathologic studies of patients with pectus excavatum demonstrated compression of the heart between the vertebral column and the depressed sternum. The left lung was also compressed more than the right because of the frequent asymmetry of the deformity. Translation of these anatomic findings into their physiologic components has been the goal of many subsequent studies. Reviews in 1988 and 2008 tabulated this long series of studies.[30,31]

## PULMONARY FUNCTION EVALUATION

Deformity of the chest wall led many early authors to attribute the symptomatic improvement after pectus surgery to an improvement in pulmonary function. In an early work, Brown performed respiratory studies on patients before and after surgical repair. Vital capacity was normal in these patients, but maximal breathing capacity was markedly diminished (50% or more) in 9 of 11 cases.[32] Maximal breathing capacity increased an average of 31% after surgical repair.

Orzalesi and Cook performed studies in 12 children with severe pectus excavatum deformities.[33] The data for individual patients were within two standard deviations of normal values based on height, except for three patients with low vital capacity and one with low maximal breathing capacity. In the aggregate, however, the group showed a significant ($P < 0.001$) decrease in vital capacity, total lung capacity, and maximal breathing capacity compared with height-matched normal children. Weg and colleagues evaluated 25 Air Force recruits referred for respiratory symptoms and pectus excavatum and compared them with 50 unselected basic trainees.[34] Although the lung compartments of both groups were equal, as were mean vital capacity and maximal voluntary ventilation, which best reflects chest wall function, muscular ability and patient effort showed a significant deviation from predicted normal values ($P = 0.005$).

Liese and Bühlmann determined preoperative and postoperative lung volume and physical work capacity in an upright position on a bicycle ergometer in 12 adults with severe funnel chest.[35] Postoperative studies were performed 3 to 11 years (mean, 8 years) after surgical correction. Absolute lung volume increased only in patients who had grown in height after surgery. Work capacity increased in 9 of 10 patients but was difficult to assess, given the interval between testing. Godfrey reported on a select group of five patients with pectus excavatum and segmental bronchomalacia involving the left mainstem bronchus.[36] Radionuclide pulmonary scans demonstrated severe gas trapping in the left lung in two patients and underventilation and underperfusion of the left lung in a third patient. This appeared to be a clinically distinct group of patients with bronchomalacia demonstrated at bronchoscopy in all cases. It is not clear that the bronchomalacia was caused by the pectus deformity.

Castile and colleagues extensively evaluated eight patients, seven with pectus excavatum and one with pectus carinatum deformity.[37] Five patients were symptomatic with exercise but were asymptomatic at rest. Complete pulmonary mechanics studies were performed, including standard lung volume, forced vital capacity (FVC), static pressure-volume curve, and progressive steady-state exercise testing on a bicycle ergometer. Flow and volume for the one patient with pectus carinatum were normal. The mean total lung capacity as a percentage of predicted in the pectus excavatum patients was 79%, a mild restrictive deficit. Flow volume configurations were normal and did not suggest airway obstruction. Workload tests revealed a normal dead-space response to exercise; tidal volume ratio and alveolar-arterial oxygen difference did not suggest a significant ventilation-perfusion abnormality in the symptomatic patients. However, the measured oxygen uptake increasingly exceeded predicted values as the workload approached maximum; this was a strikingly different pattern when compared with normal subjects, who exhibit a linear response. The mean oxygen uptake at maximal effort exceeded the predicted values by 25.4% in the symptomatic patients. The three asymptomatic patients demonstrated normal linear oxygen uptake during exercise. Increased oxygen uptake suggests increased work of breathing in these symptomatic individuals, despite normal or mildly reduced vital capacity. Increases in tidal volume with exercise were uniformly depressed in those with pectus excavatum. No postoperative studies were performed in these subjects.

Cahill and colleagues performed preoperative and postoperative studies (3 to 9 months postoperatively) in 19 children and adolescents with pectus carinatum (5) and excavatum (14), ranging from 6 to 17 years of age.[38] No preoperative abnormalities or postoperative changes were demonstrated in the pectus carinatum patients. The pectus excavatum patients demonstrated low-normal vital capacity that was unchanged by operation.

Surgical correction did, however, result in a small improvement in their total lung capacity ($3.21 \pm 1.12$ to $3.49 \pm 1.07$;

$P < 0.02$) and a significant improvement in maximal voluntary ventilation ($65.1 \pm 31.5$ to $78.9 \pm 31.5$ L/minute; $P < 0.001$). Exercise tolerance was also improved after surgery, as determined by both total exercise time and maximal oxygen consumption ($1.26 \pm 0.44$ to $1.46 \pm 0.42$ mL/kg/minute; $P < 0.01$), although both these factors are clearly effort related. The heart rates at three identical work rates were assessed for each patient in the preoperative and postoperative workload study. There was a consistent decrease in heart rate at a given power output in the postoperative study ($P < 0.02$ by paired $t$-test) of the excavatum patients, but no decrease was observed in the carinatum patients. No difference in oxygen consumption at each work rate after surgery could be defined to support an improved efficiency of work. The observed decrease in heart rate at each workload level supported the hypothesis that some of the improvement in exercise capacity was a result of increased cardiac stroke volume. Mead and colleagues studied rib cage mobility by assessing intra-abdominal pressure. The finding of normal abdominal pressure tracings in subjects with pectus excavatum suggested normal rib cage mobility.[39]

Derveaux and colleagues used pulmonary function tests to evaluate 88 subjects with pectus excavatum and pectus carinatum before and 1 to 20 years (mean, 8 years) after repair involving a fairly extensive chest wall dissection.[40] Preoperative studies were within the normal range (i.e., >80% predicted values), except in those subjects with both scoliosis and pectus excavatum. The postoperative values for forced expiratory volume in 1 second ($FEV_1$) and vital capacity were decreased in all groups when expressed as a percentage of predicted values, although the absolute values at follow-up may have been greater than at the preoperative evaluation. Radiologic evaluation of these individuals confirmed improved chest wall configuration; so, the deterioration in pulmonary function was not the result of recurrence of the pectus deformity. An inverse relationship was found between preoperative and postoperative function. Those with less than 75% of predicted function preoperatively had improved function after surgery, whereas postoperative results were worse if the preoperative values were greater than 75%. Almost identical results were found in a study by Morshuis and colleagues who evaluated 152 subjects before and a mean of 8 years after surgery for pectus excavatum.[41] These physiologic results were in contrast to the subjective improvement in symptoms reported by the subjects and their improved chest wall configurations. The decline in pulmonary function in the postoperative studies was attributed to the surgery, because the preoperative defect appeared to be stable on sequential studies, regardless of the age at initial repair. Both these studies were marred by the obvious lack of an age-matched and severity-matched control group without surgery.

Derveaux and colleagues evaluated transpulmonary and transdiaphragmatic pressures at total lung capacity in 17 individuals with pectus excavatum. Preoperative and long-term follow-up evaluations were performed at a mean of 12 years apart.[42] Reduced transpulmonary and transdiaphragmatic pressures showed that the increased restrictive defect was produced by extrapulmonary rather than pulmonary factors, suggesting that surgery produced increased rigidity of the chest wall.

Wynn and colleagues assessed 12 children with pectus excavatum by pulmonary function tests and exercise testing.[43] Eight had repair and were evaluated preoperatively and postoperatively. Four had two sets of evaluations but no surgery. A decline in total lung capacity was identified in the repaired children, whereas values were stable in the control group. Cardiac output and stroke volume increased appropriately with exercise before and after operation in both groups, and operation was thought to have no physiologically significant effect on the response to exercise.

Kaguraoka and colleagues evaluated pulmonary function in 138 individuals before and after repair of pectus excavatum.[44] A decrease in vital capacity occurred during the initial 2 months after surgery, with recovery to preoperative levels by 1 year after surgery. At 42 months, the values were maintained at baseline, despite a significant improvement in chest wall configuration. Tanaka and colleagues had similar results and demonstrated that individuals with a more extensive sternal turnover procedure had more significant and long-term decreases in vital capacity.[45]

Morshuis and colleagues evaluated 35 subjects with pectus excavatum repaired as teenagers or young adults (age $17.9 \pm 5.6$ years).[46] Preoperative evaluations were performed and repeated 1 year after surgery. Preoperative total lung capacity ($86.0 \pm 14.4\%$ of predicted) and vital capacity ($79.7 \pm 16.2\%$) were significantly lower than predicted values and decreased further after surgery ($-9.2 \pm 9.27\%$ and $-6.6 \pm 10.7\%$, respectively). The efficiency of breathing at maximal exercise improved significantly after operation. Ventilatory limitation of exercise occurred in 43% of the subjects after surgery, and there was a tendency toward improvement after operation. The group with no ventilatory limitation, however, initially demonstrated a limitation after operation, with a significant increase in oxygen consumption.

Haller and colleagues evaluated 36 patients with pectus excavatum and 10 normal controls. Six months after surgery, the studies were repeated on 15 patients and 6 controls.[47] Before surgical correction, a decrease in FVC was seen in the excavatum cohort, and no change occurred after repair. Although 58% of patients had subjective complaints of exercise limitation that improved after surgery in 66%, they exercised at similar workloads as controls. The respiratory parameters during exercise were similar between the two groups, suggesting that exercise was not limited by restrictive disease. After surgery, the subjects could exercise longer and had higher pulse oxygen levels than before surgery, with no change in the controls. The enhanced exercise tolerance was attributed to improved cardiac function, as demonstrated by increased pulse oxygen levels and no change in pulmonary function parameters.

Borowitz and colleagues performed an early evaluation of patients undergoing the minimally invasive repair of pectus excavatum (MIRPE) technique.[48] In that study of 10 patients, normal pulmonary function was demonstrated both before and after surgical repair. Sigalet and colleagues also reported on the early effects of MIRPE in 11 patients, based on an evaluation of pulmonary function, exercise tolerance, and cardiac function as assessed by echocardiography.[49] Although patients reported a subjective improvement in their exercise tolerance, pulmonary function (FVC and vital capacity) was significantly reduced at 3 months; similarly, maximal oxygen uptake was reduced. In contrast, cardiac function was enhanced, with an increase in stroke volume.

Malek and colleagues evaluated 21 physically active patients with pectus excavatum.[50] The observed values for FVC, $FEV_1$, maximal voluntary ventilation, and diffusing capacity of the lung for carbon monoxide were significantly lower than normal values, but those for total lung capacity and residual volume

were not. Exercise testing revealed that the maximal oxygen uptake and oxygen tension were significantly lower than in normal controls. It was thought that the subjects' limitation in maximal exercise had a cardiovascular rather than a pulmonary cause, as demonstrated by an abnormally low metabolic threshold for lactate accumulation. This impairment was greatest in those with the most severe pectus deformities.

Lawson and colleagues reported pulmonary function tests on 408 patients with pectus excavatum before operation and a subset of 45 who had pulmonary function studies after Nuss operation and bar removal. Observed preoperative values for FVC, $FEV_1$, and forced expiratory flow between 25% and 75% (FEF25-75) were lower than average values by 13% to 20%. The postoperative group had statistically significant improvement after surgery for all parameters. Patients older than 11 years at the time of surgery had lower preoperative values and larger mean postbar removal improvement than younger patients.[51]

A multicenter study of 327 patients with pectus excavatum showed that prior to surgical repair, in patients with a mean CT index of 4.4, FVC was 90% of predicted (that is, average) values for the population; FEV1, 89%; and FEF25-75 85%. Each of these was statistically decreased with the *P* value of difference from 100% being less than 0.0001. Postoperative values are not yet reported in this study.[19]

Until recently, most studies of pulmonary function were carried out on small numbers of patients and failed to document consistent improvement in pulmonary function resulting from surgical repair. In fact, many studies demonstrated deterioration in pulmonary function at long-term evaluation, attributable to increased chest wall rigidity after open surgery. Despite this finding, several workload studies have shown improvement in exercise tolerance after repair.

In the last decade, increased interest in the condition has allowed studies of hundreds of patients with pectus excavatum to be performed in collaboration with pediatric pulmonologists. These demonstrate that pectus excavatum is associated with diminution in pulmonary function. The usual distribution of values around the mean is "shifted to the left." The amount of the decrement is, on average, to about 85% of "predicted" values; 80% predicted is two standard deviations less than the mean or "predicted" number for controls. The improvements in measured function occur in patients with normal pulmonary parenchyma and airways (asthma occurs at the same rate as in the general population).

## CARDIOVASCULAR FUNCTION

Posterior displacement of the sternum can produce deformity of the heart, particularly anterior indentation of the right ventricle. Garusi, using angiography, showed displacement of the heart to the left side, with a sternal imprint on the anterior wall of the right ventricle.[52] Bevegard, in 1962, studied 16 patients with pectus excavatum using right heart catheterization and workload studies.[53] The physical work capacity at a given heart rate was significantly lower in the sitting than in the supine position. Those with a 20% or greater decrease in physical work capacity from the supine to the sitting position had a shorter sternovertebral distance than did those with a less than 20% decrease. Measured stroke volume at rest decreased from the supine to the sitting position a mean of 40.3%, similar to normal subjects. In the supine position, stroke volume increased 13.2% with exercise. In the sitting position, the increase in stroke volume from rest to exercise was 18.5%, significantly lower ($P < 0.001$) than the 51% increase measured in normal subjects. Thus increased cardiac output can be achieved primarily by increased heart rate, despite a limited stroke volume. This explains the lower work capacity achieved at any given heart rate in the sitting position. Intracardiac pressures were normal in all subjects measured at rest and with exercise, despite the apparent limitation of ventricular volume.

Beiser and colleagues provided further evidence that cardiac function is impaired during upright exercise yet is relatively normal in the supine position.[54] Cardiac catheterization was performed in six subjects with moderate pectus excavatum. Normal right atrial, right ventricular, pulmonary artery, and pulmonary capillary wedge pressures were obtained at rest in the supine position. The cardiac index during moderate exercise was normal, although the response to upright exercise was below that predicted in two subjects and at the lower limit of normal in three. The difference in cardiac performance in an upright position was produced primarily by a smaller stroke volume in subjects with pectus excavatum. Stroke volume was 31% lower and cardiac output was 28% lower during upright exercise compared with supine exercise. Postoperative studies were performed in three subjects; two achieved a higher level of exercise after repair. The cardiac index increased an average of 38%. An enhanced stroke volume response produced this increase, because heart rate at maximal exercise was not higher after repair.

Radionuclide angiography was used by Peterson and colleagues to assess cardiac volume and output in 13 subjects with pectus excavatum.[55] Eleven subjects were symptomatic before surgical repair, but the degree of symptoms could not be correlated with the severity of the anatomic deformity. Upright exercise was performed with a bicycle ergometer at progressive workloads, until 85% of the age-predicted maximal heart rate was achieved or the patient could not continue because of fatigue or shortness of breath. Ten of the 13 subjects were able to reach the target heart rate before surgical repair, yet only 4 did so without symptoms. After operation, all but 1 subject reached the target heart rate during the exercise protocol, and 9 of 13 subjects did so without becoming symptomatic. This documentation of a marked decrease in symptoms after surgical correction of pectus excavatum in a regulated exercise protocol substantiated many anecdotal reports in the early literature regarding symptomatic improvement. The role of conditioning and subjective response to surgery is difficult to assess. Radionuclide injections were performed on subjects at rest and then at the target heart rate or exercise end point. This study failed to demonstrate any significant change after pectus repair in the left ventricular ejection fraction either at rest or during exercise. The left ventricular end-diastolic volume was consistently increased after repair at rest, and the mean stroke volume increased 19% after repair but did not consistently increase with exercise. The cardiac index did not increase significantly after operation at rest or during exercise. Kowalewski and colleagues performed a similar study with echocardiographic evaluation of cardiac function in 42 patients both before and 6 months after repair of pectus excavatum.[56] Statistically significant changes were seen in the right ventricular volume indices (systolic, diastolic, and stroke volume) after surgery. No correlation could be

defined between the changes in the pectus index and the cardiac changes. These results support those cited earlier by Haller and colleagues,[47] Sigalet and colleagues,[49] and Malek and colleagues,[50] which all suggest that limitations in the stroke volume result from right ventricular compression. Dramatic demonstration of the effect of mechanical compression by the sternum on the heart was published by Heiter and colleagues, describing a patient with a very severe deformity who had ischemic changes correlated by catheterization, CT scan, and electrocardiogram (ECG).[57]

Additional studies are needed to further define the relationship between pectus excavatum and cardiopulmonary function. Dynamic or exercise studies have been most promising in this area.

Methods to better evaluate preoperative cardiopulmonary function are needed to identify which children may achieve symptomatic and physiologic improvement after surgical repair.

### ECHOCARDIOGRAPHIC STUDIES

Prospective echocardiographic studies in adults with pectus excavatum demonstrated mitral valve prolapse in 6 of 33 subjects (18%) studied by Udoshi and colleagues,[58] in 11 of 17 subjects (65%) studied by Saint-Mezard and colleagues,[59] and 216 of 1215 patients (18%) at Children's Hospital of The King's Daughters (CHKD), Norfolk, Virginia. Anterior compression of the heart by the depressed sternum may deform the mitral valve annulus or the ventricular chamber and produce mitral valve prolapse in these subjects. Resolution of mitral valve prolapse was seen in 10 of 23 children and adolescents after repair in one report, and in 20 of 44 (44%) in another.[60]

### BODY IMAGE

Concerns about the appearance of the chest prompt many, if not most, patients to undergo surgical correction. A large percentage of pectus excavatum patients are self-conscious about their chests. Children and adolescents with physical differences may be at risk for body image and interpersonal difficulties.[61] We have been referred to children who have attempted suicide in response to depression precipitated in part by concern about their chest. Nevertheless, patients with pectus excavatum are often dismissed by pediatricians as having an inconsequential problem.[62] Pediatricians frequently tell children and parents that the chest wall deformity is "only cosmetic."

Validated psychometric assessments administered to more than 300 children less than 21 years old, before and after operation, demonstrated marked improvement in psychosocial functioning.[19] An enormously important finding was that severity of the depression by CT scan did not correlate with the patients' or parents' perception of body image concerns. In other words, even a depression which is "mild" to the physician can be very concerning to the patient and family. Physicians generally support surgical treatment of cleft lip, syndactyly, revision of burn scars, and other conditions in which the only justification for operative risk is anatomic abnormality. Pectus excavatum is reasonably viewed as a correctible anatomic deformity that worsens during the decade of life during which body image is crucial.

## Evaluation Before Operation

In recent years, efforts to develop objective criteria for surgery have been advocated by some centers and rejected by others, where they are thought to not be helpful. Most surgeons agree that patients with mild or moderate depression of the chest are best managed by exercise and posture brace treatment only, with intermittent (e.g., annual) follow-up. At our centers, a minority of patients who present are treated surgically, despite prior screening. Centers with a formal selection process may include three-dimensional imaging (CT or MRI scan of the chest), static and/or exercise pulmonary function testing, and echocardiography to look for mitral valve prolapse. Many agree that surgical correction is warranted if the patient has two or more of the following criteria: (1) progressive or symptomatic pectus excavatum; (2) restrictive disease, decreased work production, or decreased oxygen uptake, as determined by pulmonary function studies; (3) CT scan showing cardiac compression or displacement, pulmonary atelectasis, and a Haller CT index greater than 3.25; (4) cardiac abnormalities, including mitral valve prolapse or bundle branch block; and (5) recurrent pectus excavatum after a failed repair.

Although surgical correction can be performed in very young children with good results, at this time we believe that repair is best deferred until around the time of the pubertal growth spurt (10 to 15 years of age). In younger children (e.g., 4 to 8 years old) with severe exercise intolerance, operation at a younger age may be required. Although in prior years correction in infancy was often advised, at this time it is the exceptional infant who requires operation. The condition may be successfully treated in adult patients, though an upper age for correction remains controversial.

Prior to operation, patients should be asked about metal allergies whenever a metal implant is planned. Patients with a personal or family history of metal allergy should undergo patch testing before having a stainless steel bar implanted. If an allergy to nickel or another component of stainless steel is detected, a titanium bar should be used. Titanium is less malleable than stainless steel, and it is thought that scratches in the bar will cause tissue ingrowth, making it difficult to extract. For these reasons, titanium bars are bent using computer-assisted design/computer-assisted manufacturing (CAD/CAM) techniques at the factory, using the patient's CT scan (Biomet Microfixation, Jacksonville, Fla.). Titanium is much more expensive than stainless steel. Patients with Currarino-Silverman deformity do not respond to the Nuss procedure and should undergo an open operation.

## History of Surgical Treatment

Meyer,[63,39] in 1911, and Sauerbruch,[64] in 1913, first achieved surgical repair of pectus excavatum. Significant changes in the method of repair have evolved as experience has increased, and the primary components of the deformity have been identified. In 1939, Ochsner and DeBakey[65] summarized the early, sometimes fatal experience with a variety of repairs. Ravitch,[66] in 1949, reported a technique that involved excision of all deformed costal cartilages with the perichondrium, division of the xiphoid from the sternum, division of the intercostal bundles from the sternum, and transverse sternal

osteotomy displacing the sternum anteriorly with Kirschner wires in the first two patients and silk sutures in later patients. His technique was later modified to preserve the perichondrial sheaths, but he continued to separate the intercostal bundles and the sheaths from the sternum.[67] In his 1953 textbook, Gross reported correction in eight patients using cartilage incisions bilaterally, median sternotomy, and external splint fixation.[68] In 1957 and 1958, Baronofsky[69] and Welch,[70] respectively, reported similar techniques that emphasized total preservation of the perichondrial sheaths of the costal cartilage, preservation of the upper intercostal bundles, sternal osteotomy, and anterior fixation of the sternum with silk sutures. Haller and colleagues[71] subsequently developed a technique called tripod fixation in which subperichondrial resection of the abnormal cartilages is followed by a posterior sternal osteotomy. The most cephalad normal cartilages are then divided obliquely in a posterolateral direction. When the sternum is elevated, the sternal ends of the cartilage rest on the costal ends, providing further anterior support of the sternum.

Several authors used rib or cartilage placed posterior to the sternum for support, but this technique was never widely accepted.[67,72] A variation on this technique uses a vascularized rib.[73] Support of the sternum by an external brace secured to the mobilized sternum with sutures or wire has also been used by numerous authors, but the duration of its use must be limited to avoid infection of the surgical wound.[11,65,74–76] Support of the sternum by metal struts has also been promoted by multiple authors.[77,78] Rehbein[79] developed struts that could be placed into the marrow cavity of the ribs at the costochondral junction. The struts were secured anterior to the sternum to create an arch, and the sternum was attached to this arch. Paltia[80] placed a transverse strut through the caudal end of the sternum with the two ends of the strut supported laterally by the ribs, firmly fixing its location. Adkins and Blades[81] and later Jensen and colleagues[82] used retrosternal elevation by a metal strut. Willital[24] used a similar retrosternal strut after creating multiple chondrotomies in the costal cartilages to provide flexibility to the sternum and the chest wall. Innovations in these methods include the use of bioabsorbable struts, Marlex mesh or a Dacron vascular graft as a strut, or miniature metallic plates. There is no evidence, however, that any of these are preferable to traditional methods.[39,83–88]

In 1954 and 1956, Judet[89] and Jung,[90] respectively, proposed the sternal turnover in the French literature. This method has been used primarily in Japan, where a large series was reported by Wada and colleagues.[91] This technique uses a free graft of sternum that is rotated 180 degrees and then secured back to the costal cartilages from which it was divided. This method has a significant incidence of severe complications, including wound infection, dehiscence, and necrosis of the sternum. Taguchi modified this method by preserving the internal mammary artery in an effort to prevent osteonecrosis and wound infection.[92] Others have described microvascular anastomosis of one set of internal mammary vessels to preserve perfusion of the sternum.[93] Sternal turnover is a radical approach for children with pectus excavatum deformity, given the acceptable alternatives for repair.

A method of repair favored by some plastic surgeons is implantation of a Silastic mold into the subcutaneous space to fill the deformity.[94–96] Although this approach may improve the contour of the chest, it achieves no increase in intrathoracic volume and is often complicated by early seroma or hematoma formation.

In 1998, Nuss reported correction accomplished by inserting a convex steel bar under the sternum with the convexity facing posteriorly. When the bar is in position, it is turned over 180 degrees, thereby correcting the deformity (see Figs. 62-4 to 62-9). The technique is possible because of the malleability and flexibility of the anterior chest wall; it requires no cartilage incision or resection and no sternal osteotomy.

## SURGICAL TECHNIQUE (OPEN PROCEDURE)

The surgical technique is depicted in Figure 62-2. In females, particular care is taken to place the incision within the projected inframammary crease to avoid injury to the breast bud or the creation of a scar extending onto the breast.[97] Most surgeons performing the open procedure use a retrosternal strut to secure the sternum firmly in an anterior position. Preservation of the connections between the intercostal bundles, the perichondrium, and the rectus muscles provides a more normal chest contour than results when the sternum is skeletonized.

Perioperative antibiotics are used, giving one dose immediately before surgery and three doses postoperatively. All patients are warned not to take aspirin or ibuprofen-containing compounds for 2 weeks before surgery to avoid abnormalities of platelet function. The Hemovac drain (Snyder Laboratories, New Philadelphia, Ohio) is removed when the drainage is less than 15 mL for an 8-hour shift. Rehbein or retrosternal struts are removed 6 months after repair, to allow solid fixation of the sternum. The retrosternal struts are removed through a small incision over one end of the strut.

## COMPLICATIONS
